Summary of the Guidelines Updates

Primary Evaluation, Clinical Diagnosis (PN-1)
Primary Treatment Tis, Ta (PN-1)
Primary Treatment T1, T2 or Greater (PN-2)
Management of Non-Palpable Inguinal Lymph Nodes (PN-3)
Management of Palpable Non-Bulky Inguinal Lymph Nodes (PN-4)
Management of Palpable Bulky Inguinal Lymph Nodes (PN-5)
Management of Enlarged Pelvic Lymph Nodes (PN-6)
Surveillance Schedule (PN-8)
Management of Recurrent Disease (PN-9)
Management of Metastatic Disease (PN-10)

 Principles of Penile Organ-Sparing Approaches (PN-A)
 Principles of Surgery (PN-B)
 Principles of Radiotherapy (PN-C)
 Principles of Systemic Therapy (PN-D)
 Principles of Imaging (PN-E)

Staging (ST-1)

Abbreviations (ABBR-1)
Terminologies in all NCCN Guidelines are being actively modified to advance the goals of equity, inclusion, and representation. Updates in Version 1.2024 of the NCCN Guidelines for Penile Cancer from Version 1.2023 include:

**PN-1**
- Primary Evaluation
  - Bullet 1, sub-bullet 1: Balanitis, chronic inflammation, penile trauma, lack of neonatal circumcision, tobacco use, lichen sclerosus, poor hygiene, sexually transmitted disease (*eg, HIV screening*)

**PN-5**
- Lower pathway moved to PN-6

**PN-6**
- Node status modified: *Palpable bulky inguinal lymph nodes*: Unilateral lymph nodes (fixed) or bilateral lymph nodes (fixed or mobile)
- Treatment after neoadjuvant TIP chemotherapy, response, and ILND/PLND/RT/Chemo RT added: Consider RT or chemo/RT if extranodal extension (category 2B)
- Footnote removed: Consider postoperative RT or chemo/RT (category 2B).

**PN-7**
- Treatment added after surgical candidate, stable or clinical response, consolidation therapy: Consider postoperative RT or chemo/RT if pN2-3 or presence of extranodal extension (category 2B)

**PN-10**
- Treatment after no response/disease progression modified: Consider subsequent-line systemic therapy or consider RT for local control and/or *clinical trial and/or best supportive care/clinical trial* (See NCCN Guidelines for Palliative Care)

**MS-1**
- The Discussion was updated to reflect the changes in the algorithm.
INTRODUCTION

NCCN and the NCCN Penile Cancer Panel believe that the best management for any patient with cancer is in a clinical trial. Participation in clinical trials is especially encouraged.
These Guidelines are for treatment of squamous cell carcinoma of the penis.

Principles of Penile Organ-Sparing Approaches (PN-A).

Note: All recommendations are category 2A unless otherwise indicated.

Clinical Trials: NCCN believes that the best management of any patient with cancer is in a clinical trial. Participation in clinical trials is especially encouraged.
NCCN Guidelines Version 1.2024
Penile Cancer

PATHOLOGIC DIAGNOSIS

T1

Grade 1–2

Wide local excision\(^b\)
or
Partial penectomy\(^{c,d}\)
or
Glansectomy in select cases\(^b\)
or
Mohs surgery in select cases\(^b\) (category 2B)
or
Laser therapy\(^b\) (category 2B)
or
RT\(^d\) (category 2B)

T2 or greater

Grade 3–4

Wide local excision\(^b\)
or
Partial penectomy\(^{c,d}\)
or
Total penectomy\(^{c,d}\)
or
RT\(^d\) (category 2B)
or
Chemo/RT\(^{d,e}\) (category 3)

Management of Non-Palpable Inguinal Lymph Nodes (PN-3)

Management of Palpable Inguinal Lymph Nodes (PN-4)

Note: All recommendations are category 2A unless otherwise indicated.
Clinical Trials: NCCN believes that the best management of any patient with cancer is in a clinical trial. Participation in clinical trials is especially encouraged.

\(^b\) Principles of Penile Organ-Sparing Approaches (PN-A).
\(^c\) Principles of Surgery (PN-B).
\(^d\) Principles of Radiotherapy (PN-C).
\(^e\) Principles of Systemic Therapy (PN-D).
**Management of Non-Palpable Inguinal Lymph Nodes**

<table>
<thead>
<tr>

</tbody>
</table>

- **Principles of Surgery (PN-B).**
- Ta verrucous carcinoma is by definition a well-differentiated tumor. Therefore, only surveillance of the inguinal lymph nodes is required.
- Cross-sectional imaging may include CT, MRI, PET/CT, and/or chest x-ray. When appropriate, imaging should be done with contrast unless contraindicated. See Principles of Imaging (PN-E).
- A modified/superficial inguinal dissection with intraoperative frozen section is an acceptable alternative to stage the inguinal lymph nodes.
- Consider prophylactic external beam radiation therapy (EBRT) (category 2B) to inguinal lymph nodes in patients who are not surgical candidates or who decline surgical management.
- DSNB is recommended provided the treating physician has experience with this modality.
- If positive lymph nodes are found on DSNB, ILND is recommended.

**Note:** All recommendations are category 2A unless otherwise indicated.

Clinical Trials: NCCN believes that the best management of any patient with cancer is in a clinical trial. Participation in clinical trials is especially encouraged.
# Management of Palpable Non-Bulky Inguinal Lymph Nodes

## Nodal Status

### Imaging

<table>
<thead>
<tr>
<th>Palpable Inguinal Lymph Nodes</th>
<th>Cross-sectional Imaging of Chest/Abdomen/Pelvis</th>
</tr>
</thead>
<tbody>
<tr>
<td>Unilateral lymph node(s) ≤4 cm (fixed or mobile)</td>
<td></td>
</tr>
<tr>
<td>Unilateral lymph node(s) ≥4 cm (fixed or mobile)</td>
<td>Enlarged pelvic lymph nodes</td>
</tr>
</tbody>
</table>

## Risk Stratification Based on Physical/Imaging Findings

- **Low-risk primary lesion**
- **High-risk primary lesion**

## Treatment

### Negative

- Excisional biopsy or Surveillance

### Positive

- **Bilateral ILND**
- Consider neoadjuvant TIP (paclitaxel, ifosfamide, cisplatin) chemotherapy followed by ILND

### pN1

- Pelvic lymph node dissection (PLND) ± (if pelvic nodes positive, adjuvant RT or chemotherapy [category 2B]) or chemo/RT (category 2B) or chemotherapy (category 2B)

### pN2-3

- Management of Palpable Bulky Inguinal Lymph Nodes (PN-5)

## Management of Enlarged Pelvic Lymph Nodes (PN-7)

- Pelvic lymph node dissection (PLND) ± (if pelvic nodes positive, adjuvant RT or chemotherapy [category 2B]) or chemo/RT (category 2B) or chemotherapy (category 2B)

---

**Note:** All recommendations are category 2A unless otherwise indicated.

Clinical Trials: NCCN believes that the best management of any patient with cancer is in a clinical trial. Participation in clinical trials is especially encouraged.
MANAGEMENT OF PALPABLE BULKY INGUINAL LYMPH NODES

NODE STATUS | LYMPH NODES | TREATMENT
--- | --- | ---
Palpable bulky inguinal lymph node(s): Unilateral ≥4 cm (fixed or mobile) or Unilateral lymph node(s) <4 cm (fixed) or Bilateral (fixed or mobile) | Neoadjuvant TIP chemotherapy\textsuperscript{e} followed by ILND (preferred), consider PLND\textsuperscript{c} or ILND\textsuperscript{c} (preferred), consider PLND\textsuperscript{c} (in patients not eligible for TIP) or RT\textsuperscript{d} or Chemo/RT\textsuperscript{d,e} | 0–1 positive nodes with viable disease |
| Percutaneous lymph node biopsy\textsuperscript{p} | ≥2 positive nodes or extranodal extension | Adjuvant chemotherapy\textsuperscript{e} (if not already given) and/or If pelvic nodes positive, adjuvant RT\textsuperscript{d} or Chemo/RT\textsuperscript{d,e} (category 2B) |
Negative | Excisional biopsy | Surveillance (PN-8) |
Positive | Surveillance (PN-8) |

\textsuperscript{c} Principles of Surgery (PN-B). 
\textsuperscript{d} Principles of Radiotherapy (PN-C). 
\textsuperscript{e} Principles of Systemic Therapy (PN-D). 
\textsuperscript{n} The size threshold of 4 cm represents the largest diameter of contiguous inguinal lymph node(s) tissue as measured on either physical examination and/or axial imaging (CT or MRI) and suspected of harboring metastatic disease. 
\textsuperscript{p} Ultrasound- or CT-guided biopsy of the most accessible node, inguinal or pelvic. 

Note: All recommendations are category 2A unless otherwise indicated. Clinical Trials: NCCN believes that the best management of any patient with cancer is in a clinical trial. Participation in clinical trials is especially encouraged.
MANAGEMENT OF PALPABLE BULKY INGUINAL LYMPH NODES

NODE STATUS | LYMPH NODES | TREATMENT
---|---|---
Negative | Excisional biopsy | Negative → Surveillance (PN-8)
Positive | | Positive

Percutaneous lymph node biopsy

Neoadjuvant TIP chemotherapy

Consider RT or chemo/RT if extranodal extension (category 2B)

ILNDc (preferred) and PLNDC,q (preferred) or RTc or Chemo/RTd,e

Surveyance (PN-8)

No response

No Response/Disease Progression (PN-10)

Positive

Not eligible for neoadjuvant chemotherapy

Response

P Ultrasound- or CT-guided biopsy of the most accessible node, inguinal or pelvic.

c Data suggest that in the setting of ≥4 positive inguinal lymph nodes, bilateral PLND should be performed. Zargar-Shoshtari K, et al. J Urol 2015;194:696-701.

See-Principles of Surgery (PN-B).

d See-Principles of Radiotherapy (PN-C).

e See-Principles of Systemic Therapy (PN-D).

The size threshold of 4 cm represents the largest diameter of contiguous inguinal lymph node(s) tissue as measured on either physical examination and/or axial imaging (CT or MRI) and suspected of harboring metastatic disease.

Note: All recommendations are category 2A unless otherwise indicated.

Clinical Trials: NCCN believes that the best management of any patient with cancer is in a clinical trial. Participation in clinical trials is especially encouraged.
## MANAGEMENT OF ENLARGED PELVIC LYMPH NODES

<table>
<thead>
<tr>
<th>NODE STATUS</th>

- See Principles of Radiotherapy (PN-C).
- See Principles of Systemic Therapy (PN-D).
- Cross-sectional imaging may include CT, MRI, PET/CT, and/or chest x-ray. When appropriate, imaging should be done with contrast unless contraindicated. See Principles of Imaging (PN-E).
- If M1 disease is identified, see Management of Metastatic Disease (PN-10).
- Ultrasound- or CT-guided biopsy of the most accessible node, inguinal or pelvic.
- On CT or MRI, not pathologic stage.
- If not technically feasible, PET/CT scan can be used to evaluate lymph nodes.
- Consolidation surgery consists of bilateral superficial and deep ILND and unilateral/bilateral PLND.

Note: All recommendations are category 2A unless otherwise indicated.

Clinical Trials: NCCN believes that the best management of any patient with cancer is in a clinical trial. Participation in clinical trials is especially encouraged.
## SURVEILLANCE SCHEDULE

<table>
<thead>
<tr>
<th>ANATOMIC SITE</th>
<th>INITIAL TREATMENT</th>
<th>SURVEILLANCE(^v)</th>
</tr>
</thead>
</table>
| Primary lesion | Topical or local therapy | • Clinical examination\(^w,x\)  
  ‣ Years 1–2: every 3 mo, then  
  ‣ Years 3–5: every 6 mo, then  
  ‣ Years 5–10: every 12 mo |
|               | Partial or radical penectomy | • Clinical examination\(^w,x\)  
  ‣ Years 1–2: every 6 mo, then  
  ‣ Years 3–10: every 12 mo |
| Lymph nodes   | pNX\(^u\)          | • Clinical examination\(^w,x\)  
  ‣ Years 1–2: every 6 mo, then  
  ‣ Years 3–4: every 12 mo |
|               | pN0, N1            | • Clinical examination\(^w,x\)  
  ‣ CT abdomen/pelvis and chest radiograph  
  ‣ Years 1–2: every 6 mo, then  
  ‣ Years 3–4: every 12 mo |
|               | pN2, N3            | • Clinical examination\(^w,x\)  
  ‣ CT abdomen/pelvis and chest CT  
  ‣ Year 1: every 3 mo, then  
  ‣ Years 2–4: every 6 mo |

\(^u\) Patients on active surveillance of clinically negative nodes and at low risk for inguinal metastases.  
\(^w\) Clinical examination includes examination of the penis and inguinal region.  
\(^x\) If an abnormal clinical examination, patient affected by obesity, or prior inguinal surgery, then ultrasound, CT with contrast, or MRI with contrast of the inguinal region can be considered.

For patients with recurrence at either local or distant sites, see Management of Recurrent Disease (PN-9)

\(^v\) See NCCN Guidelines for Survivorship.

Note: All recommendations are category 2A unless otherwise indicated.

Clinical Trials: NCCN believes that the best management of any patient with cancer is in a clinical trial. Participation in clinical trials is especially encouraged.
MANAGEMENT OF RECURRENT DISEASE

Recurrence of penile lesion after initial penile sparing treatment

Treat according to recurrence stage (PN-1 and PN-2)

<table>
<thead>
<tr>
<th>No prior inguinal lymphadenectomy or RT</th>

</tr>
</tbody>
</table>

Note: All recommendations are category 2A unless otherwise indicated.

Clinical Trials: NCCN believes that the best management of any patient with cancer is in a clinical trial. Participation in clinical trials is especially encouraged.

See Principles of Surgery (PN-B).
Principles of Radiotherapy (PN-C).
Principles of Systemic Therapy (PN-D).
Ultrason- or CT-guided biopsy of the most accessible node, inguinal or pelvic.
MANAGEMENT OF METASTATIC DISEASE

Metastatic penile cancer → Systemic chemotherapy\textsuperscript{e,y} → Cross-sectional imaging of chest/abdomen/pelvis\textsuperscript{g} →

- Complete/partial response or stable → Consolidation surgery\textsuperscript{t} → Surveillance (PN-8)
- No response/Disease progression →
  - Consider subsequent-line systemic therapy\textsuperscript{e} or
  - Consider RT\textsuperscript{d} for local control and/or Clinical trial and/or Best supportive care (See NCCN Guidelines for Palliative Care)

\textsuperscript{d} Principles of Radiotherapy (PN-C).
\textsuperscript{e} Principles of Systemic Therapy (PN-D).
\textsuperscript{g} Cross-sectional imaging may include CT, MRI, PET/CT, and/or chest x-ray. When appropriate, imaging should be done with contrast unless contraindicated. See Principles of Imaging (PN-E).
\textsuperscript{t} Consolidation surgery consists of bilateral superficial and deep ILND and unilateral/bilateral PLND.
\textsuperscript{y} Discuss palliative care and therapies for local control.

Note: All recommendations are category 2A unless otherwise indicated. Clinical Trials: NCCN believes that the best management of any patient with cancer is in a clinical trial. Participation in clinical trials is especially encouraged.
PRINCIPLES OF PENILE ORGAN-SPARING APPROACHES

Tis, Ta, and T1 penile cancer lesions may be amenable to conservative penile organ-sparing approaches, including topical therapy, wide local excision, laser therapy, glansectomy, and Mohs surgery.

Topical Therapy

- For patients with Tis or Ta disease:
  - Imiquimod 5%: apply at night three times per week for 4–16 weeks.
  - 5-FU cream 5%: apply twice daily for 2–6 weeks.

Laser Therapy (category 2B)

- The use of therapeutic lasers (CO2, Nd:YAG, and KTP) to treat selected (clinical stage Tis, Ta, and T1 Grade 1–2) primary penile tumors has been reported with acceptable outcomes.
- Perioperative application of 3%–5% acetic acid to the potentially affected genital skin can be used to identify suspected sites of HPV infected skin that turns white upon exposure, making these acetowhite areas appropriately targetable for laser ablation.
- A plume (smoke) evacuator is required during penile laser treatments to minimize exposure to HPV and other viral particles as well as combustion-related carcinogens.
- The following is a table of the therapeutic lasers commonly used to treat penile cancer including suggested settings.

<table>
<thead>
<tr>

Note: All recommendations are category 2A unless otherwise indicated.

Clinical Trials: NCCN believes that the best management of any patient with cancer is in a clinical trial. Participation in clinical trials is especially encouraged.
PRINCIPLES OF PENILE ORGAN-SPARING APPROACHES

Wide Local Excision

- This is designated for early-stage penile cancer confined to the skin with little or no invasion (clinical stage Tis, Ta, T1).
- The surgical margins for wide local excision depend on the location of the penile tumor.
  - Penile tumors of the shaft may be treated with wide local excision, with or without circumcision.
  - Circumcision alone may be reasonable for tumors of the distal prepuce.
- Complete excision of the skin with a wide negative margin is needed and may require the use of a split-thickness skin graft (STSG) or full-thickness skin graft (FTSG) (if a primary tension-free reapproximation cannot be completed).
- If positive surgical margins, re-resection may be considered.
- Glans resurfacing may be considered in highly select patients.

Glansectomy

- Glansectomy may be considered for select patients with distal tumors (clinical stage Ta, Tis, T1) on the glans or prepuce.
  - For patients with Ta or Tis disease, a complete glansectomy is a category 2B recommendation.
  - For patients with T1 G1–2 disease, glansectomy is not recommended unless required to ensure complete tumor eradication with negative margins.
- Negative surgical margins should be determined from frozen sections of the cavernosal bed and urethral stump.
- Treatment is followed in certain instances with an STSG or FTSG to create a neoglans.

Mohs Micrographic Surgery (category 2B)

- Mohs surgery is an alternative to wide local excision in select cases.²
  - Thin layers of cancerous skin are excised and viewed microscopically until a tissue layer is negative for the tumor.
  - Mohs surgery allows for increased precision, although the success rate declines with higher stage disease.
- This may be preferable for a small superficial lesion on the proximal shaft to avoid total penectomy for an otherwise fairly low-risk lesion.

**PRINCIPLES OF SURGERY**

**Penectomy**
- Partial penectomy should be considered the standard for high-grade primary penile tumors, provided that a functional penile stump can be preserved and negative margins are obtained. If a partial penectomy is not possible, a total penectomy should be performed.
- Partial or total penectomy when invasion into the corpora cavernosum is necessary to achieve a negative margin.
- Intraoperative frozen sections are recommended to determine negative margins.

**Surgical Management of Inguinal and Pelvic Lymph Nodes**
- Standard or modified ILND or DSNB is indicated in patients with penile cancer in the absence of palpable inguinal adenopathy if high-risk features for nodal metastasis are seen in the primary penile tumor:
  - Lymphovascular invasion
  - ≥pT1G3 or ≥T2, any grade
  - >50% poorly differentiated
- DSNB is only recommended if the treating physician has experience with this modality.
- If positive lymph nodes are found on DSNB, ILND is recommended.
- PLND should be considered at the time or following ILND in patients with ≥2 positive inguinal nodes on the ipsilateral ILND site or in the presence of extranodal extension on final pathologic review.
- A bilateral PLND should be considered either at the time or following ILND in patients with ≥4 positive inguinal nodes (in total among both sides).\(^1\)
- See Discussion for further details regarding ILND and PLND.

---

Primary Radiation/Chemoradiation Therapy (Penile Preservation)

T1–2, N0
If tumor <4 cm
• Circumcision followed by either:
  ▶ Brachytherapy alone\(^1,2\) (category 2B) (should be performed with interstitial implant);
  or
  ▶ EBRT (category 2B): Total dose 65–70 Gy with conventional fractionation using appropriate bolus to primary penile lesion with 2-cm margins.
  ▶ EBRT with concurrent chemotherapy (category 3)\(^3\): total dose 65–70 Gy with conventional fractionation using appropriate bolus to primary penile lesion with 2-cm margins.
  ▶ Consider prophylactic EBRT to inguinal lymph nodes in patients who are not surgical candidates or who decline surgical management.

If tumor ≥4 cm
• Circumcision followed by either:
  ▶ EBRT with concurrent chemotherapy (category 3)\(^3\): 45–50.4 Gy to a portion of or whole penile shaft depending on bulk and extent of lesion plus pelvic/inguinal nodes, then boost primary lesion with 2-cm margins (total dose, 65–70 Gy);
  or
  ▶ Brachytherapy alone (category 2B) in select cases and with careful post-treatment surveillance.

T3–4 or N+ (surgically unresectable)
• Circumcision followed by:
  ▶ EBRT with concurrent chemotherapy (category 3)\(^3\): 45–50.4 Gy to whole penile shaft, pelvic lymph nodes, and bilateral inguinal lymph nodes, then boost primary lesion with 2-cm margins and gross lymph nodes (total dose, 60–70 Gy).

Primary Site Margin Positive Following Penectomy
• Postsurgical EBRT: If no gross disease: 45–60 Gy to the primary site and scar. If gross disease remains, follow guideline for T3–4, or N+.
  ▶ Treat bilateral inguinal lymph nodes and pelvic lymph nodes if no or inadequate lymph node dissection.
  ▶ Brachytherapy may be considered in select cases.

Adjuvant Chemo/RT
• Inguinal and/or pelvic lymph node positive
  ▶ Recommended for palpable bulky inguinal lymph nodes or enlarged pelvic lymph nodes\(^3\): consider for palpable non-bulky inguinal lymph nodes pN2–3 disease (category 2B) or for local recurrence to inguinal region (category 2B).
  ▶ Inguinal and pelvic lymph node EBRT to 45–50.4 Gy.
  ▶ Boost gross nodes and areas of extracapsular extension to a total dose of 65–70 Gy.
  ▶ Treat primary site of disease if positive margin.

Palliative RT
• Consider a palliative dose of 30 Gy in 10 fractions.

\(^3\) For potential radiosensitizing agents and combinations, see Principles of Systemic Therapy (PN-D 2 of 4).
PRINCIPLES OF SYSTEMIC THERAPY

**Neoadjuvant Chemotherapy Prior to ILND or PLND**

<table>
<thead>
<tr>
<th>Preferred Regimen</th>
</tr>
</thead>
<tbody>
<tr>
<td>• TIP (paclitaxel, ifosfamide, and cisplatin)</td>
</tr>
</tbody>
</table>

- Neoadjuvant chemotherapy with TIP is preferred (prior to ILND) in patients with ≥4 cm inguinal lymph nodes (fixed or mobile), if fine-needle aspiration (FNA) is positive for metastatic penile cancer.¹
  - Patients with initially unresectable (T4) primary tumors may be downstaged by response to chemotherapy.
  - Patients not eligible to receive TIP and who are surgical candidates should undergo surgery without neoadjuvant chemotherapy.
- A TX, N2–3, M0 penile cancer can receive four courses of neoadjuvant TIP. Stable or responding disease should then undergo consolidative surgery with curative intent. The phase II response rate was 50% in the neoadjuvant setting. The estimated rate of long-term progression-free survival for intent to treat was 36.7%. Improved progression-free and overall survival times were associated with objective response to chemotherapy.²

**Adjuvant Chemotherapy Following ILND or PLND**

<table>
<thead>

</table>

- There are no sufficient data to form conclusions about the use of adjuvant chemotherapy. By extrapolation from the neoadjuvant data, it is reasonable to give 4 courses of TIP in the adjuvant setting if it was not given preoperatively and the pathology shows high-risk features. 5-FU plus cisplatin can be considered as an alternative to TIP in the adjuvant setting (see Management of Palpable Bulky Inguinal Lymph Nodes, PN-5). Adjuvant EBRT or chemo/RT can also be considered for patients with high-risk features.
- High-risk features include any of the following:
  - Pelvic lymph node metastases
  - Extranodal extension
  - Bilateral inguinal lymph nodes involved
  - 4-cm tumor in lymph nodes
### First-line Systemic Therapy for Metastatic/Recurrent Disease

<tbody>
<tr>
<td>TIP</td>
<td>5-FU + cisplatin</td>
</tr>
</tbody>
</table>

- Not recommended: Bleomycin-containing regimens are associated with unacceptable toxicity.\(^5\)
- TIP is a reasonable first-line treatment for patients with metastatic penile cancer, including palliative treatment of patients with distant metastases.\(^2\)
- 5-FU + cisplatin has been used historically for metastatic penile cancer and can be considered as an alternative to TIP.\(^4\) It appears to be effective for some patients, although the toxicities may be limiting and may require dose reductions.\(^3,4\)
- There are no randomized clinical trials due to the rarity of penile cancer in industrialized countries.

### Subsequent-line Systemic Therapy for Metastatic/Recurrent Disease

<table>

</thead>
<tbody>
<tr>
<td>Clinical trial</td>
</tr>
<tr>
<td>Pembrolizumab, if unresectable or metastatic, microsatellite instability-high (MSI-H) or mismatch repair-deficient (dMMR) tumor that has progressed following prior treatment and no satisfactory alternative treatment options, or if tumor mutational burden-high (TMB-H), TMB ≥10 mut/Mb in patients who have progressed on previously approved lines of therapy.(^9)</td>
</tr>
</tbody>
</table>

### Useful in Certain Circumstances

- Paclitaxel
- Cetuximab

- No standard subsequent-line systemic therapy exists.
- A clinical trial is preferred. The evidence to support the palliative use of second-line therapy is limited.\(^10\)
- Paclitaxel\(^11\) or cetuximab\(^12\) may be considered in select patients, especially if not previously treated with a similar class of agent.

### Radiosensitizing Agents and Combinations\(^13\) (Chemo/RT)

Combination Chemotherapy Regimens

TIP\(^2\) (preferred)
- Paclitaxel 175 mg/m\(^2\) IV over 3 hours on Day 1
- Ifosfamide 1200 mg/m\(^2\) IV over 2 hours on Days 1–3
- Cisplatin 25 mg/m\(^2\) IV over 2 hours on Days 1–3
Repeat every 3 to 4 weeks

5-FU + cisplatin\(^3,4\) (not recommended for neoadjuvant setting)
- Continuous infusion 5-FU 800–1000 mg/m\(^2\)/day IV on Days 1–4 or Days 2–5
- Cisplatin 70–80 mg/m\(^2\) IV on Day 1
Repeat every 3 to 4 weeks

Note: All recommendations are category 2A unless otherwise indicated.
Clinical Trials: NCCN believes that the best management of any patient with cancer is in a clinical trial. Participation in clinical trials is especially encouraged.
PRINCIPLES OF SYSTEMIC THERAPY

REFERENCES

PRINCIPLES OF IMAGING

Initial Workup
• Cross-sectional imaging of chest/abdomen/pelvis\(^a\):
  ▶ Abdomen/pelvis CT or MRI with contrast
  ▶ Chest x-ray or CT with contrast
  ▶ CT/MRI of pelvis with contrast for nodal evaluation if difficult to clinically assess.

Staging
• Cross-sectional imaging of chest/abdomen/pelvis\(^a\):
  ▶ Abdomen/pelvis CT or MRI with contrast
  ▶ Chest x-ray or CT with contrast
  ▶ Consider: FDG-PET/CT (skull base to mid-thigh in patients with suspected inguinal lymph node-positive disease)

Treatment Response Assessment
• Cross-sectional imaging of chest/abdomen/pelvis\(^a\):
  ▶ Abdomen/pelvis CT or MRI with contrast
  ▶ Chest x-ray or CT with contrast
  ▶ Consider: FDG-PET/CT (skull base to mid-thigh)
  ◊ Imaging to assess treatment response and disease progression in patients with suspected inguinal lymph node-positive disease.

Surveillance (Staging System AJCC, 8th Edition)
• Consider imaging of the inguinal region\(^b\):
  ▶ CT with contrast
    or
  ▶ MRI with contrast
    or
  ▶ Ultrasound – Imaging at the time of clinical examination if abnormal clinical examination, patient affected by obesity, or prior inguinal surgery.

\(^a\) When appropriate, imaging should be done with contrast unless contraindicated.

Note: All recommendations are category 2A unless otherwise indicated.
Clinical Trials: NCCN believes that the best management of any patient with cancer is in a clinical trial. Participation in clinical trials is especially encouraged.

Overview
Squamous cell carcinoma (SCC) of the penis is a rare disease, representing 0.4% to 0.6% of all malignant neoplasms among males in the United States and Europe. In 2023, the estimated number of new cases of penile and other male genital cancers in the United States is 2050, with 470 predicted cancer-specific deaths. The incidence is higher in the developing countries of Asia, Africa, and South America. The most common age at presentation is between 50 and 70 years. Early diagnosis is of utmost importance, as this is a disease that can result in devastating disfigurement and has a 5-year survival rate of approximately 50% (>85% for patients with negative lymph nodes and 29%–40% for patients with positive nodes, with the lowest survival rates at 0% for patients with pelvic lymph node [PLN] involvement). As the rarity of this disease makes it difficult to perform prospective, randomized trials, the NCCN Panel relied on the experience of penile cancer experts and the best currently available evidence-based data to collectively lay a foundation to help standardize the management of this malignancy.

Guidelines Update Methodology
The complete details of the Development and Update of the NCCN Guidelines are available at www.NCCN.org.

Literature Search Criteria
Prior to the update of this version of the NCCN Guidelines for Penile Cancer, an electronic search of the PubMed database was performed to obtain key literature published since the previous Guidelines update, using the search term: penile cancer. The PubMed database was chosen because it remains the most widely used resource for medical literature and indexes peer-reviewed biomedical literature.

The search results were narrowed by selecting studies in humans published in English. Results were confined to the following article types: Clinical Trial; Guideline; Meta-Analysis; Randomized Controlled Trial; Systematic Reviews; and Validation Studies. The data from key PubMed articles as well as articles from additional sources deemed as relevant to these guidelines as discussed by the panel during the Guidelines update have been included in this version of the Discussion section. Recommendations for which high-level evidence is lacking are based on the panel’s review of lower-level evidence and expert opinion.

Sensitive/Inclusive Language Usage
NCCN Guidelines strive to use language that advances the goals of equity, inclusion, and representation. NCCN Guidelines endeavor to use language that is person-first; not stigmatizing; anti-racist, anti-classist, anti-misogynist, anti-ageist, anti-ableist, and anti-weight-biased; and inclusive of individuals of all sexual orientations and gender identities. NCCN Guidelines incorporate non-gendered language, instead focusing on organ-specific recommendations. This language is both more accurate and more inclusive and can help fully address the needs of individuals of all sexual orientations and gender identities. NCCN Guidelines will continue to use the terms men, women, female, and male when citing statistics, recommendations, or data from organizations or sources that do not use inclusive terms. Most studies do not report how sex and gender data are collected and use these terms interchangeably or inconsistently. If sources do not differentiate gender from sex assigned at birth or organs present, the information is presumed to predominantly represent cisgender individuals. NCCN encourages researchers to collect more specific data in future studies and organizations to use more inclusive and accurate language in their future analyses.
Risk Factors

In the United States the median age at diagnosis is 68 years, with an increase in risk for individuals >50 years. Early detection is assisted by the ability to perform a good physical examination. Phimosis may hinder the capability to properly inspect the areas of highest incidence—the glans, inner preputial layer, coronal sulcus, and shaft. Patients with phimosis carry an increased risk for penile cancer of 25% to 60%. A review of penile SCC in the United States showed that 34.5% of patients had the primary lesion on the glans, 13.2% on the prepuce, and 5.3% on the shaft, with 4.5% overlapping and 42.5% unspecified. Other risk factors include balanitis, chronic inflammation, penile trauma, lack of neonatal circumcision, tobacco use, lichen sclerosus, poor hygiene, and a history of sexually transmitted disease(s), especially HIV and human papillomavirus (HPV). Overall, approximately 45% to 80% of penile cancers are related to HPV, with a strong correlation with types 16, 6, and 18. While HPV infection is a risk factor for penile cancer, HPV- or p16-positivity have also been reported as favorable prognostic factors, in terms of better disease-specific survival (DSS). There is an increased risk of HPV infection and associated disease for patients with HIV. One study reported that females who are HIV-positive have a higher risk of HPV acquisition (relative risk, 2.64; 95% CI, 2.04–3.42) and lower HPV clearance (hazard ratio [HR], 0.72; 95% CI, 0.62–0.84) compared to those who are HIV-negative. Oral HPV is also reportedly common in males who are HIV-positive (17.6%; 95% CI, 13.5–22.8%).

Neonatal circumcision is associated with a lower rate of penile cancer, although the protective effect is not seen in adults who have the foreskin removed. This reduced incidence of penile cancer in patients who have been circumcised in infancy may reflect other known risk factors including the elimination of phimosis and lower incidence and duration of HPV infections in this population (reviewed by Morris et al). However, due to the rarity of the disease, the number of neonatal circumcisions that would need to be performed to prevent one case of penile cancer is relatively high. A small study suggests that the benefits of circumcision may reduce invasive penile cancer but not carcinoma in situ (CIS, also called TIS). People who smoke cigarettes are noted to be 3 to 4.5 times more likely to develop penile cancer. Patients with lichen sclerosus have a 2% to 9% risk of developing penile carcinoma. Patients with psoriasis undergoing psoralen plus ultraviolet A (PUVA) treatment have an increased penile cancer incidence of 286 times compared to the general population. Therefore, they should be shielded during treatment and any penile lesion should be closely monitored. A study of patients with advanced penile SCC receiving systemic therapy identified visceral metastases and an Eastern Cooperative Oncology Group (ECOG) performance score greater than or equal to 1 as poor prognostic factors for both overall survival (OS) and progression-free survival (PFS). However, studies remain limited on predictive factors of prognosis in this patient population.

Clinical Presentation

Most often penile SCC presents as a palpable, visible lesion on the penis, which may be associated with penile pain, discharge, bleeding, or a foul odor if the patient delays seeking medical treatment. The lesion may be characterized as nodular, ulcerative, or fungating, and may be obscured by phimosis. The patient may exhibit signs of more advanced disease, including palpable nodes and/or constitutional symptoms (eg, fatigue, weight loss).

Characterization and Clinical Staging

Approximately 95% of penile cancers originate in squamous epithelial cells and are further categorized as either SCC or penile intraepithelial neoplasia (PIN). PIN is a premalignant condition at high risk of...
developing into SCC of the penis and includes the clinical entities of
bowenoid papulosis, erythroplasia of Queyrat, and Bowen’s disease.\textsuperscript{27}
The AJCC recognizes four subtypes of SCC: verrucous, papillary squamous, warty, and basaloid.\textsuperscript{28} The verrucous subtype is considered
to demonstrate low malignant potential, while other variants reported—adenosquamous and sarcomatoid variants—carry a worse prognosis.\textsuperscript{29,30} The primary lesion is further characterized by its growth pattern with superficial spread, nodular or vertical-phase growth, and verrucous pattern. In addition to the penile lesion, evaluation of lymph nodes is also critical, as involvement of the inguinal lymph nodes (ILNs), the number and site of positive nodes, and extracapsular nodal involvement provide the strongest prognostic factors of survival.\textsuperscript{5,31}

The AJCC TNM (tumor, node, and metastasis) Staging System for penile carcinoma has been used for staging, with the most recent update (eighth edition) published in 2017. It was initially introduced in 1968 and was subsequently revised in 1978, 1987, 2002, and 2010.\textsuperscript{32-36} In 2010, the AJCC made the distinction between clinical and pathologic staging while eliminating the difference between superficial and deep inguinal metastatic nodes.\textsuperscript{32} The eighth edition of the AJCC staging system\textsuperscript{28} includes changes to the primary tumor (T) definitions, including: 1) broadening the Ta definition to include noninvasive localized squamous carcinoma; 2) describing T1 by the location of the tumor on the penis (eg, glans, foreskin, shaft) and defining invasion for each location; 3) adding perineural invasion as a prognostic indicator to define T1b from T1a; 4) including corpus spongiosum invasion within the T2 definition; and 5) including corpora cavernosum invasion within the T3 definition. In addition, the eighth edition includes changes to the regional lymph node definitions, the most notable being pN1 defined as ≤2 unilateral inguinal metastases without extranodal extension and pN2 being defined as ≥3 unilateral inguinal metastases or bilateral metastases. Finally, stage II disease has been split into stage IIA and stage IIB with T1b or T2, N0, M0 defining stage IIA and T3, N0, M0 defining stage IIB\textsuperscript{28} (see Staging in the algorithm).

The AJCC recommends a grading system for SCC of the penis based on the 3-tiered World Health Organization (WHO)/International Society of Urological Pathology (ISUP) grading system with the following definitions: grade 1, well differentiated; grade 2, moderately differentiated; and grade 3, poorly differentiated/undifferentiated. Any proportion of anaplastic cells categorizes the tumor as grade 3.\textsuperscript{28} The overall degree of cellular differentiation with high-risk, poorly differentiated tumors is an important predictive factor for metastatic nodal involvement.\textsuperscript{37} The AJCC also recommends collection of site-specific factors, including: the percentage of tumor that is poorly differentiated, the depth of invasion in verrucous carcinoma, the presence of lymphovascular or perineural invasion, the size of the largest lymph node metastasis, and the total number of lymph nodes removed.\textsuperscript{28}

**Management of Primary Lesions**

**Diagnosis**

Evaluation of the primary lesion, regional lymph nodes, and distant metastasis will dictate the appropriate and adequate management of SCC of the penis, beginning with the first evaluation at presentation and then throughout follow-up. Vital to the initial management is a good physical examination of the penile lesion(s) that remarks on the diameter of the lesion(s) or suspicious areas; location(s) on the penis; number of lesions; morphology of the lesion(s); whether the lesion(s) are papillary, nodular, ulcerous, or flat; and the relationship with other structures including submucosal, urethra, corpora spongiosa, and/or corpora cavernosa. Invasion into the corpora cavernosa has been associated with worse cancer-specific survival and higher rates of lymph node metastasis compared to corpus spongiosum invasion.\textsuperscript{38}
To complete the initial evaluation, a histologic diagnosis with a punch, excisional, or incisional biopsy is paramount in determining the treatment algorithm based on a pathologic diagnosis. This will provide information on the grade of the tumor, and will assist in the risk stratification of the patient for regional lymph node involvement. HPV and HIV status should also be assessed, as HPV or HIV positivity has prognostic significance, could prompt screening for sexual partners, and may be considered in treatment decision-making. MRI or ultrasound can be used to evaluate the depth of tumor invasion. Imaging may also be considered for evaluation of ILNs that are difficult to assess. For the evaluation of lymph nodes, see Management of Regional Lymph Nodes.

Penile Organ-Sparing Approaches

Tis, Ta, and T1 penile cancer lesions may be amenable to conservative penile organ-sparing approaches, including topical therapy, laser therapy, wide local excision, glansectomy, and Mohs surgery. An analysis of the National Cancer Database reported that OS rates were comparable for patients with pT1–T2 penile cancer that was treated with organ-sparing surgery compared to partial or total penectomy. A multivariable model for predictors of patient survival in this study found that organ-sparing surgery did not predict poor patient survival (HR, 0.88; 95% CI, 0.64–1.21). A systematic review of 88 studies including 9578 patients with penile cancer yielded a similar conclusion, noting that both penile-sparing and amputative approaches are effective treatment options for penile cancer, with amputative surgery having a more negative impact on sexual function and quality of life. However, this review also noted a higher 5-year recurrence-free survival rate for amputative surgery (93.3%) compared to penile-sparing surgery (76.6%) as reported from retrospective comparative studies, likely due to a higher risk of local recurrence with penile-sparing approaches. Careful consideration should be given to penile-preserving techniques if the patient is willing and able to undergo close follow-up.

Topical Therapy

Topical therapy is a valuable outpatient treatment due to ease of administration; however, patients should be monitored for adherence to therapy and for toxicity or adverse events (AEs). Local skin and application site reactions may occur and are generally mild to moderate, although severe reactions may occur with a higher frequency of application. Modification of the application frequency can resolve these complications. Despite significant response rates, the probability of relapse is higher following topical therapy than with other more aggressive therapies. Therefore, patients who are eligible for topical therapy should be routinely monitored for recurrence.

While topical therapy for the treatment of PIN has been reported in numerous case studies and case reports, the data are limited by the small sample sizes and variation in treatment protocols. A retrospective review from a prospective database of patients diagnosed with PIN over a 10-year range identified patients who received either 5-fluorouracil (5-FU) as first-line therapy or imiquimod as the second-line topical agent. Topical chemotherapy was given to 45 patients with a mean follow-up of 34 months. Therapy was standardized to 12 hours every 48 hours for 28 days. A complete response (CR) was reported in 25 patients (57%), while a partial response was seen in 6 patients (13.6%); no response was observed in the remaining 13 patients (29.5%). Following application of 5-FU, local toxicity and AEs occurred in 10% and 12% of patients, respectively. In another study, 5-FU treatment duration ranged from 3 to 7 weeks and was determined based on clinical response. Out of 19 patients, 14 (73.7%) had a CR and none of the patients had recurrence at the median time of follow-up (3.5 years). Topical 5-FU for 6 weeks has also been reported with good
response rates at 5 years. A systematic review of treatment options for PIN reported response rates of 40% to 100% for imiquimod and 48% to 74% for topical 5-FU. Twelve percent of patients in the study discontinued topical treatment due to side effects. Another observational study of penile CIS treated with topical 5-FU or imiquimod reported similar results, with CR in 65% of patients, partial response in 25%, and no response in 10%. Grade 1–2 AEs were reported in 50% of patients and only 65% completed the full course of treatment. Discontinuation of treatment was associated with a diminished CR rate of 28.6%, highlighting the importance of monitoring patients for acute toxicity so it may be promptly addressed.

Imiquimod has been investigated as a second-line therapy for PIN. Due to its ability to produce significant inflammation, initiation of imiquimod therapy at a lower frequency (eg, 2 times per week) may be beneficial to evaluate for toxicity or AEs before increasing the frequency of application. Early studies suggested a 100% response to imiquimod (n = 47; 70% CR), although a subsequent review identified a lower response to therapy with 63% of patients showing a CR and 29% of patients showing no response. The study highlighted that the difference in response may be related to the frequency and duration of application as well as the PIN subtype. In this study, Bowenoid papulosis and Bowen’s disease subtypes responded better to imiquimod than the erythroplasia of Queyrat subtype. Longer, less frequent application (ie, <4 times per week for an average of 113 days) was demonstrated to have a better response than a shorter, more frequent application (ie, ≥4 times per week for an average of 53 days) (81% vs. 68%, respectively).

**Laser Therapy**

Laser therapy in select patients with Tis, Ta, or T1 G1–2 penile cancer has reported acceptable outcomes (see *Principles of Penile Organ-Sparing Approaches* in the algorithm). Four types of therapeutic lasers have been used and include carbon dioxide, Nd:YAG, argon, and potassium titanyl phosphate (KTP) lasers. Nd:YAG and carbon dioxide lasers are the most commonly used, although KTP laser may also be considered. Nd:YAG lasers have the deepest penetration capability of 3 to 4 mm compared with the carbon dioxide laser that penetrates to a depth of 0.1 mm and KTP lasers that penetrate to 1 to 2 mm.

Retrospective studies of laser therapy reported local recurrence rates of approximately 18%, comparable to that of surgery, with good cosmetic and functional results. Peniscopically controlled laser excision of TIS or T1 penile carcinoma in 224 patients compared outcomes based on primary treatment with excisional surgery for CIS or initially invasive flat tumors. Reductive chemotherapy was given prior to surgery for exophytic lesions to broaden the indication of laser excision. Complete excision with adequate lateral margins was achieved in 221 patients and with adequate deep margins in 217 patients. The 10-year recurrence rate was 17.5% (95% CI, 16.4%–18.6%), and the 10-year amputation rate was 5.5% (range, 5.2%–5.7%). In a subsequent study from this group, 56 patients with pT1 disease were treated with carbon dioxide laser therapy. There were 53 patients alive and disease free at a median follow-up of 66 months. The 3 deaths in the study were the result of unrelated and intercurrent disease. Among the 53 patients evaluated at follow-up, 13 had local recurrence and 2 had positive ILNs. The local recurrence correlated to positive margins. Another study evaluated Nd:YAG laser treatment of patients with T1, T2, or CIS disease. Local recurrence was reported in 48% of patients, with recurrence elsewhere in the glans penis occurring in 20% of cases. There were 10 cases of nodal metastases, of which 8 were in patients with T2 disease. These data emphasize the greater benefit of laser therapy in CIS or T1 disease. A systematic review of studies using laser and light therapies for erythroplasia of Queyrat reported complete
remission in 81.4%, 62.5%, and 58.3% of patients treated with carbon dioxide laser, methyl aminolevulinate photodynamic therapy, or aminolevulinic acid photodynamic therapy, respectively. Another systematic review reported response rates between 52% and 100% for treatment of PIN with laser therapies, although 7% to 48% showed recurrence and 50% had changes in penile sensitivity.

**Glansectomy**
Glansectomy, removal of the glans penis, may be considered for patients with distal tumors (clinical stage Ta, Tis, T1) on the glans or prepuce. Negative surgical margins should be determined from frozen sections of the cavernosal bed and urethral stump. Treatment in certain instances may include a split- or full-thickness skin graft.

A retrospective study of 177 patients with SCC of the glans who received glansectomy and split-thickness skin graft had a 9.3% incidence of local recurrence (median follow-up, 41.4 months). In total, 13 patients received treatment for operative complications and 18 patients (10.7%) died from penile cancer. An earlier retrospective study including 25 patients demonstrated a DSS of 92%. A systematic review of 20 studies on glansectomy reported a local recurrence rate of 2.6% to 16.7% and incidence of salvage penectomy due to positive margins and/or recurrence of 1.2% to 8.3%. The DSS in this study was 89% to 96.6%. Taken together, studies indicate a low level of recurrence.

**Mohs Surgery**
Mohs surgery is an alternative to wide local excision in select patients. This technique removes thin layers of cancerous skin, which are evaluated microscopically until the tissue is negative for tumor. A retrospective study including 33 patients with SCC of the penis, ranging from TIS to T3 disease, reported outcomes for patients who were treated with Mohs surgery. Follow-up data were available for 25 patients, of which 8 had local recurrence. Seven patients underwent repeat Mohs surgery while one patient received a penectomy. One patient in this study died of metastatic disease. A systematic review reported a 4% recurrence rate for PIN treated with Mohs surgery. Although precision is higher with Mohs surgery, the success rate declines with higher stage of disease. Therefore, Mohs surgery may have the greatest benefit for patients with a small superficial lesion on the proximal shaft to avoid penectomy for an otherwise fairly low-risk lesion.

**NCCN Recommendations**

**Tis or Ta**
For patients with penile CIS or noninvasive verrucous carcinoma, penis-preserving techniques may be used, including topical imiquimod (5%) or 5-FU cream, circumcision and wide local excision, laser therapy (category 2B), complete glansectomy (category 2B), or Mohs surgery in
select cases (category 2B). Among these, topical therapy\textsuperscript{67-69} and excisional organ-sparing surgery\textsuperscript{70} are the most widely used.

For topical therapy, NCCN recommends application of imiquimod 5% cream at night 3 times per week for 4 to 16 weeks. Topical 5% 5-FU cream should be applied twice daily for 2 to 6 weeks. Laser therapy for the treatment of primary penile tumors has demonstrated acceptable outcomes with a perioperative application of between 3\% and 5\% acetic acid. Following application of acetic acid to the affected genital skin, suspected sites of HPV-infected skin will turn white and can be targeted for laser ablation. Gas and solid-state lasers may be considered (see Principles of Surgery in the algorithm).

T1G1–2
Careful consideration should be given to penile-preserving techniques if the patient is willing and able to undergo close follow-up. These techniques include wide local excision,\textsuperscript{66} glansectomy in select cases, Mohs surgery in select cases (category 2B), laser therapy (category 2B),\textsuperscript{71} and radiation therapy (RT) (category 2B) delivered as brachytherapy with interstitial implant (preferred) or external beam RT (EBRT).\textsuperscript{72-76} Circumcision should always precede RT to prevent radiation-related complications. In cases where a penile-preserving technique is not feasible based on the size or location of the tumor, partial penectomy may be appropriate.

T1G3–4 or T≥2
These lesions typically require more extensive surgical intervention with partial or total penectomy depending on the characteristics of the tumor and depth of invasion.\textsuperscript{77} Intraoperative frozen sectioning is recommended to achieve negative surgical margins. If the tumor encompasses less than half of the glans and the patient agrees to very close observation, then a more conservative approach such as wide local excision or glansectomy may be considered for patients with T1G3–4 diagnosis. The patient should understand that there is an increased risk for recurrence and potential for a repeat wide local excision should a local recurrence be noted, provided there is no invasion of the corpora cavernosa.\textsuperscript{53,62} A clear and frank discussion should be had with the patient in whom a partial or total penectomy will likely be required should a larger or more invasive lesion be present.

The tumor size is an important factor when choosing RT as treatment. As the average length of the glans is approximately 4 cm, this serves as a cutpoint to reduce the risk of undertreating cavernosal lesions. In a study of 144 patients with penile cancer restricted to the glans treated by brachytherapy, larger tumors, especially those larger than 4 cm, were associated with higher risk of recurrence.\textsuperscript{78} A high, 10-year, cancer-specific survival rate of 92\% was achieved in this series.

There was nonuniform consensus among NCCN panelists on the use of RT as primary therapy due to scant data. For T1G3–4 or T2 tumors smaller than 4 cm with negative nodes, brachytherapy with interstitial implant, EBRT alone (category 2B), or EBRT with chemotherapy (category 3) are treatment options after circumcision. Consider prophylactic ILN irradiation if selecting EBRT.

For tumors 4 cm or larger or if there is node-positive disease that is surgically unresectable, circumcision should be performed followed by EBRT combined with chemotherapy. Brachytherapy following circumcision may be appropriate in select cases of tumors 4 cm or larger, but careful monitoring is necessary as the risks of complications and disease progression increase.\textsuperscript{79} Crook and colleagues reported a 10-year cause-specific survival of 84\% in 67 patients with T1–2 (select cases of T3) penile lesions treated with primary brachytherapy.\textsuperscript{76} A meta-analysis comparing the efficacy of brachytherapy and penectomy reported similar 5-year OS rates between these two treatments (76\% for penectomy vs. 74\% for brachytherapy; odds ratio [OR], 0.79; 95\% CI,
0.64–0.98), although patients who underwent penectomy had higher 5-year local control rates (85% vs. 80%; OR, 0.72; 95% CI, 0.58–0.90) and 5-year disease-free survival rates (77% vs. 72%; OR, 0.77; 95% CI, 0.63–0.93). However, one must be cautious in interpreting from this that brachytherapy and penectomy offer equally effective oncologic outcomes since selection criteria can affect the efficacy and suitability of these primary treatment options for the individual patients.

Brachytherapy is not recommended following penectomy or partial penectomy but may be considered following wide local excision or excisional biopsy of small lesions. Brachytherapy should only be performed in centers with significant experience using this treatment modality.

Post-surgical RT to the primary tumor site may be considered for positive margins.

Management of Regional Lymph Nodes

Evaluation and Risk Stratification

The presence and extent of regional ILN metastases has been identified as the single most important prognostic indicator in determining long-term survival in patients with invasive penile SCC. Evaluation of the groin and pelvis is an essential component of the metastatic workup of a patient. The involvement of the ILN can be clinically evident (ie, palpable vs. nonpalpable), adding to the difficulty in management. Clinical examination for ILN involvement should attempt to evaluate and assess for palpability, number of inguinal masses, unilateral or bilateral localization, number of nodes identified in each inguinal region, and the relationship to other structures, particularly with respect to the mobility or fixation of the node(s) or mass(es) to adjacent structures and/or involvement of the overlying skin.

Cross-sectional imaging of the chest, abdomen, and pelvis by CT or MRI may be used to assess the size, extent, location, and structures that are in close proximity to the ILN, as well as the presence of pelvic and retroperitoneal lymph nodes and distant metastasis. Imaging is an important addition to bilateral palpation as 13% to 16% of patients without palpable lymph nodes still have occult metastases and 20% to 40% of patients with palpable lymph nodes are found to be non-metastatic. When considering one imaging modality to evaluate the stage of the primary lesion and lymph node status, MRI appears to be the best choice to enhance the physical examination in patients where the inguinal region is difficult to assess (eg, morbidity, previous chemotherapy/RT). Fluorodeoxyglucose (FDG)-PET/CT is best used as a diagnostic modality in those patients with cN+ penile cancer following other imaging studies showing concern for more extensive burden of metastatic disease. A systematic review and meta-analysis evaluating the accuracy of FDG-PET/CT for diagnosing ILN involvement in penile cancer found that PET/CT had a relatively low pooled sensitivity for detection of ILN metastasis in patients with cN0 disease (56.5%) but a higher pooled sensitivity for patients with cN+ disease (96.4%), supporting the use of PET/CT as an imaging modality only in patients with clinically node-positive disease.

Consideration needs to be given to whether or not the primary lesion demonstrated any adverse prognostic factors. If one or more of these high-risk features is present, then pathologic ILN staging must be performed. Up to 25% of patients with nonpalpable lymph nodes harbor micrometastases. Therefore, several predictive factors have been
evaluated for their ability to identify the presence of occult lymph node metastasis. Slaton et al concluded that patients with pathologic stage T2 or greater disease were at significant risk (42%–80%) of nodal metastases if they exhibited greater than 50% poorly differentiated cancer and/or vascular invasion, and therefore should be recommended to undergo an inguinal lymph node dissection (ILND). These factors can then further define patients into low-, intermediate-, and high-risk groups for lymph node metastasis. The European Association of Urology determined risk stratification groups for patients with nonpalpable ILNs, and validated this in both uni- and multivariate analyses of prognostic factors. Patients can be stratified based on stage and/or grade into risk groups based on the likelihood of harboring occult node-positive disease, with the low-risk group defined as patients with Tis, Ta, or T1a disease; the intermediate group as those with T1b disease (lymphovascular invasion); and the high-risk group as those with T2 or G3/G4 disease. Other systematic and retrospective reviews identified lymphovascular invasion, higher grade tumors, higher stage tumors (both clinical and pathological), infiltrative and reticular invasion, increased depth of invasion, perineural invasion, and younger age at diagnosis as clinical risk factors predictive of inguinal lymph node metastases in penile SCC. Of these risk factors, lymphovascular invasion and tumor grade were most strongly associated with lymph node metastasis.

There is a paucity of data regarding the predictive value of lymph node removal. A singular study suggests that DSS following radical lymphadenectomy can be predicted by the lymph node count and lymph node density. Removal of greater than or equal to 16 lymph nodes in patients with pathologic negative nodes was associated with a significantly longer DSS rate (P < .05). Furthermore, the 5-year disease-free survival rate in patients with pathologic positive nodes was 81.2% in patients with lymph node density (defined as the number of positive nodes divided by the total number of lymph nodes removed) greater than 16% compared to 24.4% in patients with less than 16% lymph node density (P < .001). Although this study suggests that lymph node count and density may be useful in predicting DSS, a larger validation study is necessary to support these preliminary data.

Dynamic Sentinel Node Biopsy

The work by Cabanas used lymphangiograms and anatomic dissections to evaluate the sentinel lymph node drainage for penile cancer with nonpalpable ILNs. This technique has been shown to have false-negative rates as high as 25%; therefore, it is no longer recommended. Advancements have been made with the dynamic sentinel node biopsy (DSNB) technique developed for penile cancer by the Netherlands Cancer Institute using lymphoscintigraphy and performed with technetium-99m–labeled nanocolloid and patent blue dye isosulfan blue. Initially, this technique was associated with a low sensitivity and high false-negative rate (16%–43%). Refinement of the technique to include serial sectioning and immunohistochemical staining of pathologic specimens, preoperative ultrasonography with and without fine-needle aspiration (FNA) cytology, and exploration of groins in which no sentinel node is visualized on intraoperative assessment decreased the false-negative rate from 19% to only 5%. Using FNA with ultrasound can increase the diagnostic yield in metastases greater than 2 mm in diameter. Crashaw et al used ultrasound with DSNB and noted improved accuracy in identifying patients with occult lymph node metastases. With modification of the National Cancer Institute (NCI) protocol, Hadway et al were able to achieve a similar false-negative rate (5%) with an 11-month follow-up. An observational cohort study of 1000 patients treated between 1956 and 2012 suggests that DSNB can improve 5-year survival in patients with clinically node-negative groins. Data in this study showed that patients treated prior to 1994
(the year DSNB was incorporated into treatment) had an 82% 5-year survival compared to the 91% 5-year survival seen in patients treated between 1994 and 2012 ($P = .021$). However, there are several limitations of this study, including the possibility that improved staging resulted in more patients being grouped into a higher risk group. In addition, a systematic review of studies on DSNB for clinically impalpable lymph nodes published between 2000 and 2022 concluded that the diagnostic accuracy of DSNB requires further improvement as a high proportion of patients with a positive DSNB undergo unnecessary radical lymph node dissection. Therefore, incorporation of DSNB into treatment should be limited to centers with experience. Secondary to the technical challenges associated with DSNB, to be accurate and reliable, it is recommended that DSNB be performed at tertiary care referral centers where at least 20 procedures are done per year.

It should be noted that DSNB is not recommended in patients with palpable ILNs.

**Inguinal Lymph Node Dissection**

The most frequent sites of metastasis from penile cancer are the ILNs, typically presenting as palpable inguinal lymphadenopathy. The management of ILNs by ILND has been fraught with concerns of surgical morbidity. Early treatment of lymph node involvement has been shown to have a positive impact on survival, except if the patient has bulky nodal spread or other sites of metastases. Palpable lymphadenopathy at the time of diagnosis does not warrant an immediate ILND. Of the patients with palpable disease, 30% to 50% will be secondary to inflammatory lymph node swelling instead of metastatic disease. Although the distinction between reactive lymph nodes and metastatic disease has traditionally been done with a 6-week course of antibiotics, percutaneous lymph node biopsy is the favored approach among penile cancer experts for patients with palpable nodes. An antibiotic course may still be used but is limited to the setting of an overlying infection. Data on robotic ILND are limited, although a systematic review has reported that the robotic approach is safe and effective, with lower morbidity than open surgery when carefully selecting for patients with non-palpable or non-bulky inguinal nodes.

The boundaries of the standard, full-template ILND (ie, Daseler’s quadrilateral area) are: superiorly, the inguinal ligament; inferiorly, the fossa ovalis; laterally, the medical border of sartorius muscle; and medially, the lateral edge of adductor longus muscle. Historically, it has been recommended to keep the patient on bed rest for 48 to 72 hours, especially after myocutaneous flaps or repair of large skin defects, although the necessity for this is debatable and not corroborated with rigorous scientific data. Closed suction drains are placed at surgery and are typically removed when drainage is less than 50 to 100 mL per day.

**Modified Template Lymphadenectomy**

In attempts to decrease the morbidity associated with standard ILND, a modified template lymphadenectomy has been proposed that uses a shorter skin incision, limiting the field of inguinal dissection by excluding the area lateral to the femoral artery and caudal to the fossa ovalis, with preservation of the saphenous vein and elimination of the need to transpose the sartorius muscle while providing an adequate therapeutic effect. This technique is commonly reserved for patients with a primary tumor that places them at increased risk for inguinal metastasis but with clinically negative groins on examination. The modified technique has shown a decrease in complications. Contemporary modified ILND
should include the central and superior zones of the inguinal region, as these sections were not included in the dissection leading to a false-negative rate of 15%.\textsuperscript{128,129} It is important to note that if nodal involvement is detected on frozen section, the surgical procedure should be converted to a standard, full-template lymphadenectomy. A standard full-template lymphadenectomy should be considered in all patients who have resectable inguinal lymphadenopathy. However, studies would favor neoadjuvant chemotherapy prior to proceeding with surgery, particularly in patients with bulky ILN metastases (ie, fixed nodes or nodal diameter $\geq$3 cm).\textsuperscript{130-132} Generally, ILND is performed within 4 to 6 weeks following the completion of systemic chemotherapy to allow patient recovery while minimizing the risk of cancer progression post-chemotherapy.

**Delayed Inguinal Lymphadenectomy**

Since data exist that suggest patients with clinically negative groins undergoing immediate ILND have better survival outcomes than patients undergoing delayed ILND once their groins are clinically positive, it is recommended that in most circumstances, patients with high-risk penile tumors should undergo immediate ILND. However, patients with lower-risk tumors who are undergoing active surveillance or patients with high-risk tumors who refuse immediate ILND may experience an inguinal nodal recurrence at some time point during follow-up. The median time to inguinal recurrence after treatment of the primary penile tumor is approximately 6 months, with 90% occurring by year 3 and 100% by year 5.\textsuperscript{133-135}

**Unilateral Versus Bilateral Lymphadenectomy**

In patients with intermediate- or high-risk features who do not have palpable lymph nodes, bilateral lymphadenectomy is generally performed, because it is not possible to predict the laterality of inguinal nodal metastasis based on the location of the tumor on the penis.

Similarly, in patients who have a unilateral palpable node, approximately 30% will have contralateral positive nodes that are not palpable.\textsuperscript{136} Therefore, bilateral lymphadenectomy is recommended in patients undergoing immediate ILND for high-risk penile tumors or because of palpable nodes. When there is a delayed (>1 year after treatment of the primary penile tumor) inguinal recurrence of cancer, it is usually unilateral, and some authors have suggested that ipsilateral ILND is adequate while others have advocated for bilateral ILND in this circumstance.\textsuperscript{5}

**Pelvic Lymphadenectomy**

Approximately 20% to 30% of patients with positive ILNs will also have cancer within PLNs. Interestingly, penile tumors do not appear to metastasize to the PLNs without first affecting the inguinal node echelon (ie, no skip lesions).\textsuperscript{104,135} Patients who have only one positive inguinal node have a risk of pelvic nodal involvement of less than 5% as reported by the Netherlands Cancer Institute.\textsuperscript{137} The presence of cancer within the PLN is associated with a very poor 5-year survival rate that is typically less than 10%. Based on these prior reports, pelvic lymphadenectomy (resection of external iliac, internal iliac, and obturator lymph nodes) is recommended in patients with three or more positive ILNs and in the clinical context of high-grade cancer within the ILN pathologic specimen. Pelvic lymph node dissection (PLND) can be conducted during the same operative session as the ILND if the intraoperative frozen section is positive in three or more of the inguinal nodes (raising the importance of obtaining a lymph node count intraoperatively) or in a delayed staged fashion based on the pathologic features of the ILND specimen.\textsuperscript{138,139}

One area of controversy is whether the PLND should be performed ipsilaterally or bilaterally in patients with unilateral positive ILNs. Data suggest that the number of positive ILNs identified at the time of...
dissection may direct clinicians to unilateral or bilateral dissection. In a single retrospective study, the presence of four or more positive ILNs supported bilateral PLND. Unilateral PLND was recommended if three or fewer ILN metastases were identified and if there was no suspicion of contralateral pelvic lymphadenopathy on preoperative imaging or intraoperatively. Crossover (right to left or left to right) of inguinal to pelvic nodes has not been well-studied; hence, both approaches are feasible and left at the discretion of the surgeon based on case-specific characteristics.

Perioperative Therapy for Lymph Node Dissection

Patients with penile cancer that has metastasized to the lymph nodes often have a poor prognosis, with a 5-year survival rate of 70% or less following lymph node dissection, depending on the presence of adverse features. While it is clear that lymph node dissection alone is inadequate for many patients with node-positive penile cancer, there is a lack of prospective data to inform optimal strategies for perioperative therapy in this situation. The phase III International Penile Advanced Cancer Trial (InPACT) seeks to provide data on potential strategies for perioperative therapy by incorporating two sequential randomizations. The InPACT-Neoadjuvant randomization randomizes patients to ILND (no neoadjuvant therapy), neoadjuvant chemotherapy followed by ILND, or neoadjuvant chemoradiotherapy followed by ILND. The InPACT-Pelvic randomization randomizes patients with pathologically high-risk disease from ILND to prophylactic PLND or no prophylactic surgery with both arms receiving adjuvant chemoradiotherapy if the patient did not receive neoadjuvant chemoradiotherapy.

Chemotherapy

A patient who presents with resectable bulky disease will rarely be cured with a single treatment modality; therefore, consideration should be given to neoadjuvant chemotherapy prior to ILND. Patients who may benefit from surgical consolidation would be those who had stable, partial, or CR following systemic chemotherapy, thus increasing their potential for disease-free survival. Pagliaro et al performed a phase II clinical trial in 30 patients, with stage N2 or N3 (stage III or stage IV) penile cancer without distant metastases, receiving neoadjuvant chemotherapy with paclitaxel, ifosfamide, and cisplatin. In this series, 50% of patients were noted to have a clinically meaningful response, and 22 patients (73.3%) subsequently underwent surgery. There was an improved time to progression and OS associated with chemotherapy responsiveness ($P < .001$ and $P = .001$, respectively), absence of bilateral residual tumor ($P = .002$ and $P = .017$, respectively), and absence of extranodal extension ($P = .001$ and $P = .004$, respectively) or skin involvement ($P = .009$ and $P = .012$, respectively). A systematic review and meta-analysis of 10 studies of patients who received neoadjuvant chemotherapy for locally advanced penile SCC reported similar results, with an objective response rate (ORR) of 53% (95% CI, 42–64) and 16% showing pathologic CR. This review favored platinum-based neoadjuvant chemotherapy over taxane-based due to higher response rates and lower rates of grade three or higher AEs for platinum-based chemotherapy in the stratified subanalysis.

A retrospective analysis evaluated the benefit of adjuvant chemotherapy on OS of patients with positive PLN following lymph node dissection. Less than half of the patients in this multi-institutional study received adjuvant chemotherapy (36 out of 84). These patients were younger, had a less aggressive pathology, were less inclined to receive adjuvant RT, and demonstrated less bilateral inguinal disease and more inguinal extranodal extension. The median OS was higher for these patients compared to patients who did not receive adjuvant chemotherapy (21.7 vs. 10.1 months; $P = .021$). Adjuvant chemotherapy was further shown to be an independent factor in the improved OS based on multivariate
analysis (HR, 0.40; 95% CI, 0.19–0.87; \(P = .021\)). Therefore, patients with positive PLNs following surgical resection may benefit from adjuvant RT or systemic chemotherapy. A systematic review and meta-analysis comparing the effectiveness of adjuvant chemotherapy to neoadjuvant chemotherapy in patients with lymph node-positive penile cancer did not find clear evidence to support one over the other. While no differences were found when comparing adjuvant versus neoadjuvant chemotherapy or adjuvant versus no intervention, OS was higher with neoadjuvant chemotherapy compared to no intervention and PFS was higher with adjuvant compared to neoadjuvant chemotherapy.

**Radiotherapy**

A multicenter, retrospective analysis evaluated the benefit of adjuvant pelvic RT on OS and disease recurrence in 92 patients with positive PLNs following PLND. Patients who received adjuvant pelvic RT (n = 40) had a longer median DSS than those who did not receive RT (14.4 vs. 8 months; \(P = .023\)). Additionally, patients who did not undergo adjuvant RT had worse OS (HR, 1.7; 95% CI, 1.01–2.92; \(P = .04\)) and DSS (HR, 1.9; 95% CI, 1.09–3.36, \(P = .02\)).

Studies investigating the role of adjuvant RT for positive lymph nodes following ILND have been mixed. A retrospective analysis of National Cancer Database records showed improved OS with adjuvant RT following ILND for stage III penile cancer (HR, 0.58; 95% CI, 0.39–0.86). Patients with higher nodal burden of disease showed greater benefit from adjuvant RT. However, a systematic review by the European Association of Urology Penile Cancer Guidelines Panel reported that the few studies comparing recurrence and survival between patients who did or did not receive adjuvant RT after ILND for lymph-node positive disease received no significant benefit from the adjuvant RT. Therefore, adjuvant RT is recommended following a PLND after a positive result on ILND.

**Chemoradiotherapy**

Chemoradiotherapy has demonstrated improved responses in patients with other SCCs, specifically patients with vulvar and anal cancer. Anecdotal data for the use of chemoradiotherapy in patients with penile cancer have been reported with mixed results. Based on the limited data, chemoradiotherapy is a treatment option in select patients.

For patients with T1 or T2 disease, EBRT with concurrent chemotherapy may be considered, although brachytherapy is preferred for tumors smaller than 4 cm. Similarly, EBRT with concurrent chemotherapy can be used for T3 or T4 disease or in patients with nodal involvement. Postoperative adjuvant chemotherapy is recommended in patients who have ILN-positive disease.

Chemoradiotherapy can be considered for patients with high-risk features including PLN metastases, extranodal extension, bilateral ILN involvement, and tumors in lymph nodes larger than 4 cm.

Chemoradiotherapy is a recommended strategy for patients with resistant disease. The use of chemoradiotherapy as primary treatment is a category 3 recommendation due to the limited studies that have investigated its role for treatment of penile cancer. For patients with palpable, non-bulky pN2 or pN3 disease, treatment may entail adjuvant RT, chemoradiotherapy, or chemotherapy following ILND or PLND. Chemoradiotherapy is recommended for the management of enlarged PLNs in non-surgical candidates or for local recurrence in the inguinal region or metastatic penile cancer.

**NCCN Recommendations**

**Nonpalpable Nodes**

Most patients with low-risk disease (Tis, Ta, T1a) are followed with a surveillance protocol, as the probability of occult micrometastases in ILNs is less than 17%. For patients at intermediate (T1b,G1–2) or
high (T1b,G3–4; T2 or greater) risk, a modified or radical bilateral inguinal lymphadenectomy is strongly recommended as occult metastatic disease ranges between 68% and 73%. If positive nodes are present on the frozen section, then a superficial and deep inguinal lymphadenectomy should be performed (with consideration of a PLND). Prophylactic EBRT (category 2B) to the ILNs should be considered in patients who are unable or unwilling to undergo surgical management.

Alternatively, bilateral DSNB may be done for intermediate- or high-risk lesions if the treating physician has experience with this modality. As DSNB is currently not widely practiced in the United States, this technique should be performed in tertiary care referral centers with substantial experience. DSNB is not recommended for low-risk (Tis, Ta, or T1a) tumors, as observation alone is sufficient in the absence of palpable adenopathy.

Unilateral Palpable Nodes <4 cm (mobile)

Percutaneous lymph node biopsy is considered standard for these patients if no risk feature is present in the primary lesion. Risk features include T1 tumors; high grade; lymphovascular or perineural invasion; and poor differentiation in more than half of the tumor cells. The NCCN Panel recommends omitting the procedure for patients with high-risk primary lesions to avoid delay of lymphadenectomy. A negative lymph node biopsy may be confirmed with an excisional biopsy. Alternatively, careful surveillance may be considered following a negative lymph node biopsy. Positive findings from either procedure warrant an immediate bilateral ILND or consideration of neoadjuvant chemotherapy followed by ILND. Additionally, in cases of pN2–3 disease, a PLND with or without adjuvant RT, chemotherapy (category 2B), or chemoradiotherapy (category 2B) is recommended. Alternatively, chemoradiotherapy or chemotherapy alone may be given (both are category 2B recommendations). Following treatment, all patients should enter active surveillance.

Unilateral Palpable Nodes ≥4 cm (mobile)

Large, unilateral, mobile nodes should first be confirmed by percutaneous lymph node biopsy. A negative biopsy should be confirmed by an excisional biopsy. If results are negative again, the patient should be closely followed. It is preferred that patients with confirmed nodes receive a standard or modified ILND, with consideration of PLND. Neoadjuvant cisplatin-based chemotherapy is recommended before surgery, although ILND and/or PLND can be performed without neoadjuvant therapy in patients who are not eligible for cisplatin-based chemotherapy. Alternatively, RT or chemoradiotherapy may be administered following a positive percutaneous lymph node biopsy.

No further treatment is necessary if no viable tumor elements are detected in the surgical specimen or if only one node is positive. If two or more positive nodes or extranodal extension is detected, adjuvant chemotherapy (if not already given) and/or adjuvant RT (if PLNs are positive) is recommended. Alternatively, adjuvant chemoradiotherapy may be given (category 2B). Data suggest that in the setting of four or more positive ILNs, a bilateral PLND should be performed, if not already done. Postoperative RT or chemoradiotherapy may be considered in patients after PLND, particularly in the setting of a positive surgical margin, if there is viable cancer in multiple ILNs or PLNs, and/or if there is a presence of extranodal extension on the final pathologic specimen.

Unilateral Fixed Lymph Nodes or Bilateral Palpable Nodes (fixed or mobile)

For large, unilateral, fixed nodes or bilateral ILNs, patients should undergo a percutaneous lymph node biopsy of the lymph nodes. A negative result should be confirmed with excisional biopsy. If results are
again negative, the patient should be closely followed. Patients with a positive aspiration or biopsy should receive neoadjuvant systemic chemotherapy followed by ILND and PLND if there is a response to the chemotherapy. Postoperative RT or chemoradiotherapy may be considered if there is extranodal extension (category 2B). As previously mentioned, in the setting of four or more positive ILNs, a bilateral PLND should be performed. Alternatively, radiotherapy or chemoradiotherapy may be done instead of ILND/PLND, although this is not the preferred option for most patients. If the patient’s disease does not respond to neoadjuvant chemotherapy, treatment may follow options for progressive metastatic disease. If the patient is not eligible for neoadjuvant chemotherapy (eg, cisplatin ineligibility), the recommended surgical (preferred) or radiotherapy options may be performed without neoadjuvant chemotherapy.

**Enlarged Pelvic Lymph Nodes**

Patients with abnormal PLNs on imaging (CT or MRI) should undergo a percutaneous lymph node biopsy if technically feasible. If positive, patients are stratified by resectability. Nonsurgical candidates should be treated with chemoradiotherapy. Surgical candidates should receive neoadjuvant systemic chemotherapy followed by cross-sectional imaging of the chest, abdomen, and pelvis to assess for response. Patients with disease that responds to therapy or that becomes stable should undergo bilateral superficial and deep ILND and unilateral/bilateral PLND if deemed resectable. Postoperative RT or chemoradiotherapy may be considered if advanced pathologic nodal staging (pN2-3) or extranodal extension are present (category 2B). Patients with disease that progresses may receive additional systemic chemotherapy with consideration of local-field RT or participation in a clinical trial.

**Surveillance**

Initial treatment of the primary tumor and lymph nodes dictates the follow-up schedule (see Surveillance Schedule in the algorithm). A large retrospective review of 700 patients found that penile-sparing therapies carry a significantly higher risk of local recurrence (28%) than partial or total penectomy (5%) and thus require closer surveillance. Patients without nodal involvement had a regional recurrence rate of 2% compared to 19% for patients with node-positive disease. Of all recurrences, 92% were detected within 5 years of primary treatment.

A retrospective analysis of 551 patients with penile cancer who were treated with ILND found that recurrence occurred in 31.9% of patients. Median time to recurrence was 10 months for distant recurrence, 12 months for inguinal recurrence, 10.5 months for pelvic recurrence, and 44.5 months for local recurrence. Greater than 95% of distant, inguinal, and pelvic recurrence occurred within 48 months of ILND, compared to 127 months for local recurrences, supporting a shorter imaging surveillance schedule for detection of regional or distant recurrences. However, it took 127 months for 95% of local recurrences to be detected, supporting long-term surveillance of the primary site by clinical examination.

Follow-up for all patients includes a clinical examination of the penis and inguinal region. Imaging is not routinely indicated for early disease (except for patients who have obesity or who have undergone inguinal surgery since a physical examination may be challenging), but may be used on abnormal findings. For patients with N2 or N3 disease, imaging of the chest, abdomen, and pelvic area is recommended.

**Recurrence**

Invasive disease is an adverse finding after initial organ-sparing treatment and should be treated according to the stage of the
For noninvasive primary tumor recurrences, treatment should also be based on the stage of recurrence.

A recurrence in the inguinal region carries a poor prognosis (median survival, <6 months) and optimal management remains elusive. If no prior inguinal lymphadenectomy or RT was given, primary treatment for the management of ILNs can be followed. If the patient previously received lymphadenectomy or RT, subsequent-line therapies include chemotherapy followed by ILND, ILND alone, or chemoradiotherapy (if no prior RT). A study suggests that ILND may be beneficial in patients with penile cancer with locally recurrent ILN metastases. While potentially curative, patients must be advised of the high incidence of postoperative complications.

Metastatic Disease

Imaging of the chest, abdomen, and pelvis should be obtained when metastasis is suspected to evaluate for pelvic and/or retroperitoneal lymph nodes and more distant metastases. PLN metastasis is an ominous finding, with a 5-year survival rate of 0% to 66% for all cases and 17% to 54% for microscopic invasion only, with a mean 5-year survival of approximately 10%. In patients with ILN metastases, 20% to 30% will have PLN metastases. This can be further characterized such that if two to three ILNs are involved, there is a 23% probability of PLN involvement. With involvement of three or more ILNs, this probability increases to 56%.

Lughezzani et al identified three independent predictors of PLN metastases that included the number of inguinal metastases (OR, 1.92; \( P < .001 \)), the diameter of the metastases (OR, 1.03; \( P = .001 \)), and extranodal extension (OR, 8.01; \( P < .001 \)). Similar to previous studies, patients with three or more ILN metastases had a 4.77-fold higher risk of PLN metastasis. An ILN metastasis diameter of 30 mm or greater correlated with a 2.53-fold higher risk of PLN metastasis. Patients who showed no risk factors had a 0% risk of metastasis, suggesting that this group may not require PLND.

Pettaway et al evaluated the treatment options for stage IV penile cancer—clinical stage N3 (deep inguinal nodes or pelvic nodes) or M1 disease (distant metastases)—including chemotherapy, RT, and inguinal lymphadenectomy and concluded that treatment with cisplatin-based chemotherapy should be considered and might facilitate curative resection. The role of RT was considered to be mostly palliative. Cisplatin-based regimens (paclitaxel, ifosfamide, and cisplatin [TIP] or alternatively 5-FU plus cisplatin) are the most active first-line systemic chemotherapy regimens. Therefore, the NCCN Panel recommends first-line chemotherapy using either TIP or 5-FU plus cisplatin for metastatic penile cancer. Vinflunine has also shown activity as a first-line treatment in a phase II clinical trial of 25 patients with inoperable, locally advanced or metastatic squamous cell carcinoma of the penis, although this treatment is not currently recommended in the Guidelines. The panel does not recommend regimens containing bleomycin because of high pulmonary-related toxicity. A retrospective analysis of 30 patients with non-metastatic N2 or N3 penile cancer who received neoadjuvant cisplatin-based chemotherapy as first-line treatment demonstrated a poor response to treatment when disease progressed (median OS, <6 months). Patients with a proven objective response to systemic chemotherapy are amenable to consolidative ILND with curative potential or palliation. However, surgical consolidation should not be performed on patients with disease that progresses during systemic chemotherapy except for local symptomatic control. Preoperative RT may also be given to patients who have lymph nodes greater than or equal to 4 cm without skin fixation to improve surgical resectability and decrease local recurrence.
If there is no response or disease progression following first-line chemotherapy, subsequent therapy options include subsequent-line systemic therapy, RT for local control, and/or best supportive care. For patients with unresectable inguinal or bone metastases, RT may provide a palliative benefit after chemotherapy. The NCCN Panel strongly recommends consideration of clinical trial participation as data are limited in the second-line setting.

The immune checkpoint inhibitor, pembrolizumab, has received two tumor-agnostic indications, one for unresectable or metastatic microsatellite instability-high (MSI-H) or mismatch repair-deficient (dMMR) solid tumors; and the second is for unresectable or metastatic tumor mutational burden-high (TMB-H) solid tumors. Both of these indications are for patients with disease that has progressed following prior treatment and who have no satisfactory alternative treatment options. The phase II KEYNOTE-158 study evaluated the efficacy of pembrolizumab in patients with MSI-H/dMMR previously treated, advanced non-colorectal cancer. After a median follow-up of 13.4 months, ORR was 34.3%, median PFS was 4.1 months, and median OS was 23.5 months. Grade 3 or higher AEs occurred in 14.6% of patients, with one treatment-related fatality from pneumonia. An earlier phase II trial that also investigated use of pembrolizumab for dMMR disease across several tumor types reported similar results. The phase II KEYNOTE-158 study evaluated the use of pembrolizumab based on TMB status of advanced solid tumors. The ORR in the TMB-H group was 29% and only 6% in the non-TMB-H group. Fifteen percent of patients experienced an AE of grade 3 or higher, with colitis being most common. One treatment-related death due to pneumonia was reported. In addition to these trial results, small case reports have also suggested that pembrolizumab is effective and well-tolerated as subsequent-line therapy for metastatic penile cancer. A multicenter retrospective study of 92 patients with advanced or metastatic penile cancer treated with immune checkpoint inhibitors reported a median OS of 9.8 months (95% CI, 7.7–12.8 months) and a median PFS of 3.2 months (95% CI, 2.5–4.2 months). For the full patient population in the study, ORR was 13%, but raised to 35% in the 20 patients with lymph node-only metastases. The authors conclude that while the study demonstrates that checkpoint inhibitors are active in a subset of patients with advanced penile cancer, further studies are needed to define which patients receive the most benefit.

Due to the paucity of data on subsequent-line systemic therapy for metastatic penile cancer, the NCCN Panel recommends a clinical trial or pembrolizumab (if tumor is dMMR/MSI-H or TMB-H) as preferred treatment options in this setting. Paclitaxel or cetuximab may also be considered as subsequent-line treatment, especially if previous treatments did not include a similar class of agent. Emerging knowledge of the molecular landscape of metastatic penile cancer may also lead to future developments in targeted systemic therapy. Best supportive care remains an option for advanced cases or cases refractory to systemic therapy, RT, or chemoradiotherapy.

Summary

SCC of the penis is a disease that mandates prompt medical/surgical intervention and patient adherence to therapy to obtain the most favorable outcomes. A thorough history and physical examination is the initial step in this process, followed by a biopsy of the primary lesion to establish a pathologic diagnosis. Accurate clinical staging allows for a comprehensive treatment approach to be devised, thus optimizing therapeutic efficacy and minimizing treatment-related morbidity. Prognostic factors help predict if lymph node metastases are suspected in the absence of any palpable inguinal lymphadenopathy. When clinically indicated, an ILND has curative potential, particularly when
performed early, with contemporary surgical series demonstrating its reduced morbidity.
