

European Association of Urology Guidelines

2017 edition

European Association of Urology Guidelines 2017

Introduction

We are honoured to present the 2017 edition of the European Association of Urology (EAU) Guidelines. The EAU Guidelines are the most comprehensive continuously updated guidelines, available for urologists and related specialities, produced by a dedicated Guidelines Office involving approximately 300 international experts. The EAU guidelines are recognised worldwide as an important resource to assist clinicians in their everyday practice, they are currently available in more than 30 languages and endorsed by more than 55 national and scientific societies throughout Europe and the world. Furthermore, this year we are delighted to announce the inclusion of two new topics, Renal Transplantation and Thromboprophylaxis.

Clinical practice guidelines not only play a pivotal role in health care practice, but are also a vital resource for the advancement of medical education. The EAU Guidelines Office are committed to actively pursuing effective collaborations both within the EAU and externally which help to further the medical education of young clinicians. A key example of this is the EAU Guidelines Office systematic review programme, the success of which is measurable in the numerous European Urology publications it has produced to date. In this endeavour the EAU Guidelines Office is exceptionally grateful for the continued support and active collaboration of Prof. Dr. J. Catto editor-in-chief of European Urology. Other highly productive collaborations include the hosting of multiple European School of Urology courses on changes in the guidelines and evidence-based medicine methodology for which the continued support of Prof. Dr. J. Palou has been invaluable. In the coming year we will continue to build upon and grow these collaborations.

Adherence to national and international clinical guidelines is sub-optimal throughout Europe therefore, the development of clinical guidelines must fundamentally be supported by an effective dissemination and implementation strategy. Dissemination should be an active process in which tailor-made information is actively imparted to the appropriate audience/users. Effective implementation of clinical guidelines involves the identification of barriers to knowledge transfer, or more importantly, the identification of the optimum interventions to limit or overcome such barriers. During the course of 2017 both the EAU Guidelines Social Media (SoMe) and IMPact Assessment of Guidelines Implementation and Education (IMAGINE) groups will continue to actively drive these processes forward, allowing for the continued optimisation of urological healthcare resources ultimately, focused on improving patient outcomes.

Moving forward, as of 2018, the EAU Guidelines will begin to adopt a modified version of the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach to measure the quality of evidence of studies included in the guidelines and to grade guidelines recommendations. The strength of each recommendation will be determined by the balance between desirable and undesirable consequences of alternative interventions, the quality of evidence for each intervention as well as the nature and variability of patients' values and preferences. The strength of each recommendation will be represented by the words 'strong' or 'weak'. The panels will provide both 'strong' and 'weak' recommendations 'for' or 'against' each intervention. This system will be introduced across all EAU Guidelines, in a staged process, the aim being to provide transparency between the underlying evidence and a given recommendation.

The yearly publication of the EAU Guidelines would not be possible without the unwavering support of the EAU Executive Committee and Management team, our highly valued Guidelines Panels and young Guidelines Associates, our EAU membership and every user of the Guidelines globally. So, on behalf of the EAU Guidelines Office Board, thank you for your support and inspiration.

We hope you enjoy using the 2017 update of the EAU Guidelines!

Methodology section

Clinical guidelines development is one of the core activities of the European Association of Urology (EAU), with the 2017 Guidelines covering the majority of the urological field. The EAU clinical guidelines, which are updated based on systematic reviews of the available clinical evidence, are developed to support clinicians in making informed decisions in their care of patients.

The Guidelines Office (GO), consisting of more than 300 clinicians, is responsible for the production of these documents. Their efforts are supported by a number of expert Committees, each with specific tasks and responsibilities.

The EAU GO unified production methodology aims to:

- ensure scientific quality, accuracy and currency of information;
- promote a sustained quality improvement;
- contribute to the dissemination and implementation of all EAU Guidelines publications.

Systematic Review development

The EAU GO have set up a management structure to support development of systematic reviews (SR) involving young clinicians (Guidelines Associates) who are supported by methodologists and statisticians. These SRs are based on clinical questions prioritised by the Guideline Panel responsible for each topic and their findings are incorporated into the EAU guidelines as they become available. Benefits and harms of interventions are addressed in detail, both in the development stage of the clinical question and when review findings are being incorporated and treatment recommendations formulated. Whenever possible, patient input is sought at both the development stage of the SR questions as well as when guidelines recommendations are being drafted. Patient organisations are invited to take part in review of the EAU Guidelines documents prior to publication. This is a rolling programme, with the ambition to address the majority of key clinical questions covered by the EAU guidelines.

All SRs are performed using standard Cochrane SR methodology: (<http://www.cochranelibrary.com/about/about-cochrane-systematic-reviews.html>). Two independent reviewers screen abstracts and full texts, carry out data abstraction, assess risk of bias and do a GRADING exercise [1-4]. The results are presented in tables showing baseline characteristics and summaries of findings. Meta-analyses are performed only as part of a SR when several randomised controlled trials have addressed the same question and outcomes are reported homogeneously. For lower level data, narrative syntheses of the evidence are provided. The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidance is followed [5].

Independently of these SRs, each Guideline Panel has undertaken a separate systematic search, tailored to their individual guideline. These are broad searches (Scope/Horizon searches) which are developed to:

- ensure that the available clinical evidence is identified in a structured unbiased fashion;
- ensure that significant data are not missed;
- inform on the need to update guidelines documents;
- identify gaps in the literature and prioritise future systematic review activities.

The results of these searches are selected and assessed in a structured fashion by Guideline Associates and Guideline Panel members, although no detailed evidence summaries are produced. The search histories are available online in the Appendices and Publications sections of each guideline topic (www.uroweb.org/guidelines/).

Level of evidence and grading systems

Modified Oxford Centre for Evidence-Based Medicine Levels of Evidence approach

The majority of recommendations in this text are assessed according to their level of evidence (LE) and Guidelines are given a grade of recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [6].

Table 1: Level of evidence*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials.
1b	Evidence obtained from at least one randomised trial.
2a	Evidence obtained from one well-designed controlled study without randomisation.
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study.
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports.
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities.

Table 2: Grade of recommendation*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial.
B	Based on well-conducted clinical studies, but without randomised clinical trials.
C	Made despite the absence of directly applicable clinical studies of good quality.

* Modified from [6].

Modified Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach

Moving forward, the EAU GO have adopted a modified GRADE approach to assess the quality of evidence of studies included in the guidelines and to grade guidelines recommendations [7-9]. Assessment of the evidence using GRADE methodology has been the standard for all new systematic reviews undertaken by the GO in the past two years. GRADE methodology will now be introduced across all EAU Guidelines documents, in a staged process, which will be completed by 2018.

To allow for a transparent assessment of how recommendation statements have been developed, a Summary of Evidence (SOE) table will be provided for each recommendation within the guidelines which will address a number of key elements:

1. The overall quality of the evidence which exists for the recommendation;
2. The magnitude of the effect (individual or combined effects);
3. The certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. The balance between desirable and undesirable outcomes;
5. The impact of patient values and preferences on the intervention;
6. The certainty of those patient values and preferences.

These key elements in the SOE tables are the basis which panels use to define the strength of each recommendation. The strength of each recommendation will no longer be represented by alphabetic characters, but rather by the words 'strong' or 'weak' [9]. The panels will provide both 'strong' and 'weak' recommendations 'for' or 'against' recommending an action based on the information found in the SOE tables. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

The assistance and support of National Urological Associations has been invaluable for the European Association of Urology guidelines project over the past years. Whilst in many European countries the EAU guidelines are being used in clinical practice, or form the basis of national urological guidelines, the EAU Guidelines Office have only recently started to formalise endorsement of their guidelines. Formal replies have been sent in by the following National Urological Associations within Europe and beyond:

National Societies Endorsements

The Algerian Association of Urology	The Italian Association of Urology
The Argentinian Society of Urology	The Kosova Urological Association
The Armenian Association of Urology	The Latvian Association of Urology
The Urological Society of Australia and New Zealand	The Lithuanian Urological Society
The Austrian Urological Society	The Luxembourg Society of Urology
The Belarusian Association of Urology	The Macedonian Association of Urology
Belgische Vereniging Urologie	The Malaysian Urological Association
The British Association of Urological Surgeons	The Maltese Association of Urology
Brazilian Urological Association	The Mexican Society of Urologists (SMU)
The Bulgarian Association of Urology	Norwegian Urological Association
La Sociedad Chilena de Urología	The Polish Urological Association
The Chinese Urological Association	The Portuguese Urological Association
La Sociedad Colombiana de Urología	The Russian Society of Urology
The Croatian Society of Urology	The Romanian Association of Urology
The Cyprus Urological Association	Société Belge d'Urologie
The Czech Urological Society	The Slovak Urological Society
The Danish Urological Society	The Slovenian Urological Association
The Dutch Association of Urology	The Spanish Association of Urology
The Estonian Society of Urologists	The Sri Lanka Association of Urological Surgeons
The Finnish Urological Association	The Swedish Urology Association
The French Association of Urology	The Swiss Society of Urology
The German Urological Association	The Taiwan Urological Association
The Georgian Urological Association	The Tehran University of Medical Sciences
The Hellenic Urological Association	Faculty of Urology
The Hong Kong Urological Association	The Turkish Association of Urology
The Hungarian Urological Association	The Thai Urological Association
The Icelandic Urological Association	The Urological Society of India
The Indonesian Urological Association	The Urological Association of Serbia
The Irish Society of Urology	The Ukrainian Association of Urology

Furthermore, the EAU Guidelines Office is most grateful for the continued support of the European Board of Urology.

Acknowledgement of reviewers - 2017 edition of the EAU Guidelines

Reviewers were identified based on their expert knowledge within the urological field and bordering specialities. The EAU Guidelines Office Board is most grateful for their time and diligence in providing complete and extensive reviews of the individual EAU Guidelines. Whenever feasible, feedback from lay reviewers and patient advocacy groups has been sought.

1. INTRODUCTION

1.1 Aim and scope

This overview represents the updated European Association of Urology (EAU) guidelines for Non-muscle-invasive Bladder Cancer (NMIBC), TaT1 and carcinoma *in situ* (CIS). The information presented is limited to urothelial carcinoma, unless specified otherwise. The aim is to provide practical recommendations on the clinical management of NMIBC with a focus on clinical presentation and recommendations.

Separate EAU guidelines documents are available addressing upper tract urothelial carcinoma (UTUC) [1], muscle-invasive and metastatic bladder cancer (MIBC) [2], and primary urethral carcinoma [3]. It must be emphasised that clinical guidelines present the best evidence available to the experts, but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Guidelines Panel on NMIBC consists of an international multidisciplinary group of clinicians, including urologists, uro-oncologists, a pathologist and a statistician. Members of this panel have been selected based on their expertise and to represent the professionals treating patients suspected of suffering from bladder cancer. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website Uroweb: <https://uroweb.org/guideline/non-muscle-invasive-bladder-cancer/>.

1.3 Available publications

A quick reference document (Pocket guidelines) is available, both in print and in a number of versions for mobile devices, presenting the main findings of the NMIBC Guidelines. These are abridged versions which may require consultation together with the full text version. Several scientific publications are available, the latest publication dating to 2016 [4], as are a number of translations of all versions of the EAU NMIBC Guidelines. All documents are accessible through the EAU website Uroweb: <https://uroweb.org/guideline/non-muscle-invasive-bladder-cancer/>.

1.4 Publication history and summary of changes

1.4.1 Publication history

The EAU Guidelines on Bladder Cancer were first published in 2000. This 2017 NMIBC guidelines document presents a limited update of the 2016 publication.

1.4.2 Summary of changes

New references have been added throughout the 2017 NMIBC Guidelines document.

Key changes in this 2017 print:

- Section 4.3 - T1 subclassification. This is a new section.
- Section 5.5 - Urinary Cytology. Diagnostic categories based on the Paris Working Group Classification have been added.
- Section 5.10.2 - Surgical and technical aspects of tumour resection. This section has been revised and enlarged, resulting in changes in the recommendations (Section 5.14).
- Section 5.12 - Second resection. Additional literature has been included, resulting in changes in the recommendations (Section 5.14).
- Section 6.4 - Subgroup of highest risk tumours. This is a new section.
- Section 7.2.1.3.2 - Device-assisted intravesical chemotherapy. This is a new section.

Changes in recommendations

Section 5.9: A new recommendation has been added.

Recommendations for the primary assessment of NMIBC	GR
Repeat urine cytology in patients with suspicious initial cytology results.	C

Section 5.14: Additional information has been included.

Recommendations for transurethral resection of the bladder (TURB) and/or biopsies and pathology report	
Perform <i>en-block</i> resection or resection in fractions (exophytic part of the tumour, the underlying bladder wall and the edges of the resection area). The presence of detrusor muscle in the specimen is required in all cases except for TaG1/LG tumours.	B
Perform a second TURB in the following situations: <ul style="list-style-type: none"> • after (suspicion of) incomplete initial TURB (in the case of any doubt about completeness of a TURB); • if there is no muscle in the specimen after initial resection, with exception of TaLG/G1 tumours and primary CIS; • In T1 tumours. 	A
Register the results of a second TURB as it reflects the quality of the initial resection.	A

Section 7.5: A new recommendation have been included.

Recommendations for adjuvant therapy in TaT1 tumours and for therapy of CIS	GR
In patients with bacillus Calmette-Guérin failure, who are not candidates of radical cystectomy due to comorbidities, use preservation strategies (device-assisted instillations of chemotherapy, intravesical chemotherapy, intravesical immunotherapy).	C

Section 8.1: A new recommendation has been added.

Recommendations for follow-up of patients after transurethral resection of the bladder for NMIBC	GR
In patients initially diagnosed with TaLG/G1-2 bladder cancer, use ultrasound of the bladder during surveillance in case cystoscopy is not possible, or refused by the patient.	C

2. METHODS

2.1 Data Identification

For the 2017 NMIBC Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature.

A broad and comprehensive scoping exercise covering all areas of the NMIBC Guidelines was performed. Excluded from the search were basic research studies, case series, reports and editorial comments. Only articles published in the English language, addressing adults, were included. The search was restricted to articles published between June 1st 2015 and April 22nd 2016. Databases covered by the search included Pubmed, Ovid, EMBASE and the Cochrane Central Register of Controlled Trials and the Cochrane Database of Systematic Reviews. After deduplication, a total of 973 unique records were identified, retrieved and screened for relevance. A detailed search strategy is available on line:

<https://uroweb.org/guideline/non-muscle-invasive-bladder-cancer/?type=appendices-publications>.

Recommendations in this text are assessed according to their level of evidence (LE) and Guidelines are given a grade of recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [5]. Additional methodology information can be found in the general Methodology section of this print, and online at the EAU website: <http://uroweb.org/guidelines/>. A list of Associations endorsing the EAU Guidelines can also be viewed on line at the above address.

2.2 Review

Chapter 7, Disease Management was peer reviewed prior to publication in 2016. All other chapters of the NMIBC Guidelines were peer-reviewed in 2015.

2.3 Future goals

The results of an ongoing systematic review will be included in the 2018 update of the NMIBC Guidelines. These reviews are performed using standard Cochrane systematic review methodology; <http://www.cochranelibrary.com/about/about-cochrane-systematic-reviews.html>.

Ongoing systematic review:

1. Is there a difference between the 2004 WHO grading system and the 1973 WHO grading system for NMIBC in terms of prognostic performance and reproducibility? [6].

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Bladder cancer (BC) is the seventh most commonly diagnosed cancer in the male population worldwide, while it drops to eleventh when both genders are considered [7]. The worldwide age-standardised incidence rate (per 100,000 person/years) is 9.0 for men and 2.2 for women [7]. In the European Union the age-standardised incidence rate is 19.1 for men and 4.0 for women [7]. In Europe, the highest age-standardised incidence rate has been reported in Belgium (31 in men and 6.2 in women) and the lowest in Finland (18.1 in men and 4.3 in women) [7].

Worldwide, the BC age-standardised mortality rate (per 100,000 person/years) was 3.2 for men vs. 0.9 for women in 2012 [7]. Bladder cancer incidence and mortality rates vary across countries due to differences in risk factors, detection and diagnostic practices, and availability of treatments. The variations are, however, partly caused by the different methodologies used and the quality of data collection [8]. The incidence and mortality of BC has decreased in some registries, possibly reflecting the decreased impact of causative agents [9].

Approximately 75% of patients with BC present with a disease confined to the mucosa (stage Ta, CIS) or submucosa (stage T1); in younger patients (< 40) this percentage is even higher [10]. Patients with TaT1 and CIS have a high prevalence due to long-term survival in many cases and lower risk of cancer-specific mortality compared to T2-4 tumours [7, 8].

3.2 Aetiology

Tobacco smoking is the most important risk factor for BC, accounting for approximately 50% of cases [8, 9, 11] (LE: 3). Tobacco smoke contains aromatic amines and polycyclic aromatic hydrocarbons, which are renally excreted.

Occupational exposure to aromatic amines, polycyclic aromatic hydrocarbons and chlorinated hydrocarbons is the second most important risk factor for BC, accounting for about 10% of all cases. This type of occupational exposure occurs mainly in industrial plants, which process paint, dye, metal and petroleum products [8, 9, 12, 13]. In developed industrial settings, these risks have been reduced by work-safety guidelines, therefore, chemical workers no longer have a higher incidence of BC compared to the general population [8, 12, 13].

While family history seems to have little impact [14] and, to date, no overt significance of any genetic variation for BC has been shown, genetic predisposition has an influence on the incidence of BC via its impact on susceptibility to other risk factors [8, 15, 16].

Although the significance of fluid intake is uncertain, the chlorination of drinking water and subsequent levels of trihalomethanes are potentially carcinogenic, also exposure to arsenic in drinking water increases risk [8, 17] (LE: 3). The association between personal hair dye use and risk remains uncertain; an increased risk has been suggested in users of permanent hair dyes with a slow NAT2 acetylation phenotype [8]. Dietary habits seem to have little impact [18-20].

Exposure to ionizing radiation is connected with increased risk; weak association was also suggested for cyclophosphamide and pioglitazone [8, 17] (LE: 3). Schistosomiasis, a chronic endemic cystitis based on recurrent infection with a parasitic trematode, is also a cause of BC [8] (LE: 3).

3.3 Pathology

The information presented in this text is limited to urothelial carcinoma, unless otherwise specified.

3.4 Summary of evidence for epidemiology, aetiology and pathology

Summary of evidence	LE
Worldwide, bladder cancer is the eleventh most commonly diagnosed cancer.	2a
Several risk factors connected with the risk of bladder cancer diagnosis have been identified.	3

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Definition of non-muscle-invasive bladder cancer

Papillary tumours confined to the mucosa and invading the lamina propria are classified as stage Ta and T1, respectively, according to the Tumour, Node, Metastasis (TNM) classification system [21]. Flat, high-grade tumours that are confined to the mucosa are classified as CIS (Tis). These tumours can be treated by transurethral resection of the bladder (TURB), eventually in combination with intravesical instillations and are therefore grouped under the heading of NMIBC for therapeutic purposes. However, molecular biology techniques and clinical experience have demonstrated the highly malignant potential of CIS and T1 lesions as compared to Ta lesions. The terms “NMIBC” and “superficial BC” are therefore suboptimal descriptions.

4.2 Tumour, Node, Metastasis Classification (TNM)

The 2009 TNM classification approved by the Union International Contre le Cancer (UICC) was updated in 2017 (8th Edn.), but with no changes in relation to bladder tumours (Table 4.1) [21].

Table 4.1: 2017 TNM classification of urinary bladder cancer

T - Primary tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Ta	Non-invasive papillary carcinoma
Tis	Carcinoma <i>in situ</i> : ‘flat tumour’
T1	Tumour invades subepithelial connective tissue
T2	Tumour invades muscle
T2a	Tumour invades superficial muscle (inner half)
T2b	Tumour invades deep muscle (outer half)
T3	Tumour invades perivesical tissue
T3a	Microscopically
T3b	Macroscopically (extravesical mass)
T4	Tumour invades any of the following: prostate stroma, seminal vesicles, uterus, vagina, pelvic wall, abdominal wall
T4a	Tumour invades prostate stroma, seminal vesicles, uterus or vagina
T4b	Tumour invades pelvic wall or abdominal wall
N - Regional lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N2	Metastasis in multiple regional lymph nodes in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N3	Metastasis in common iliac lymph node(s)
M - Distant metastasis	
M0	No distant metastasis
M1a	Non-regional lymph nodes
M1b	Other distant metastases

4.3 T1 subclassification

The depth and extent of invasion into the lamina propria (T1 substaging) has been demonstrated to be of prognostic value in retrospective cohort studies [22, 23] (LE: 3). Its use is recommended by the most recent 2016 World Health Organization (WHO) classification [24]. The optimal system to substage T1 remains to be defined.

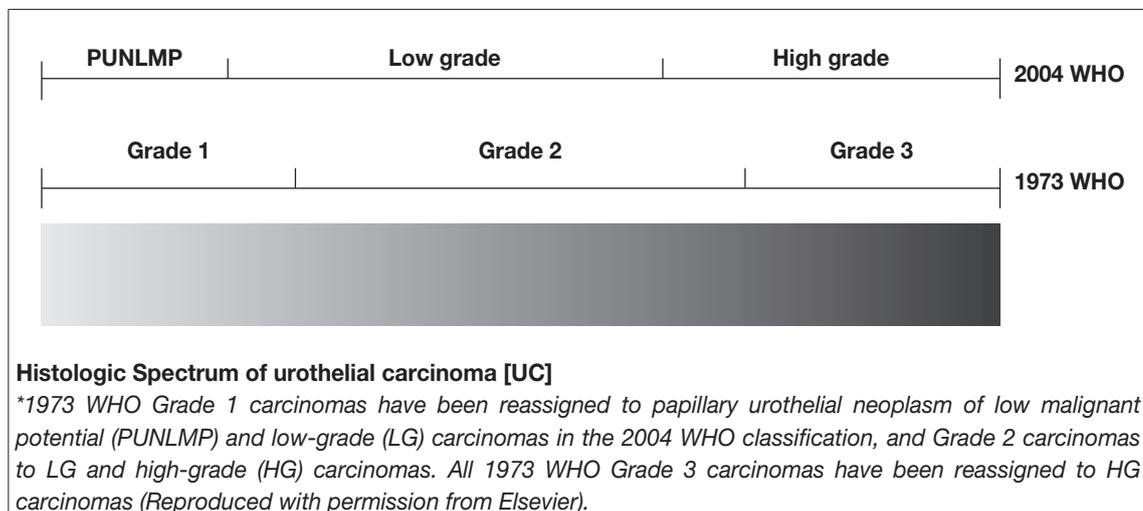

4.4 Histological grading of non-muscle-invasive bladder urothelial carcinomas

In 2004, the WHO and the International Society of Urological Pathology published a new histological classification of urothelial carcinomas which provides a different patient stratification between individual categories compared to the older 1973 WHO classification [25, 26] (Tables 4.2 and 4.3, Fig 4.1). Recently an update of the 2004 WHO grading classification was published [24] but the following guidelines are still based on the 1973 and 2004 WHO classifications since most published data rely on these two classifications [25, 26].

Table 4.2: WHO grading in 1973 and in 2004 [25, 26]

<p>1973 WHO grading</p> <p>Grade 1: well differentiated</p> <p>Grade 2: moderately differentiated</p> <p>Grade 3: poorly differentiated</p> <p>2004 WHO grading system (papillary lesions)</p> <p>Papillary urothelial neoplasm of low malignant potential (PUNLMP)</p> <p>Low-grade (LG) papillary urothelial carcinoma</p> <p>High-grade (HG) papillary urothelial carcinoma</p>
--

The prognostic value of both WHO 1973 and 2004 grading systems has been confirmed. Attempts to demonstrate better prognostic value of one over the other, however, have yielded controversial results [27-29]. (LE: 2a). Moreover, the 2004 WHO system have not been fully incorporated into prognostic models yet.

Figure 4.1: Stratification of tumours according to grade in the WHO 1973 and 2004 classifications [30]*

4.5 Carcinoma *in situ* and its classification

Carcinoma *in situ* (CIS) is a flat, high-grade, non-invasive urothelial carcinoma. It can be missed or misinterpreted as an inflammatory lesion during cystoscopy if not biopsied. Carcinoma *in situ* is often multifocal and can occur in the bladder, but also in the upper urinary tract, prostatic ducts, and prostatic urethra [31].

Classification of CIS according to clinical type [32]:

- Primary: isolated CIS with no previous or concurrent papillary tumours and no previous CIS;
- Secondary: CIS detected during follow-up of patients with a previous tumour that was not CIS;
- Concurrent: CIS in the presence of any other urothelial tumour in the bladder.

Table 4.3: WHO 2004 histological classification for flat lesions

<ul style="list-style-type: none"> • Urothelial proliferation of uncertain malignant potential (flat lesion without atypia or papillary aspects). • Reactive atypia (flat lesion with atypia). • Atypia of unknown significance. • Urothelial dysplasia. • Urothelial CIS is always high grade.
--

4.6 Inter- and intra-observer variability in staging and grading

There is significant variability among pathologists for the diagnosis of CIS, for which agreement is achieved in only 70-78% of cases [33] (LE: 2a). There is also interobserver variability in the classification of stage T1 vs. Ta tumours and tumour grading in both the 1973 and 2004 classifications. The general conformity in staging and grading is between 50% and 60% [28, 34-36] (LE: 2a). The published comparisons have not clearly confirmed that the WHO 2004 classification provides better reproducibility than the 1973 classification [27, 28, 36, 37].

4.7 Further pathology parameters

According to a meta-analysis of retrospective trials, the presence of lymphovascular invasion (LVI) in TURB specimens is connected with an increased risk of pathological upstaging [38] (LE: 3). Lymphovascular invasion has been reported as an unfavourable prognostic factor in T1 tumours [38] (LE: 3). Some variants of urothelial carcinoma (micropapillary, plasmocytoid, nested, sarcomatoid, microcystic, squamous and adeno variants, have a worse prognosis than classical urothelial carcinoma [2, 39-46] (LE: 3).

Molecular markers, particularly FGFR3 mutation status, are promising but need further validation [47-51].

4.8 Summary of evidence and recommendations for bladder cancer classification

Summary of evidence	LE
The depth of invasion (staging) is classified according to the TNM classification.	2a
Papillary tumours confined to the mucosa and invading the lamina propria are classified as stage Ta and T1, respectively. Flat, high-grade tumours that are confined to the mucosa are classified as CIS (Tis).	2a
T1 and CIS, as compared to Ta, have high malignant potential, the term non-muscle-invasive bladder cancer (NMIBC) is therefore a suboptimal description.	3
For histological classification of NMIBC, both the WHO 1973 and 2004 grading systems are used.	2a

Recommendations	GR
Use the 2017 TNM system for classification of the depth of tumour invasion (staging).	A
Use both the 1973 and 2004/2016 WHO grading systems for histological classification.	A
Do not use the term "superficial bladder cancer".	A
Mention the tumour stage and grade whenever the terminology NMIBC is used in individual cases.	A

5. DIAGNOSIS

5.1 Patient history

A comprehensive patient history is mandatory.

5.2 Signs and symptoms

Haematuria is the most common finding in NMIBC. Visible haematuria was found to be associated with higher stage disease compared to non-visible haematuria at first presentation [52]. Carcinoma *in situ* might be suspected in patients with lower urinary tract symptoms, especially irritative voiding.

5.3 Physical examination

Physical examination does not reveal NMIBC.

5.4 Imaging

5.4.1 Computed tomography urography and intravenous urography

Computed tomography (CT) urography is used to detect papillary tumours in the urinary tract, indicated by filling defects or hydronephrosis.

Intravenous urography (IVU) is an alternative if CT is not available [53] (LE: 3), but particularly in muscle-invasive tumours of the bladder and in UTUCs, CT urography gives more information than IVU (including status of lymph nodes and neighbouring organs).

The necessity to perform a baseline CT urography or IVU once a bladder tumour has been detected is questionable due to the low incidence of significant findings obtained [54-56] (LE: 2a). The incidence of UTUCs is low (1.8%), but increases to 7.5% in tumours located in the trigone [55] (LE: 2b). The risk of UTUC during follow up increases in patients with multiple- and high-risk tumours [57] (LE: 3).

5.4.2 Ultrasound (US)

Transabdominal US permits characterisation of renal masses, detection of hydronephrosis, and visualisation of intraluminal masses in the bladder [58] (LE: 3). Ultrasound is therefore a useful tool for detection of obstruction in patients with haematuria. However, it cannot exclude the presence of UTUC and cannot replace CT urography.

The diagnosis of CIS cannot be made with imaging methods (CT urography, IVU or US) (LE: 4).

5.5 Urinary cytology

The examination of voided urine or bladder-washing specimens for exfoliated cancer cells has high sensitivity in G3 and high-grade tumours (84%), but low sensitivity in G1 and low-grade tumours (16%) [59]. The sensitivity in CIS detection is 28-100% [60] (LE: 2b). Cytology is useful, particularly as an adjunct to cystoscopy, if G3/CIS malignancy is present. Positive voided urinary cytology can indicate an urothelial tumour anywhere in the urinary tract; negative cytology, however, does not exclude the presence of a tumour.

Cytological interpretation is user-dependent [61]. Evaluation can be hampered by low cellular yield, urinary tract infections, stones, or intravesical instillations, but in experienced hands specificity exceeds 90% [61] (LE: 2b).

A standardised reporting system redefining urinary cytology diagnostic categories was published in 2016 by the Paris Working Group [62]:

- Adequacy of urine specimens (Adequacy);
- Negative for high-grade urothelial carcinoma (Negative);
- Atypical urothelial cells (AUC);
- Suspicious for high-grade urothelial carcinoma (Suspicious);
- High-grade urothelial carcinoma (HGUC);
- Low-grade urothelial neoplasia (LGUN).

Urine collection should respect the recommendation provided in Section 5.9. One cytospin slide from the sample is usually sufficient [63]. In patients with suspicious cytology repeat investigation is advised [64] (LE: 3).

5.6 Urinary molecular marker tests

Driven by the low sensitivity of urine cytology, numerous urinary tests were developed [65-69]. None of these markers have been accepted for diagnosis or follow-up in routine practice or clinical guidelines. A list of the more established urine tests (US Food and Drug Administration [FDA] approved and those for which multi-institutional data are available) is listed in Table 5.1.

The following conclusions can be drawn regarding the existing tests:

- Sensitivity is usually higher at the cost of lower specificity, compared to urine cytology [65, 67-72] (LE: 3).
- Benign conditions and bacillus Calmette-Guérin (BCG) influence many urinary marker tests [65-69] (LE: 3).
- Requirements for sensitivity and specificity of a urinary marker test depend on the clinical context of the patient (screening, primary detection, follow up [high risk, low/intermediate risk]) [67, 68, 73] (LE: 3).
- Patient selection explains the wide range in performance of the markers listed in Table 5.1.
- Positive results of Cytology, UroVysion (FISH), NMP-22, Ucyt+ and microsatellite analysis in patients with negative cystoscopy and upper tract workup, may identify patients more likely to experience recurrence [74-77] and possibly progression [74-78] (LE: 3).

Table 5.1: Summary of more established urinary markers

Markers (or test specifications)	Overall sensitivity (%)	Overall specificity (%)	Sensitivity for high-grade tumours (%)	Point-of-care test	LE
UroVysion (FISH)*	30-86	63-95	66-70	No	2b
Microsatellite analysis	58-92	73-100	90-92	No	1b
Immunocyt/uCyt +*	52-100	63-79	62-92	No	2a
Nuclear matrix Protein 22*	47-100	55-98	75-92	Yes	2a
BTA stat*	29-83	56-86	62-91	Yes	3
BTA TRAK*	53-91	28-83	74-77	No	3
Cytokeratins	12-88	73-95	33-100	No	3

BTA = bladder tumour antigen.

** FDA approved.*

5.7 Potential application of urinary cytology and markers

The following objectives of urinary cytology or molecular tests must be considered.

5.7.1 Screening of the population at risk of bladder cancer

The application of haematuria dipstick, NMP22 or UroVysion in BC screening in high-risk populations has been

reported [79]. The low incidence of BC in the general population and the short lead-time impair feasibility and cost-effectiveness [77, 79]. Routine screening for BC is not recommended [80].

5.7.2 **Exploration of patients after haematuria or other symptoms suggestive of bladder cancer (primary detection)**

It is generally accepted that none of the currently available tests can replace cystoscopy. However, urinary cytology or markers can be used as an adjunct to cystoscopy to detect invisible tumours, particularly CIS. In this setting, sensitivity for high-grade tumours and specificity are particularly important. Urinary cytology is highly specific, but urinary markers lack such high specificity and are not recommended for primary detection.

5.7.3 **Surveillance of non-muscle-invasive bladder cancer**

Research has been carried out into the usefulness of urinary cytology vs. markers in the follow up of NMIBC [69, 81, 82].

5.7.3.1 *Follow-up of high-risk non-muscle-invasive bladder cancer*

High-risk tumours should be detected early in follow up, and the percentage of tumours missed should be as low as possible. Therefore, the best surveillance strategy for these patients will continue to include frequent cystoscopy and cytology.

5.7.3.2 *Follow-up of low/intermediate-risk non-muscle-invasive bladder cancer*

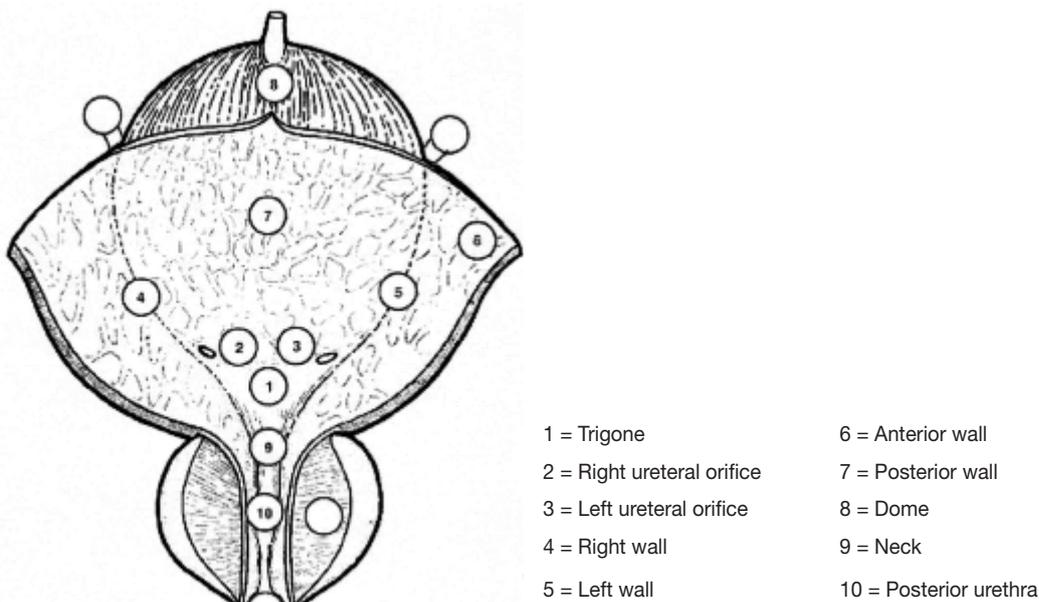

To reduce the number of cystoscopy procedures, urinary markers should be able to detect recurrence before the tumours are large and numerous. The limitation of urinary cytology is its low sensitivity for low-grade recurrences. Several urinary markers are better, but still do not detect half of the low-grade tumours identified by cystoscopy [67] (LE: 3).

According to current knowledge, no urinary marker can replace cystoscopy during follow up or help to lower cystoscopy frequency in a routine fashion. One prospective randomised study found that knowledge of positive test results (microsatellite analysis) can improve the quality of follow-up cystoscopy [83] (LE: 1b), supporting the adjunctive role of a non-invasive urine test performed before follow-up cystoscopy [83].

5.8 **Cystoscopy**

The diagnosis of papillary BC ultimately depends on cystoscopic examination of the bladder and histological evaluation of sampled tissue by either cold-cup biopsy or resection. Carcinoma *in situ* is diagnosed by a combination of cystoscopy, urine cytology, and histological evaluation of multiple bladder biopsies [84]. Cystoscopy is initially performed as an outpatient procedure. A flexible instrument with topical intra-urethral anaesthetic lubricant instillation results in better compliance compared to a rigid instrument, especially in men [85].

Figure 5.1: Bladder diagram

5.9 Summary of evidence and recommendations for the primary assessment of non-muscle-invasive bladder cancer

Summary of evidence	LE
The diagnosis of bladder cancer depends on cystoscopy examination.	1
Urinary cytology has high sensitivity in high-grade tumours including carcinoma <i>in situ</i> .	2b

Recommendations	GR
Take a patient history.	A
Renal and bladder ultrasound may be used during the initial work-up in patients with haematuria.	C
At the time of the initial diagnosis of non-muscle-invasive bladder cancer (NMIBC), perform computed tomography urography (or intravenous urography [IVU]) in selected cases (e.g., tumours located in the trigone, multiple or high-risk tumours).	B
Perform cystoscopy in all patients with symptoms suggestive of bladder cancer. It cannot be replaced by cytology or by any other non-invasive test.	A
Cystoscopy should describe all macroscopic features of the tumour (site, size, number and appearance) and mucosal abnormalities. A bladder diagram is recommended (see Figure 5.1).	C
Voided urine cytology is advocated as an adjunct to cystoscopy to detect high-grade tumour.	C
Perform cystoscopy on fresh urine with adequate fixation. Morning urine is not suitable because of the frequent presence of cytolysis.	C
Repeat urine cytology in patients with suspicious initial cytology results.	C

5.10 Transurethral resection of TaT1 bladder tumours

5.10.1 Strategy of the procedure

The goal of TURB in TaT1 BC is to make the correct diagnosis and completely remove all visible lesions. It is a crucial procedure in the diagnosis and treatment of BC. TURB should be performed systematically in individual steps (see Section 5.14).

5.10.2 Surgical and technical aspects of tumour resection

5.10.2.1 Surgical strategy of resection (resection in fractions, *en-bloc* resection)

A complete resection is essential to achieve a good prognosis [86]. A complete resection can be achieved by either resection in fractions or *en-bloc* resection.

- Resection in fractions (separate resection of the exophytic part of the tumour, the underlying bladder wall and the edges of the resection area) provides good information about the vertical and horizontal extent of the tumour [87] (LE: 3).
- *En-bloc* resection using monopolar or bipolar current, Thulium-YAG or Holmium-YAG laser is feasible in selected exophytic tumours. It provides high quality resected specimens with the presence of detrusor muscle in 96-100% of cases [88-91] (LE 3).

The technique selected is dependent on the size and location of the tumour and experience of the surgeon.

5.10.2.2 Evaluation of resection quality

It has been confirmed that the absence of detrusor muscle in the specimen is associated with a significantly higher risk of residual disease, early recurrence and tumour understaging [92] (LE: 2b). The presence of detrusor muscle in the specimen is considered as the surrogate criterion of the resection quality and is required (except of TaG1/LG tumours). It has been shown that surgical experience can improve TURB results, which supports the role of teaching programmes [93].

5.10.2.3 Monopolar and bipolar resection

Compared to monopolar resection, bipolar resection has been introduced to reduce the risk of complications (e.g., bladder perforation due to obturator nerve stimulation) and to produce better specimens for the pathologist [94] (LE: 3). Currently, the results remain controversial [95-97].

5.10.2.4 Office-based fulguration and laser vaporisation

In patients with a history of small, TaLG/G1 tumours, fulguration of small papillary recurrences on an outpatient basis can reduce the therapeutic burden and is a treatment option [94, 98] (LE: 3). There are no prospective comparative studies assessing the oncological outcomes.

Potassium titanyl-phosphate (KTP) laser vaporisation is associated with a low risk of complications. Its oncologic outcomes need to be confirmed in a larger patient population [99].

5.10.2.5 *Resection of small papillary bladder tumours at the time of transurethral resection of the prostate (TURP)*

Only limited, retrospective, data exist on the outcome of incidentally detected papillary bladder tumour during cystoscopy as the initial step of TURP. Provided these tumours are papillary by aspect, rather small and not extensively multifocal, it seems feasible to resect these tumours and continue with the resection of the prostate. However, no exact risk-assessment can be provided [100, 101].

5.10.3 **Bladder and prostatic urethral biopsies and incidental papillary tumours during transurethral resection of the prostate**

Carcinoma *in situ* can present as a velvet-like, reddish, area indistinguishable from inflammation, or it may not be visible at all. For this reason, the strategy of taking biopsies from abnormal urothelium and biopsies from normal-looking mucosa (random/mapping biopsies) is recommended (see Section 5.14). The indication for random biopsies reflects the very low likelihood of detecting CIS, especially in low-risk tumours (< 2%) [102] (LE: 2a). The risk increases in patients with high-risk tumours and with positive cytology [103].

If equipment is available, photodynamic diagnosis (PDD) is a useful tool to target the biopsy (see Section 5.11.1).

Involvement of the prostatic urethra and ducts in men with NMIBC has been reported. Palou *et al.* [104] showed that in 128 men with T1G3 BC, the incidence of CIS in the prostatic urethra was 11.7% (LE: 2b). The risk of prostatic urethra or duct involvement is higher if the tumour is located at the trigone or bladder neck, in the presence of bladder CIS and multiple tumours [105] (LE: 3). Based on this observation, a biopsy from the prostatic urethra is necessary in some cases (see recommendation in Section 5.14) [104, 106].

5.11 **New methods of tumour visualisation**

As a standard procedure, cystoscopy and TURB are performed using white light. However, the use of white light can lead to missing lesions that are present but not visible, which is why new technologies are being developed.

5.11.1 **Photodynamic diagnosis (fluorescence cystoscopy)**

Photodynamic diagnosis (PDD) is performed using violet light after intravesical instillation of 5-aminolaevulinic acid (ALA) or hexaminolaevulinic acid (HAL). It has been confirmed that fluorescence-guided biopsy and resection are more sensitive than conventional procedures for the detection of malignant tumours, particularly for CIS [107, 108] (LE: 2a). In a systematic review and meta-analysis, PDD had higher sensitivity than white light endoscopy in the pooled estimates for analyses at both the patient-level (92% vs. 71%) and biopsy-level (93% vs. 65%) [108]. A prospective randomised trial did not confirm a higher detection rate in patients with known positive cytology before TURB [109].

Photodynamic diagnosis had lower specificity than white-light endoscopy (63% vs. 81%) [108].

False-positivity can be induced by inflammation or recent TURB and during the first three months after BCG instillation [110, 111] (LE: 3). Prospective randomised studies evaluating the impact of ALA fluorescence-guided (FC) TURB on disease-recurrence rate provided controversial results [108, 112, 113].

The beneficial effect of HAL FC on recurrence rate in patients with TURB was confirmed by a multicentre, prospective, randomised trial and by a raw-data-based meta-analysis of controlled trials. A meta-analysis reported in the HAL arms an increase in detection of tumour lesions across all risk groups and an absolute reduction of < 10% in recurrence rates within twelve months [114] (LE: 1a). The beneficial effect of HAL FC on recurrence rate in patients with TURB and early intravesical instillation of chemotherapy was not confirmed by two prospective randomised trials [115, 116]. In the prospective controlled analysis of patients receiving early instillation in a real-life clinical setting, the beneficial effect of HAL FC on early recurrence rate was confirmed for low- and intermediate-risk tumours [117]. The value of fluorescence-guided TURB for the improvement of outcome in relation to progression rate, survival and clinical management remains to be demonstrated.

5.11.2 **Narrow-band imaging**

In narrow-band imaging (NBI), the contrast between normal urothelium and hyper-vascular cancer tissue is enhanced. Initial studies have demonstrated improved cancer detection by NBI-guided biopsies and resection [118, 119] (LE: 3). The reduction of recurrence rate if NBI is used during TURB has been confirmed after three and twelve months only for low-risk tumours (pTaLG, < 30 mm, no CIS) [120].

5.12 Second resection

The significant risk of residual tumour after initial TURB of TaT1 lesions has been demonstrated [86] (LE: 2a). Persistent disease after resection of T1 tumours has been observed in 33-55% of patients, after resection of TaG3 tumour in 41.4% [121-124]. Moreover, the tumour is often understaged in the initial resection. The likelihood that muscle-invasive disease is detected by second resection of initially T1 tumour ranges from 1.3-25%, and increases to 45% if there was no muscle in the initial resection [109, 125-128]. This risk increased to 50% in some radical cystectomy (RC) series, although these studies only enrolled selected patients [129-131] (LE: 2a). Treatment of a TaT1 high-grade tumour and a T2 tumour is completely different; correct staging is therefore important. It has been demonstrated that a second TURB can increase recurrence-free survival [121, 122] (LE: 2a), improve outcomes after BCG treatment [132] (LE: 3) and provide prognostic information [127, 129, 133] (LE: 3).

In a retrospective evaluation of a large multi-institutional cohort of 2,451 patients with BCG-treated T1G3/HG tumours (second resection was performed in 935 patients), the second resection improved recurrence-free survival (RFS), progression-free survival (PFS) and overall survival (OS) only in patients without muscle in the specimen from initial resection [134] (LE:3).

Retrospective evaluation showed that a second resection performed 14-42 days after initial resection provides longer RFS and PFS comparing to second resection performed after 43-90 days [135] (LE:3). Based on these arguments, a second TURB is recommended in selected cases two-six weeks after initial resection (for recommendations on patient selection, see Section 5.14).

The results of the second resection (residual tumours and understaging) reflect the quality of the initial TURB. As the goal is to improve the quality of the initial TURB, the results of the second resection should be recorded.

5.13 Pathology report

Pathological investigation of the specimen(s) obtained by TURB and biopsies is an essential step in the diagnosis and treatment decision-making process for BC. Close co-operation between urologists and pathologists is required. A high quality of resected and submitted tissue and clinical information is essential for correct pathological assessment. The presence of sufficient muscle is necessary for the correct assignment of the T category. To obtain all relevant information, the specimen collection, handling and evaluation should respect the recommendations provided below (see Section 5.14) [136].

5.14 Summary of evidence and recommendations for transurethral resection of the bladder, biopsies and pathology report

Summary of evidence	LE
Transurethral resection of the bladder (TURB) followed by pathology investigation of the obtained specimen(s) is an essential step in the treatment of NMIBC.	1
The absence of detrusor muscle in the specimen is associated with a significantly higher risk of residual disease and tumour understaging.	2b
In patients with a history of small, TaLG/G1 tumours, fulguration of small papillary recurrences on an outpatient basis is feasible and safe.	3
A second TURB can detect residual tumours and tumour understaging, increase recurrence-free survival, improve outcomes after BCG treatment and provide prognostic information.	2

Recommendations	GR
In patients suspected of having bladder cancer, perform a TURB followed by pathology investigation of the obtained specimen(s) as a diagnostic procedure and initial treatment step.	A
Perform TURB systematically in individual steps: <ul style="list-style-type: none"> • bimanual palpation under anaesthesia; • insertion of the resectoscope, under visual control with inspection of the whole urethra; • inspection of the whole urothelial lining of the bladder; • biopsy from the prostatic urethra (if indicated); • cold-cup bladder biopsies (if indicated); • resection of the tumour; • recording of findings in the surgery report/record; • precise description of the specimen for pathology evaluation. 	C

Performance of individual steps	
Perform <i>en-block</i> resection or resection in fractions (exophytic part of the tumour, the underlying bladder wall and the edges of the resection area). The presence of detrusor muscle in the specimen is required in all cases except for TaG1/LG tumours.	B
Avoid cauterisation as much as possible during TURB to avoid tissue deterioration.	C
Take biopsies from abnormal-looking urothelium. Biopsies from normal-looking mucosa (trigone, bladder dome, and right, left, anterior and posterior bladder wall) are recommended when cytology is positive or when high-risk exophytic tumour is expected (non-papillary appearance). If equipment is available, perform fluorescence-guided (PDD) biopsies.	B
Take biopsy of the prostatic urethra in cases of bladder neck tumour, when bladder carcinoma <i>in situ</i> is present or suspected, when there is positive cytology without evidence of tumour in the bladder, or when abnormalities of the prostatic urethra are visible. If biopsy is not performed during the initial procedure, it should be completed at the time of the second resection.	C
Take the biopsy from abnormal areas in the prostatic urethra and from the precollicular area (between the 5 and 7 o'clock position) using a resection loop. In primary non-muscle-invasive tumours when stromal invasion is not suspected, cold-cup biopsy with forceps can be used.	C
Refer the specimens from different biopsies and resection fractions to the pathologist in separate containers and label them separately.	C
The TURB protocol must describe tumour appearance, all steps of the procedure, as well as the extent and completeness of resection.	C
In patients with positive cytology, but negative cystoscopy, exclude an upper tract urothelial carcinoma, CIS in the bladder (random biopsies or PDD-guided biopsies) and tumour in the prostatic urethra (prostatic urethra biopsy).	C
Perform a second TURB in the following situations: <ul style="list-style-type: none"> • after (suspicion of) incomplete initial TURB (in the case of any doubt about completeness of a TURB); • if there is no muscle in the specimen after initial resection, with the exception of TaLG/G1 tumours and primary CIS; • in T1 tumours. 	A
If indicated, perform a second TURB within two-six weeks after initial resection. This second TURB should include resection of the primary tumour site.	C
Register the results of a second TURB as it reflects the quality of the initial resection.	A
Inform the pathologist of prior treatments (intravesical therapy, radiotherapy, etc.).	A
Pathological report	
The pathological report should specify tumour location, tumour grade, depth of tumour invasion, presence of CIS, and whether the detrusor muscle is present in the specimen.	A
The pathological report should specify the presence of lymphovascular invasion or unusual (variant) histology.	C
In difficult cases, consider an additional review by an experienced genitourinary pathologist.	B

6. PREDICTING DISEASE RECURRENCE AND PROGRESSION

6.1 TaT1 tumours

In order to predict, separately, the short- and long-term risks of disease recurrence and progression in individual patients, the EORTC Genito-Urinary Cancer Group has developed a scoring system and risk tables [137]. The basis for these tables are individual patient data from 2,596 patients diagnosed with TaT1 tumours, who were randomised into seven EORTC trials. Patients with CIS alone were not included. Seventy-eight percent of patients received intravesical treatment, mostly chemotherapy. However, they did not undergo a second TURB or receive maintenance BCG.

The scoring system is based on the six most significant clinical and pathological factors which are shown in Table 6.1. It also illustrates the weights applied to various factors for calculating the total scores for recurrence and progression. Table 6.2 shows the total scores stratified, into four categories that reflect various probabilities of recurrence and progression at one and five years [137] (LE: 2a).

Table 6.1: Weighting used to calculate disease recurrence and progression scores

Factor	Recurrence	Progression
Number of tumours		
Single	0	0
2-7	3	3
≥ 8	6	3
Tumour diameter		
< 3 cm	0	0
≥ 3	3	3
Prior recurrence rate		
Primary	0	0
≤ 1 recurrence/year	2	2
> 1 recurrence/year	4	2
Category		
Ta	0	0
T1	1	4
Concurrent CIS		
No	0	0
Yes	1	6
Grade		
G1	0	0
G2	1	0
G3	2	5
Total Score	0-17	0-23

Table 6.2: Probability of recurrence and disease progression according to total score

Recurrence score	Probability of recurrence at 1 year	Probability of recurrence at 5 years		
	%	(95% CI)	%	(95% CI)
0	15	(10-19)	31	(24-37)
1-4	24	(21-26)	46	(42-49)
5-9	38	(35-41)	62	(58-65)
10-17	61	(55-67)	78	(73-84)

Progression score	Probability of progression at 1 year	Probability of progression at 5 years		
	%	(95% CI)	%	(95% CI)
0	0.2	(0-0.7)	0.8	(0-1.7)
2-6	1	(0.4-1.6)	6	(5-8)
7-13	5	(4-7)	17	(14-20)
14-23	17	(10-24)	45	(35-55)

NB: Electronic calculators for Tables 6.1 and 6.2, which have been updated for the Apple and Android phones and tablets, are available at <http://www.eortc.be/tools/bladdercalculator/>.

A scoring model for BCG-treated patients that predicts the short- and long-term risks of recurrence and progression has been published by the Club Urológico Español de Tratamiento Oncológico (CUETO) (Spanish Urological Oncology Group). It is based on an analysis of 1,062 patients from four CUETO trials that compared different intravesical BCG treatments. Patients received twelve instillations over five to six months. No immediate post-operative instillation or second TURB was performed in these patients. The scoring system is based on the evaluation of seven prognostic factors:

- gender;
- age;
- prior recurrence status;
- number of tumours;
- T category;
- associated CIS;
- tumour grade.

Using these tables, the calculated risk of recurrence is lower than that obtained by the EORTC tables. For progression, probability is lower only in high-risk patients [138] (LE: 2a). The lower risks in the CUETO tables may be attributed to the use of BCG in this sample, which is a more effective instillation therapy. The CUETO risk calculator is available at: <http://www.aeu.es/Cueto.html>.

The prognostic value of the EORTC scoring system has been confirmed by data from the CUETO patients treated with BCG and by long-term follow up in an independent patient population [139, 140] (LE: 2a). In 1,812 intermediate- and high-risk patients without CIS treated with one to three years of maintenance BCG, the EORTC found that the prior disease-recurrence rate and number of tumours were the most important prognostic factors for disease recurrence, stage and grade were the most important prognostic factors for disease progression and disease-specific survival, while age and grade were the most important prognostic factors for OS. T1G3 patients do poorly, with one- and five-year disease-progression rates of 11.4% and 19.8%, respectively. Using these data the new EORTC risk groups and nomograms for BCG treated patients were designed [141] (LE: 2a).

Further prognostic factors have been described in selected patient populations:

- In T1G3 tumours important prognostic factors were female sex and CIS in the prostatic urethra in men treated with an induction course of BCG, and age, tumour size and concurrent CIS in BCG-treated patients (62% with induction course only) [104, 142] (LE: 2b).
- Attention must be given to patients with T1G3 tumours in bladder (pseudo) diverticulum because of the absence of muscle layer in the diverticular wall [143] (LE: 3).
- In patients with high-risk disease, the tumour stage at the time of the second TURB is an unfavourable prognostic factor [129, 133] (LE: 3)
- In patients with T1G2 tumours treated with TURB, recurrence at three months was the most important predictor of progression [144] (LE: 2b).
- The prognostic value of pathological factors has been discussed elsewhere (see Section 4.6). More research is needed to determine the role of molecular markers in improving the predictive accuracy of currently available risk tables [139, 145].

6.2 Carcinoma *in situ*

Without any treatment, approximately 54% of patients with CIS progress to muscle-invasive disease [146] (LE: 3). Unfortunately, there are no reliable prognostic factors that can be used to predict the course of the disease. Publications are based on retrospective analyses of small series of patients and conclusions are not homogeneous. Some studies have reported a worse prognosis in concurrent CIS and T1 tumours compared to primary CIS [147, 148], extended CIS [149] and CIS in the prostatic urethra [104] (LE: 3).

The response to intravesical treatment with BCG or chemotherapy is an important prognostic factor for subsequent progression and death caused by BC [138-140, 144]. Approximately 10-20% of complete responders eventually progress to muscle-invasive disease, compared with 66% of non-responders [150, 151] (LE: 2a).

6.3 Patient stratification into risk groups

To facilitate treatment recommendations it is important to categorise patients into risk groups. Based on available prognostic factors and in particular data from the EORTC risk tables, the Guidelines Panel recommends stratification of patients into three risk groups. Table 6.3 provides a definition of these risk groups, which takes into account the EORTC risk tables' probabilities of recurrence and especially progression.

6.4 Subgroup of highest-risk tumours

Based on prognostic factors, it is possible to substratify high-risk group patients, and identify those that are at the highest risk of disease progression. Patients diagnosed with T1G3/HG tumours associated with concurrent bladder CIS, multiple and/or large T1G3/HG tumours and/or recurrent T1G3/HG, T1G3/HG with CIS in the prostatic urethra, some forms of variant histology of urothelial carcinoma and T1 tumours with LVI (Table 6.3) are at the highest risk of progression.

Table 6.3: Risk group stratification

Risk group stratification	Characteristics
Low-risk tumours	Primary, solitary, TaG1 (PUNLMP, LG*), < 3 cm, no CIS
Intermediate-risk tumours	All tumours not defined in the two adjacent categories (between the category of low- and high risk).
High-risk tumours	Any of the following: <ul style="list-style-type: none"> • T1 tumour • G3 (HG**) tumour • carcinoma <i>in situ</i> (CIS) • Multiple, recurrent and large (> 3 cm) TaG1G2 /LG tumours (all features must be present)*. <p>Subgroup of highest risk tumours: T1G3/HG associated with concurrent bladder CIS, multiple and/or large T1G3/HG and/or recurrent T1G3/HG, T1G3/HG with CIS in the prostatic urethra, some forms of variant histology of urothelial carcinoma, lymphovascular invasion.</p>

Substratification of high-risk tumours for clinical purposes is addressed in Table 7.2.

*Low grade is a mixture of G1 and G2.

** High grade is a mixture of some G2 and all G3 (see Figure 4.1).

6.5 Summary of evidence and recommendations for stratification of non-muscle-invasive bladder cancer

Summary of evidence	LE
The EORTC scoring system and risk tables predict the short- and long-term risks of disease recurrence and progression in individual patients with non-muscle-invasive bladder cancer (NMIBC).	2a
In patients treated with BCG, the CUETO scoring model predicts the short- and long-term risks of disease recurrence and progression.	2a
In patients receiving BCG maintenance: prior recurrence rate and number of tumours are the most important prognostic factors for disease recurrence.	2a
Stage and grade are the most important prognostic factors for disease progression and disease specific survival.	2a
Patient age and grade are the most important prognostic factors for overall survival.	2a

Recommendations	GR
Stratify patients into three risk groups according to Table 6.3.	B
Apply the EORTC risk tables and calculator for the prediction of the risk of tumour recurrence and progression in different intervals after transurethral resection of the bladder, in individual patients.	B
Use the CUETO risk tables and the new EORTC risk groups for the prediction of the risk of tumour recurrence and progression in individual patients treated with bacillus Calmette-Guérin.	B

7. DISEASE MANAGEMENT

7.1 Counselling of smoking cessation

It has been confirmed that smoking increases the risk of tumour recurrence and progression [152, 153] (LE: 3). While it is still controversial whether smoking cessation in BC will favourably influence the outcome of BC treatment, patients should be counselled to stop smoking due to the general risks connected with tobacco smoking [154-157] (LE: 3).

7.2 Adjuvant treatment

7.2.1 Intravesical chemotherapy

Although TURB by itself can eradicate a Ta, T1 tumour completely, these tumours commonly recur and can progress to MIBC. The high variability in the three-month recurrence rate indicates that the TURB was incomplete or provokes recurrences in a high percentage of patients [86]. It is therefore necessary to consider adjuvant therapy in all patients.

7.2.1.1 A single, immediate, post-operative intravesical instillation of chemotherapy

Immediate single instillation (SI) has been shown to act by destroying circulating tumour cells after TURB, and by an ablative effect (chemo resection) on residual tumour cells at the resection site and on small overlooked tumours [158-161] (LE: 3).

Four large meta-analyses comprising 1,476 to 3,103 patients have consistently shown that after TURB, SI significantly reduces the recurrence rate compared to TURB alone [162-165] (LE: 1a). In the most recent systematic review and individual patient data meta-analysis of 2,278 eligible patients [162], SI reduced the five-year recurrence rate by 14%, from 59% to 45%. The number to treat (NNT) to prevent one recurrence within five years was seven eligible patients. Only patients with a prior recurrence rate of less than or equal to one recurrence per year and those with an EORTC recurrence score < 5 benefited from SI. In patients with an EORTC recurrence score ≥ 5 and/or patients with a prior recurrence rate of > 1 recurrence per year, SI was not effective as a single adjuvant treatment. Mitomycin C (MMC), epirubicin, and pirarubicin have all shown a beneficial effect [162]. No randomised comparisons of individual drugs have been conducted [162-165] (LE: 1a).

Prevention of tumour cell implantation should be initiated within the first few hours after TURB. After that, tumour cells are firmly implanted and are covered by extracellular matrix [158, 166, 167] (LE: 3). In all SI studies, the instillation was administered within 24 hours. To maximise the efficacy of SI, one should devise flexible practices that allow the instillation to be given as soon as possible after TURB, preferably within the first two hours in the recovery room or even in the operating theatre. As severe complications have been reported in patients with drug extravasation [168, 169] safety measures should be maintained (see Section 7.5).

7.2.1.2 Additional adjuvant intravesical chemotherapy instillations

The need for further adjuvant intravesical therapy depends on prognosis. In low-risk patients (Tables 6.1, 6.2 and 6.3), a SI reduces the risk of recurrence and is considered to be the standard and complete treatment [162, 163] (LE: 1a). For other patients, however, a SI remains an incomplete treatment because of the considerable likelihood of recurrence and/or progression (Tables 6.1, 6.2 and 6.3). The individual patient data meta-analysis also showed that a SI reduced recurrences in intermediate-risk patients with an EORTC recurrence score < 5, none of whom received further treatment prior to recurrence [162]. There is evidence from several studies in intermediate-risk patients that SI might have an impact on recurrence even when further adjuvant instillations are given; however, they do not take into account the EORTC recurrence score [170-172] (LE: 2a). In one study [173], further chemotherapy instillations after SI improved recurrence-free survival in intermediate-risk patients (LE: 2a). Conversely, a sufficient number of delayed repeat chemotherapy instillations without SI can also reduce recurrences [170, 172].

A large meta-analysis of 3,703 patients from eleven randomised trials showed a highly significant (44%) reduction in the odds of recurrence at one year in favour of chemotherapy over TURB alone [174]. This

corresponds to an absolute difference of 13-14% in the number of patients with recurrence. Contrary to these findings, two meta-analyses have demonstrated that BCG therapy may reduce the risk of tumour progression [175, 176] (LE: 1a) (see Section 7.2.2.1). Moreover, BCG maintenance therapy appears to be significantly better in preventing recurrences than chemotherapy [177-179] (see Section 7.2.2.1) (LE: 1a). However, BCG causes significantly more side effects than chemotherapy [179] (LE: 1a).

The length and frequency of chemotherapy instillations is still controversial. A systematic review of RCTs, comparing different schedules of intravesical chemotherapy instillations, concluded that the ideal duration and intensity of the schedule remains undefined because of conflicting data [172]. The available evidence does not support treatment longer than one year (LE: 3).

7.2.1.3 Options for improving efficacy of intravesical chemotherapy

7.2.1.3.1 Adjustment of pH, duration of instillation, and drug concentration

One RCT using MMC has demonstrated that adapting urinary pH, decreasing urinary excretion, and buffering the intravesical solution reduced the recurrence rate [180] (LE: 1b). Another trial reported that duration of a one hour instillation of MCC was more effective compared to a 30 minute instillation, but no efficacy comparisons are available for one- vs. two-hour durations of instillation [181] (LE: 3). Another RCT using epirubicin has documented that concentration is more important than treatment duration [182] (LE: 1b). In view of these data, instructions are provided (see Section 7.5).

7.2.1.3.2 Device-assisted intravesical chemotherapy

Hyperthermia

Promising data have been presented on enhancing the efficacy of MMC using microwave-induced hyperthermia in patients with high-risk tumours [183]. In one RCT comparing one year of BCG with one year MMC and microwave-induced hyperthermia in patients with intermediate and high-risk bladder cancer, a reduced RFS at 24 months in the MMC group was demonstrated [184] (LE: 1b). Different technologies which increase the temperature of instilled MMC are available, however, data about their efficacy are still lacking.

Electromotive drug administration (EMDA)

The efficacy of MMC using EMDA in patients with high-risk tumours has been demonstrated in one small RCT [185]. The definitive conclusion however, needs further confirmation.

7.2.1.4 Summary of evidence - intravesical chemotherapy

Summary of evidence	LE
In patients with non-muscle-invasive bladder cancer and a prior low recurrence rate (\leq to one recurrence per year) and in those with an EORTC recurrence score < 5 , a single instillation (SI) significantly reduces the recurrence rate compared to transurethral resection of the bladder alone.	1a
In intermediate-risk patients, SI might have an impact on recurrence even when further adjuvant instillations are given.	3
Further chemotherapy instillations after SI improve recurrence-free survival in intermediate-risk patients.	2a

7.2.2 Intravesical bacillus Calmette-Guérin (BCG) immunotherapy

7.2.2.1 Efficacy of BCG

Five meta-analyses have confirmed that BCG after TURB is superior to TURB alone or TURB + chemotherapy for preventing the recurrence of NMIBC [177, 186-188] [189] (LE: 1a). Three recent RCTs of intermediate- and high-risk tumours have compared BCG with epirubicin + interferon [190], MMC [191], or epirubicin alone [178] and have confirmed the superiority of BCG for prevention of tumour recurrence (LE: 1a). The effect is long-lasting [178, 191] and was also observed in a separate analysis of patients with intermediate-risk tumours [178]. One meta-analysis [177] has evaluated the individual data from 2,820 patients enrolled in nine RCTs that have compared MMC vs. BCG. In the trials with BCG maintenance, there was a 32% reduction in the risk of recurrence for BCG compared to MMC, but a 28% increase in the risk of recurrence for patients treated with BCG in the trials without BCG maintenance.

Two meta-analyses have demonstrated that BCG therapy delays and potentially lowers the risk of tumour progression [175, 176] (LE: 1a). A meta-analysis carried out by the EORTC-GUCG has evaluated data from 4,863 patients enrolled in 24 RCTs. Five different BCG strains were used, and in 20 of the trials, some form of BCG maintenance was used. Based on a median follow-up of 2.5 years, in 260 out of 2,658 patients (9.8%) treated with BCG, tumours progressed, compared to 304 out of 2,205 (13.8%) in the control groups (TURB alone, TURB + intravesical chemotherapy, or TURB + other immunotherapy). This shows a reduction

of 27% in the odds of progression with BCG maintenance treatment. The size of the reduction was similar in patients with TaT1 papillary tumours and in those with CIS [176]. A recent RCT with long-term observation has demonstrated significantly fewer distant metastases and better overall- and disease-specific survival in patients treated with BCG compared to epirubicin [178] (LE: 1b). On the contrary, a meta-analysis of individual patient data was not able to confirm any statistically significant difference between MMC and BCG for progression, survival and cause of death [177].

The conflicting results in the outcomes of these studies can be explained by different patient characteristics, duration of follow-up, methodology and statistical power. However, most studies showed a reduction in the risk of progression in high- and intermediate-risk tumours if BCG was applied including a maintenance schedule.

Two other meta-analyses have suggested a possible bias in favour of BCG arising from the inclusion of patients previously treated with intravesical chemotherapy [192]. In the most recent meta-analysis, however, BCG maintenance was more effective than MMC, both in patients previously treated and not previously treated with chemotherapy [177] (LE: 1a). It was demonstrated that BCG was less effective in patients > 70 years of age, but still more effective than epirubicin in a cohort of elderly patients [193] (LE: 1a).

7.2.2.2 *BCG strain*

The EORTC meta-analysis suggested no large differences in efficacy between various BCG strains [176]. Recently published smaller studies without maintenance demonstrated some differences between strains. This clearly needs further evaluation in prospective trials [194, 195] (LE: 2a).

7.2.2.3 *BCG toxicity*

BCG intravesical treatment is associated with more side effects compared to intravesical chemotherapy [176] (LE: 1a). However, serious side effects are encountered in < 5% of patients and can be treated effectively in almost all cases [196] (LE: 1b). It has been shown that a maintenance schedule is not associated with an increased risk of side effects compared to an induction course [196]. Side effects requiring treatment stoppage were seen more often in the first year of therapy [197]. Elderly patients do not seem to experience more side effects leading to treatment discontinuation [198] (LE: 2a).

Major complications can appear after systemic absorption of the drug. Thus, contraindications of BCG intravesical instillation should be respected (see Section 7.5). The presence of leukocyturia, non-visible haematuria or asymptomatic bacteriuria is not a contraindication for BCG application, and antibiotic prophylaxis is not necessary in these cases [199, 200] (LE: 3).

Bacillus Calmette-Guérin should be used with caution in immunocompromised patients; e.g. immunosuppression, human immunodeficiency virus [HIV] infection pose relative contraindications [201], although some small studies have shown similar efficacy and no increase in complications compared to non-immunocompromised patients. The role of prophylactic anti-tuberculosis medication in these patients remains unclear [202-204] (LE: 3). The management of side effects after BCG should reflect their type and grade according to the recommendations provided by the International Bladder Cancer Group (IBCG) and by a Spanish group [205, 206] (Table 7.1).

Table 7.1: Management options for side effects associated with intravesical bacillus Calmette-Guérin (BCG) [206-209]

Management options for local side effects (modified from International Bladder Cancer Group)	
Symptoms of cystitis	Phenazopyridine, propantheline bromide, or non-steroidal anti-inflammatory drugs (NSAIDs)
	If symptoms improve within a few days: continue instillations
	If symptoms persist or worsen: <ol style="list-style-type: none"> Postpone the instillation Perform a urine culture Start empirical antibiotic treatment
	If symptoms persist even with antibiotic treatment: <ol style="list-style-type: none"> With positive culture: adjust antibiotic treatment according to sensitivity With negative culture: quinolones and potentially analgesic anti-inflammatory instillations once daily for 5 days (repeat cycle if necessary) [207].
	If symptoms persist: anti-tuberculosis drugs + corticosteroids.
	If no response to treatment and/or contracted bladder: radical cystectomy.
Haematuria	Perform urine culture to exclude haemorrhagic cystitis, if other symptoms present. If haematuria persists, perform cystoscopy to evaluate presence of bladder tumour.
Symptomatic granulomatous prostatitis	Symptoms rarely present: perform urine culture.
	Quinolones.
	If quinolones are not effective: isoniazid (300 mg/day) and rifampicin (600 mg/day) for three months.
	Cessation of intravesical therapy.
Epididymo-orchitis [208]	Perform urine culture and administer quinolones.
	Cessation of intravesical therapy.
	Orchidectomy if abscess or no response to treatment.
Management options for systemic side effects	
General malaise, fever	Generally resolve within 48 hours, with or without antipyretics.
Arthralgia and/or arthritis	Rare complication and considered autoimmune reaction.
	Arthralgia: treatment with NSAIDs.
	Arthritis: NSAIDs.
	If no/partial response, proceed to corticosteroids, high-dose quinolones or anti-tuberculosis drugs [209].
Persistent high-grade fever (> 38.5°C for > 48 h)	Permanent discontinuation of BCG instillations.
	Immediate evaluation: urine culture, blood tests, chest X-ray.
	Prompt treatment with more than two antimicrobial agents while diagnostic evaluation is conducted.
	Consultation with an infectious diseases specialist.
BCG sepsis	Prevention: initiate BCG at least 2 weeks post-transurethral resection of the bladder (if no signs and symptoms of haematuria).
	Cessation of BCG.
	For severe infection: <ul style="list-style-type: none"> High-dose quinolones or isoniazid, rifampicin and ethambutol 1.2 g daily for 6 months. Early, high-dose corticosteroids as long as symptoms persist. Consider an empirical non-specific antibiotic to cover Gram-negative bacteria and/or <i>Enterococcus</i>.
Allergic reactions	Antihistamines and anti-inflammatory agents.
	Consider high-dose quinolones or isoniazid and rifampicin for persistent symptoms.
	Delay therapy until reactions resolve.

7.2.2.4 Optimal BCG schedule

Induction BCG instillations are given according to the empirical six-weekly schedule introduced by Morales [210]. For optimal efficacy, BCG must be given in a maintenance schedule [175-177, 189] (LE: 1a). Many different maintenance schedules have been used, ranging from a total of ten instillations given in eighteen

weeks to 27 over three years [211]. The EORTC meta-analysis was unable to determine which BCG maintenance schedule was the most effective [176]. In their meta-analysis, Böhle *et al.* concluded that at least one year of maintenance BCG is required to obtain superiority of BCG over MMC for prevention of recurrence or progression [175] (LE: 1a).

The optimal number of induction instillations and the optimal frequency and duration of maintenance instillations is not fully known. Moreover, it can be different in each individual patient [212]. In a RCT of 1,355 patients, the EORTC has shown that when BCG is given at full dose, three years' maintenance (three-weekly instillations 3, 6, 12, 18, 24, 30 and 36 months) reduces the recurrence rate compared to one year in high- but not in intermediate-risk patients. There were no differences in progression or OS. In the three-year arm, however, 36.1% of patients did not complete the three-year schedule [213] (LE: 1b). In a RCT of 397 patients CUETO suggested that in high-risk tumours, the maintenance schedule with only one instillation every three months for three years may be suboptimal [214] (LE: 1b).

7.2.2.5 Optimal dose of BCG

To reduce BCG toxicity, instillation of a reduced dose was proposed. However, it has been suggested that a full dose of BCG is more effective in multifocal tumours [215, 216] (LE: 1b). The CUETO study compared one-third dose to full-dose BCG and found no overall difference in efficacy. One-third of the standard dose of BCG might be the minimum effective dose for intermediate-risk tumours. A further reduction to one-sixth dose resulted in a decrease in efficacy with no decrease in toxicity [217] (LE: 1b).

The EORTC did not find any difference in toxicity between one-third and full-dose BCG, but one third dose BCG was associated with a higher recurrence rate, especially when it was given only for one year [197, 213] (LE: 1b). The routine use of one-third dose BCG is complicated by potential technical difficulties in preparing the reduced dose reliably, given uneven distribution of colony-forming-units in the dry product formulation.

7.2.2.6 Indications for BCG

Although BCG is a very effective treatment, there is a consensus that not all patients with NMIBC should be treated with BCG due to the risk of toxicity. Ultimately, the choice of treatment depends upon the patient's risk (Table 6.2). The recommendation for individual risk groups is provided in Section 7.5.

A statement by the Panel on BCG shortage can be accessed on line: <https://uroweb.org/guideline/non-muscleinvasive-bladder-cancer/?type=appendices-publications>.

7.2.2.7 Summary of evidence - BCG treatment

Summary of evidence	LE
In patients with intermediate- and high-risk tumours, intravesical bacillus Calmette-Guérin (BCG) after TURB reduces the risk of tumour recurrence; it is more effective than TURB alone or TURB + intravesical chemotherapy.	1a
For optimal efficacy, BCG must be given in a maintenance schedule.	1a
Three-year maintenance is more effective than one year to prevent recurrence in patients with high-risk tumours, but not in patients with intermediate-risk tumours.	1a

7.2.3 Combination therapy

In one RCT, a combination of MMC and BCG was shown to be more effective in reducing recurrences but more toxic compared to BCG monotherapy (LE: 1b). Using similar BCG schedules in both groups, each BCG instillation in the combination group was preceded a day before by one MMC instillation [218]. Another RCT in frequently recurrent NMIBC demonstrated significantly higher efficacy of weekly MMC followed by monthly BCG in reduction of the recurrence rate when compared to BCG and interferon [219] (LE: 1b). In contrast a recent RCT in a similar population of NMIBC comparing BCG monotherapy with a combination of epirubicin and interferon for up to two years showed the latter was significantly inferior to BCG monotherapy in preventing recurrence [220] (LE: 1b). In an RCT using MMC with EMDA, a combination of BCG and MMC with EMDA showed an improved recurrence-free interval and reduced progression rate compared to BCG monotherapy [185, 221] (LE: 2).

7.2.4 Specific aspects of treatment of Carcinoma in situ

7.2.4.1 Treatment strategy

The detection of concurrent CIS increases the risk of recurrence and progression of TaT1 tumours [137, 138], in this case further treatment according to the criteria summarised in Sections 7.2.1, 7.2.2, 7.3 and 7.4 is mandatory. CIS cannot be cured by an endoscopic procedure alone. Histological diagnosis of Carcinoma *in*

situ must be followed by further treatment, either intravesical BCG instillations or RC (LE: 4). Tumour-specific-survival rates after immediate RC for CIS are excellent, but as many as 40-50% of patients might be over treated [146] (LE: 3).

7.2.4.2 Cohort studies on intravesical BCG or chemotherapy

In retrospective evaluations of patients with CIS, a complete response rate of 48% was achieved with intravesical chemotherapy and 72-93% with BCG [146-149, 222] (LE: 2a). Up to 50% of complete responders might eventually show recurrence with a risk of invasion and/or extravesical recurrence [149, 211, 222, 223] (LE: 3).

7.2.4.3 Prospective randomised trials on intravesical BCG or chemotherapy

Unfortunately, there have been few randomised trials in patients with CIS only. A meta-analysis of clinical trials comparing intravesical BCG to intravesical chemotherapy in patients with CIS has shown a significantly increased response rate after BCG and a reduction of 59% in the odds of treatment failure with BCG [224] (LE: 1a).

In an EORTC-GUCG meta-analysis of tumour progression, in a subgroup of 403 patients with CIS, BCG reduced the risk of progression by 35% as compared to intravesical chemotherapy or different immunotherapy [176] (LE: 1b). The combination of BCG and MMC was not superior to BCG alone [225]. In summary, compared to chemotherapy, BCG treatment of CIS increases the complete response rate, the overall percentage of patients who remain disease free, and reduces the risk of tumour progression (LE: 1b).

7.2.4.4 Treatment of CIS in prostatic urethra and upper urinary tract

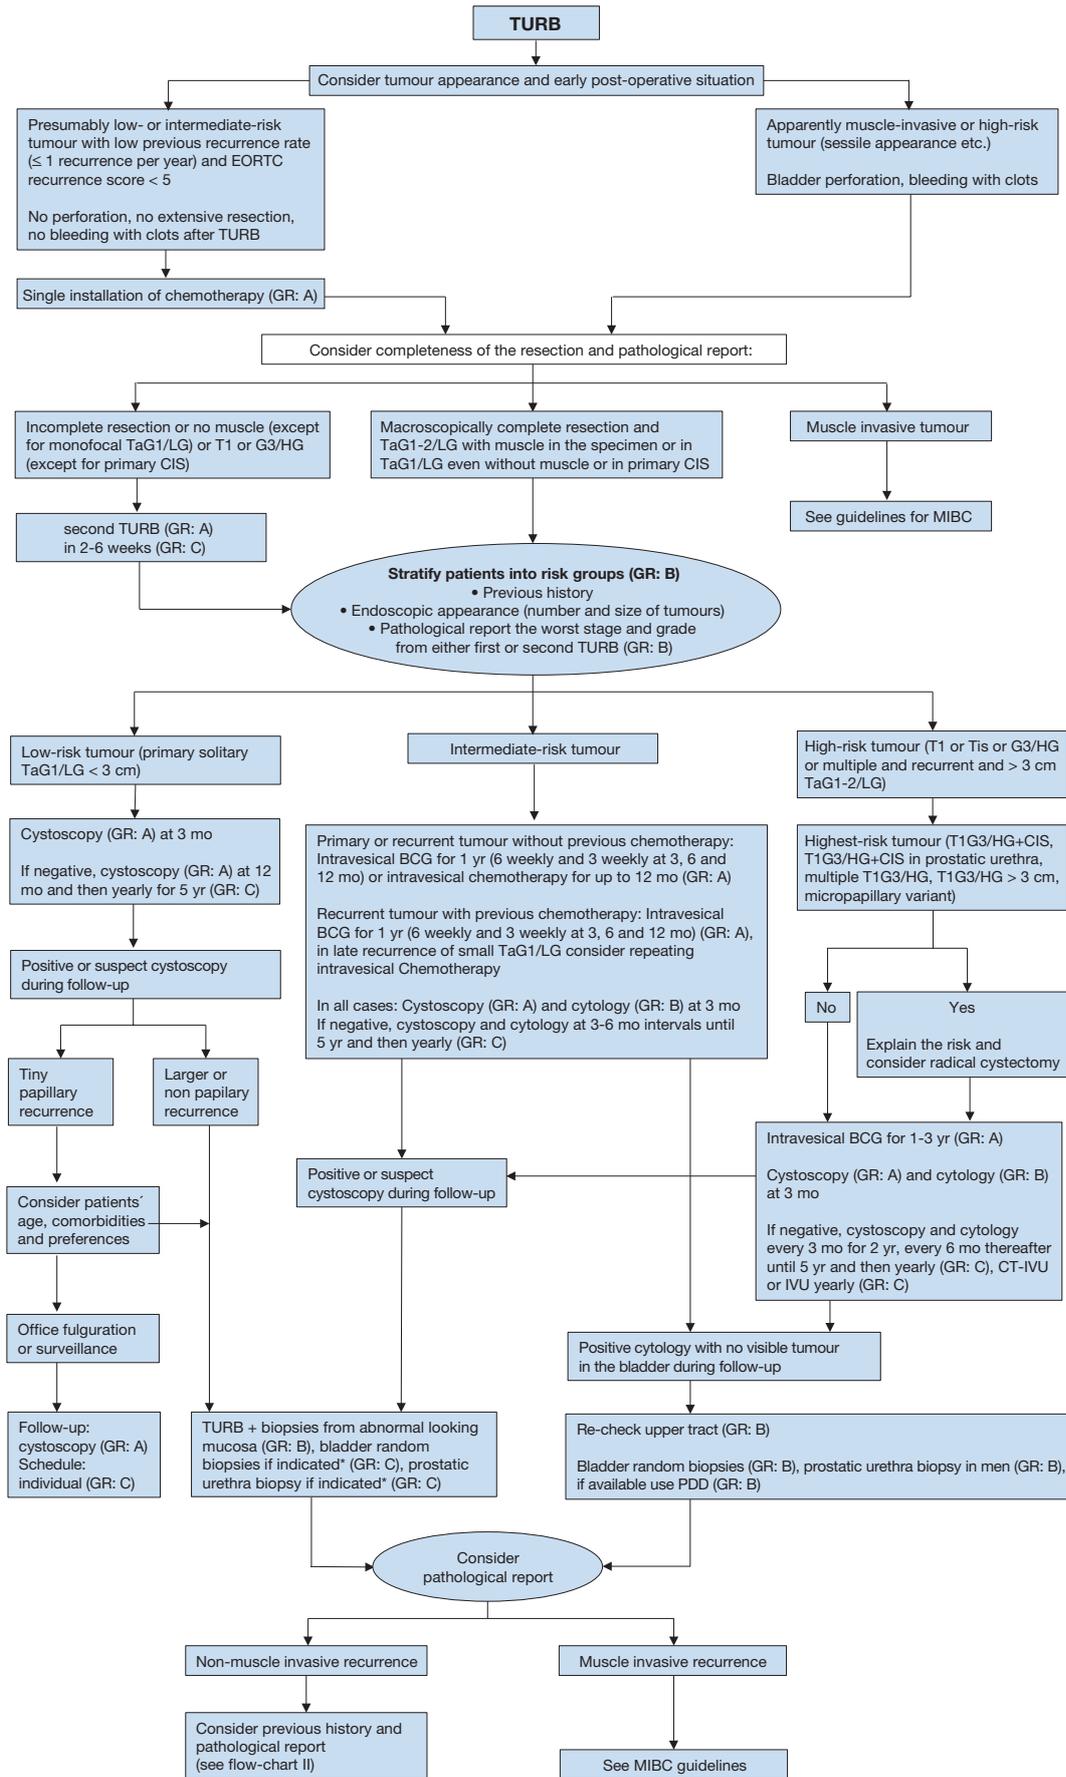

Patients with CIS are at high risk of extravesical involvement in the upper urinary tract (UUT) and in the prostatic urethra. Solsona *et al.* found that 63% of 138 patients with CIS developed extravesical involvement initially or during follow-up [226]. Patients with extravesical involvement had worse survival than those with bladder CIS alone [226] (LE: 3). In the prostate, CIS might be present only in the epithelial lining of the prostatic urethra or in the prostatic ducts [31]. These situations should be distinguished from tumour invasion into the prostatic stroma (stage T4a in bladder tumours), and for which immediate radical cystoprostatectomy is mandatory. Patients with CIS in the epithelial lining of the prostatic urethra can be treated by intravesical instillation of BCG. Transurethral resection of the prostate can improve contact of BCG with the prostatic urethra [85, 227] (LE: 3). However, potential spread of CIS has to be considered; no suprapubic trocar-placed catheter should be used.

In patients with prostatic duct involvement, there are promising results after BCG instillation, but only from small series, so the data are insufficient to provide clear treatment recommendations and radical surgery should be considered [227, 228] (LE: 3). Treatment of CIS that involves the UUT is discussed in the EAU Guidelines on Urothelial Tumours of the Upper Urinary Tract [1].

7.2.4.5 Summary of evidence – treatment of carcinoma *in situ*

Summary of evidence	LE
Carcinoma <i>in situ</i> (CIS) cannot be cured by an endoscopic procedure alone.	4
Compared to intravesical chemotherapy, bacillus Calmette-Guérin treatment of CIS increases the complete response rate, the overall percentage of patients who remain disease free, and reduces the risk of tumour progression.	1b

Flowchart 7.1: Treatment strategy in primary or recurrent tumour(s) without previous BCG*

*For details and explanations see the text of the guidelines

BCG = bacillus Calmette-Guérin; CIS = carcinoma in situ; GR = grade of recommendation; MIBC = muscle-invasive bladder cancer; PDD = photodynamic diagnosis; TURB = transurethral resection of the bladder.

7.3 Treatment of failure of intravesical therapy

7.3.1 Failure of intravesical chemotherapy

Patients with NMIBC recurrence after a chemotherapy regimen can benefit from BCG instillations. Prior intravesical chemotherapy has no impact on the effect of BCG instillation [177] (LE: 1a).

7.3.2 Recurrence and failure after intravesical bacillus Calmette-Guérin (BCG) immunotherapy

Categories of unsuccessful treatment with intravesical BCG are presented in Table 7.2.

Table 7.2: Categories of unsuccessful treatment with intravesical BCG

BCG failure
Whenever a MIBC is detected during follow-up.
BCG-refractory tumour: 1. If high-grade, non-muscle-invasive papillary tumour is present at three months [229]. Further conservative treatment with BCG is associated with increased risk of progression [150, 230] (LE: 3). 2. If CIS (without concomitant papillary tumour) is present at both three and six months. If patients with CIS present at three months, an additional BCG course can achieve a complete response in > 50% of cases [31] (LE: 3). 3. If high-grade tumour appears during BCG therapy*.
High-grade recurrence after BCG. Recurrence of high-grade/grade 3 (WHO 2004/1973) tumour after completion of BCG maintenance, despite an initial response [231] (LE: 3).
BCG intolerance
Severe side effects that prevent further BCG instillation before completing treatment [206].

* Patients with low-grade recurrence during or after BCG treatment are not considered to be a BCG failure.

7.3.3 Treatment of BCG failure and recurrences after BCG

Treatment recommendations are provided in Sections 7.5 and 7.7. They reflect the categories mentioned in Table 7.2 and tumour characteristics at the time of recurrence.

Patients with BCG failure are unlikely to respond to further BCG therapy; RC is therefore the preferred option. Various studies suggest that repeat BCG therapy is appropriate for non-high-grade and even for some high-grade recurrent tumours [232, 233] (LE: 3). Additionally, there are now several bladder preservation strategies available that can be categorised as intravesical immunotherapy [234], intravesical chemotherapy, device-assisted therapy (see Section 7.2.1.3.2), and combination therapy (see Section 7.2.3) [235]. Changing from BCG to these options can yield responses in selected cases with BCG treatment failure [232, 234-242] (LE: 3).

Treatments other than RC must be considered oncologically inferior in patients with BCG failure at the present time [150, 229, 230] (LE: 3).

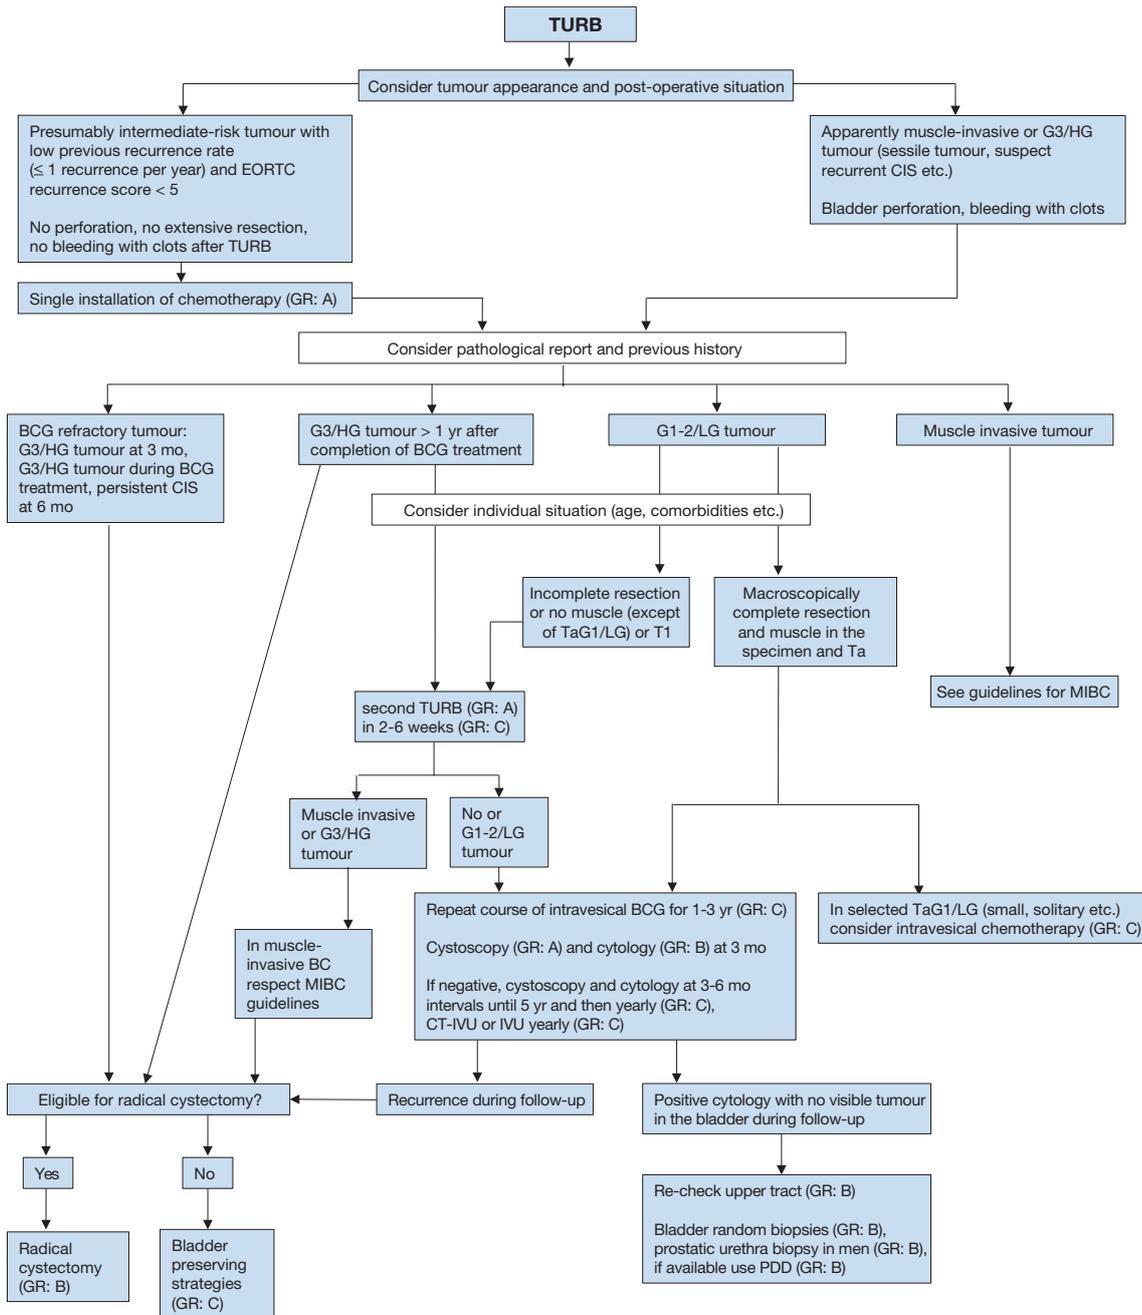

Little is known about the optimal treatment in patients with high-risk tumours who could not complete BCG instillations because of intolerance.

Non-high-grade recurrence after BCG is not considered as BCG failure. Treatment decision should be individualised according to tumour characteristics. It could include chemotherapy or repeat BCG instillations, but the published evidence is very low.

7.3.4 Summary of evidence - treatment failure of intravesical therapy

Summary of evidence	LE
Prior intravesical chemotherapy has no impact on the effect of bacillus Calmette-Guérin (BCG) instillation.	1a
Treatments other than radical cystectomy must be considered oncologically inferior in patients with BCG failure.	3

Flowchart 7.2: Treatment strategy in recurrence during or after intravesical BCG*

BCG = bacillus Calmette-Guérin; CIS = carcinoma in situ; HG = high-grade; IVU = intravenous urography; LG = low-grade; PDD = photodynamic diagnosis; TURB = transurethral resection of the bladder.

7.4 Radical cystectomy for NMIBC

If RC is indicated before progression to muscle-invasive tumour, it can be performed as an immediate (immediately after NMIBC diagnosis) or early procedure (after intravesical therapy failure, see Section 7.3).

There are several reasons to consider immediate RC for selected patients with NMIBC:

- The staging accuracy for T1 tumours by TURB is low with 27-51% of patients being upstaged to muscle-invasive tumour at RC [106, 130, 243-246] (LE: 3).
- Some patients with NMIBC experience disease progression to muscle-invasive disease (Table 6.2).

Patients who experience disease progression to muscle-invasive stage, have a worse prognosis than those who present with 'primary' muscle-invasive disease [247, 248].

The potential benefit of RC must be weighed against its risks, morbidity, and impact on quality of life. It is reasonable to propose immediate RC in those patients with NMIBC who are at highest risk of disease

progression (see Section 7.6) [46, 104, 137, 138, 249] (LE: 3).

The benefits and risks of immediate and delayed RC should be discussed with patients, in a shared decision-making process. Individual additional prognostic factors in T1 tumours mentioned in Sections 4.7 and 6.4 should be considered. Early RC is strongly recommended in patients with BCG-refractory tumours, as mentioned above. A delay in RC may lead to decreased disease-specific survival [250] (LE: 3).

In patients in whom RC is performed before progression to MIBC, the five-year disease-free survival rate exceeds 80% [251-253] (LE: 3).

7.5 Recommendations for adjuvant therapy in TaT1 tumours and for therapy of carcinoma *in situ*

	GR
Counsel smokers with confirmed non-muscle-invasive bladder cancer (NMIBC) to stop smoking.	B
The type of further therapy after transurethral resection of the bladder (TURB) should be based on the risk groups shown in Table 6.3 and Section 7.6.	A
In patients with tumours presumed to be at low risk and in those presumed to be at intermediate risk with previous low recurrence rate (\leq one recurrence per year) and expected EORTC recurrence score < 5 , one immediate chemotherapy instillation is recommended.	A
In patients with intermediate-risk tumours (with or without immediate instillation), one-year full-dose bacillus Calmette-Guérin (BCG) treatment (induction plus three-weekly instillations at 3, 6 and 12 months), or instillations of chemotherapy (the optimal schedule is not known) for a maximum of one year is recommended. The final choice should reflect the individual patient's risk of recurrence and progression as well as the efficacy and side effects of each treatment modality.	A
In patients with high-risk tumours, full-dose intravesical BCG for one-three years (induction plus three-weekly instillations at 3, 6, 12, 18, 24, 30 and 36 months), is indicated. The additional beneficial effect of the second and third years of maintenance should be weighed against its added costs and inconveniences.	A
In patients with CIS in the epithelial lining of the prostatic urethra, transurethral resection of the prostate followed by intravesical instillation of BCG can be offered.	C
Discuss immediate radical cystectomy with patients at highest risk of tumour progression (see Section 7.6).	C
Offer radical cystectomy (RC) to patients with BCG failure (see Section 7.7).	B
In patients with BCG failure, who are not candidates for RC due to comorbidities, use preservation strategies (device-assisted instillations of chemotherapy, intravesical chemotherapy, intravesical immunotherapy).	C
Intravesical chemotherapy	
When given, a single immediate instillation of chemotherapy should be administered within 24 hours after TURB, preferably within two hours.	C
A single immediate instillation of chemotherapy should be omitted in any case of overt or suspected bladder perforation or bleeding requiring bladder irrigation.	C
Give clear instructions to the nursing staff to control the free flow of the bladder catheter at the end of the immediate instillation.	C
The optimal schedule of further intravesical chemotherapy instillation and its duration is not defined, it should not exceed one year.	C
If intravesical chemotherapy is given, it is advised to use the drug at its optimal pH and to maintain the concentration of the drug by reducing fluid intake before and during instillation.	B
The length of individual instillation should be one-two hours.	C
BCG intravesical immunotherapy	
Absolute contraindications of BCG intravesical instillation are: <ul style="list-style-type: none"> • during the first two weeks after TURB; • in patients with visible haematuria; • after traumatic catheterisation; • in patients with symptomatic urinary tract infection. 	C
The management of side effects after BCG intravesical instillation should reflect their type and grade (see Table 7.1).	C

7.6 Treatment recommendations in TaT1 tumours and carcinoma *in situ* according to risk stratification

Risk category	Definition	Treatment recommendation
Low-risk tumours	Primary, solitary, TaG1 (PUNLMP, LG), < 3 cm, no CIS	One immediate instillation of intravesical chemotherapy after TURB.
Intermediate-risk tumours	All tumours not defined in the two adjacent categories (between the category of low- and high-risk).	In patients with previous low recurrence rate (less than or equal to one recurrence per year) and expected EORTC recurrence score < 5, one immediate instillation of intravesical chemotherapy after TURB. In all patients either one-year full-dose BCG treatment (induction plus three-weekly instillations at three, six and twelve months), or instillations of chemotherapy (the optimal schedule is not known) for a maximum of one year.
High-risk tumours	Any of the following: <ul style="list-style-type: none"> • T1 tumours; • G3 (HG) tumour; • CIS; • Multiple, recurrent and large (> 3 cm) TaG1G2/LG tumours (all features must be present). 	Intravesical full-dose BCG instillations for one-three years or radical cystectomy (in highest-risk tumours - <i>see below</i>).
	Subgroup of highest-risk tumours	
	T1G3/HG associated with concurrent bladder CIS, multiple and/or large T1G3/HG and/or recurrent T1G3/HG, T1G3/HG with CIS in the prostatic urethra, some forms of variant histology of urothelial carcinoma, LVI (see Sections 4.7 and 6.4). BCG failures.	Radical cystectomy should be considered. In those who refuse or are unfit for RC intravesical full-dose BCG instillations for one-three years. Radical cystectomy is recommended.

7.7 Treatment recommendations for bacillus Calmette-Guérin (BCG) failure and recurrences after BCG

Category	Treatment recommendation	GR
BCG-refractory tumour	1. Radical cystectomy 2. Bladder-preserving strategies in patients unsuitable for radical cystectomy	B
High-grade (HG) recurrence after BCG	1. Radical cystectomy 2. Bladder-preserving strategies 3. Repeat BCG course	C
Non-HG recurrence after BCG for primary intermediate-risk tumour	1. Repeat BCG or intravesical chemotherapy 2. Radical cystectomy	C

8. FOLLOW-UP OF PATIENTS WITH NMIBC

As a result of the risk of recurrence and progression, patients with NMIBC need surveillance. However, the frequency and duration of cystoscopy and imaging should reflect the individual patient's degree of risk. Using risk tables (see Tables 6.1 and 6.2), the short- and long-term risks of recurrence and progression in individual patients may be predicted and the follow-up schedule adapted accordingly [137, 138].

When planning the follow-up schedule and methods, the following aspects should be considered:

- The prompt detection of muscle-invasive and HG/G3 non-muscle-invasive recurrence is crucial because a delay in diagnosis and therapy can be life-threatening.

- Tumour recurrence in the low-risk group is nearly always low stage and LG/G1. Small, TaLG/G1 papillary recurrence does not present an immediate danger to the patient and early detection is not essential for successful therapy [254, 255] (LE: 2b). Fulguration of small papillary recurrences on an outpatient basis could be a safe option that reduces the therapeutic burden [98] (LE: 3). Some authors have even defended temporary surveillance in selected cases [255-257] (LE: 3).
- The first cystoscopy after TURB at three months is an important prognostic indicator for recurrence and progression [144, 150, 258-260] (LE: 1a). Therefore, the first cystoscopy should always be performed three months after TURB in all patients with TaT1 tumours and CIS.
- In tumours at low risk, the risk of recurrence after five recurrence-free years is low [259] (LE: 3).
- Discontinuation of cystoscopy or its replacement with less-invasive methods can be considered [260].
- In tumours originally intermediate- or high risk, recurrences after ten years tumour-free are not unusual [261] (LE: 3). Therefore, life-long follow-up is recommended [260].
- The follow-up strategy must reflect the risk of extravesical recurrence (prostatic urethra in men and UUT in both genders)
- The risk of UUT recurrence increases in patients with multiple- and high-risk tumours [57] (LE: 3).
- Positive urine test results have a positive impact on the quality of follow-up cystoscopy [83] (LE: 1b) supporting the adjunctive role of urine tests during follow-up.
- In patients initially diagnosed with TaLG/G1-2 BC, ultrasound of the bladder may be a mode of surveillance in case cystoscopy is not possible or refused by the patient [262].

No non-invasive method can replace endoscopy. Follow-up is therefore based on regular cystoscopy (see Section 5.7). There is a lack of randomised studies investigating the possibility of safely reducing the frequency of follow-up cystoscopy.

As CIS is often not visible, multiple biopsies may be necessary in selected cases to confirm the efficacy of intravesical treatment in patients treated for CIS [84]. The recommendations for follow-up are mainly based on retrospective data (see Section 8.1).

8.1 Summary of evidence and recommendations for follow-up of patients after transurethral resection of the bladder for non-muscle-invasive bladder cancer

Summary of evidence	LE
The first cystoscopy after transurethral resection of the bladder at 3 months is an important prognostic indicator for recurrence and progression.	1a
The risk of upper urinary tract (UUT) recurrence increases in patients with multiple- and high-risk tumours.	3

Recommendations	GR
Base follow-up of TaT1 tumours and carcinoma <i>in situ</i> (CIS) on regular cystoscopy.	A
Patients with low-risk Ta tumours should undergo cystoscopy at three months. If negative, subsequent cystoscopy is advised nine months later, and then yearly for five years.	C
Patients with high-risk tumours should undergo cystoscopy and urinary cytology at three months. If negative, subsequent cystoscopy and cytology should be repeated every three months for a period of two years, and every six months thereafter until five years, and then yearly.	C
Patients with intermediate-risk Ta tumours should have an in-between (individualised) follow-up scheme using cystoscopy and cytology.	C
Regular (yearly) upper tract imaging (computed tomography-intravenous urography [CT-IVU] or IVU) is recommended for high-risk tumours.	C
Endoscopy under anaesthesia and bladder biopsies should be performed when office cystoscopy shows suspicious findings or if urinary cytology is positive.	B
Consider random (R)-biopsies or photodynamic diagnosis (PDD)-guided biopsies after intravesical treatment (at three or six months) in patients with CIS.	C
During follow-up in patients with positive cytology and no visible tumour in the bladder, R-biopsies or PDD-guided biopsies (if equipment is available) and investigation of extravesical locations (CT urography, prostatic urethra biopsy) are recommended.	B
In patients initially diagnosed with TaLG/G1-2 bladder cancer, use ultrasound of the bladder during surveillance in case cystoscopy is not possible or refused by the patient.	C

1. INTRODUCTION

1.1 Aim and objectives

The European Association of Urology (EAU) Non-muscle-invasive Bladder Cancer (NMIBC) Guidelines Panel has compiled these clinical guidelines to provide urologists with evidence-based information and recommendations for the management of urothelial carcinoma of the upper urinary tract (UTUC). Separate EAU guidelines documents are available addressing non-muscle-invasive bladder cancer [1], muscle-invasive and metastatic bladder cancer (MIBC) [2], and primary urethral carcinoma [3].

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The European Association of Urology (EAU) Guidelines Panel on NMIBC consists of an international multidisciplinary group of clinicians, including urologists, uro-oncologists, a radiologist, a pathologist and a statistician. Members of this panel have been selected based on their expertise and to represent the professionals treating patients suspected of harbouring urothelial carcinoma. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU website Uroweb: <http://uroweb.org/guideline/upper-urinary-tracturothelial-cell-carcinoma/>.

1.3 Available publications

A quick reference document (Pocket guidelines) is available in print and in a number of versions for mobile devices, presenting the main findings of the UTUC Guidelines. These are abridged versions which may require consultation together with the full text version. Several scientific publications are available as are a number of translations of all versions of the EAU UTUC Guidelines. All documents are accessible through the EAU website Uroweb: <http://uroweb.org/guideline/upper-urinary-tract-urothelial-cell-carcinoma/>.

1.4 Publication history & summary of changes

The first EAU guidelines on UTUC were published in 2011. The 2017 EAU guidelines on UTUC present a limited update of the 2016 version.

1.4.1 Summary of changes

The literature for the complete document has been assessed and updated, whenever relevant. Conclusions and recommendations have been rephrased and added to throughout the current document.

Key changes for the 2017 print:

New section 3.3.1.1 - Summary of evidence for Chapter 3 (Epidemiology, aetiology and pathology) has been added.

3.3.1.1 Summary of evidence for histology and classification

Summary of evidence	LE
A small proportion of upper tract urothelial carcinoma belong to the tumour spectrum of the hereditary non-polyposis colorectal cancer.	3

New section 5.3 - Summary of evidence section has been added to the Guidelines for the diagnosis of upper tract urothelial carcinoma.

5.3 Summary of evidence and guidelines for the diagnosis of upper tract urothelial carcinoma

Summary of evidence	LE
The diagnosis of urothelial carcinoma of the upper urinary depends on computed tomography urography.	2
Selective urinary cytology has high sensitivity in high-grade tumours including carcinoma <i>in situ</i> .	3

New section 7.1.2.4 – Summary of evidence section has been added to the Guidelines for radical nephroureterectomy.

7.1.2.4 Summary of evidence and guidelines for radical nephroureterectomy

Summary of evidence	LE
Radical nephroureterectomy is the standard in high-risk upper tract urothelial carcinoma, regardless of tumour location.	2
Open and laparoscopic approaches have equivalent efficacy and safety in T1–2/N0 upper tract urothelial carcinoma.	2

2. METHODS

2.1 Data identification

Standard procedure for EAU Guidelines includes an annual assessment of newly published literature in the field to guide future updates. For the 2017 UTUC Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature. A broad and comprehensive scoping exercise covering all areas of the entire guideline was performed. Excluded from the search were basic research studies, case series, reports and editorial comments. Only articles published in the English language, addressing adults were included. The search was restricted to articles published between June 1st 2015 and April 22nd 2016. Databases searched included Pubmed, Ovid, EMBASE and both the Cochrane Central Register of Controlled Trials and the Cochrane Database of Systematic Reviews. After deduplication, a total of 973 unique records were identified, retrieved and screened for relevance. A detailed search strategy is available online: <http://uroweb.org/guideline/upper-urinary-tract-urothelial-cell-carcinoma/?type=appendicespublications>.

References used in this text are assessed according to their level of evidence (LE) and Guidelines are given a grade of recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [4]. Additional methodology information can be found in the general Methodology section of this print, and online at the EAU website: <http://uroweb.org/guidelines/>.

A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review

This document was peer-reviewed prior to publication in 2016.

2.3 Future goals

The results on ongoing and new systematic reviews will be included in the 2018 update of the UTUC Guidelines. These reviews are performed using standard Cochrane systematic review methodology: <http://www.cochranelibrary.com/about/about-cochrane-systematic-reviews.html>.

Ongoing systematic reviews:

- Oncological outcomes of laparoscopic/robotic radical nephroureterectomy versus open radical nephroureterectomy for upper tract urothelial carcinoma: an EAU Guidelines systematic review [5].
- What are the benefits and harms of lymph node dissection (LND) during radical nephroureterectomy for upper tract urothelial carcinoma (UTUC)? [6].

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

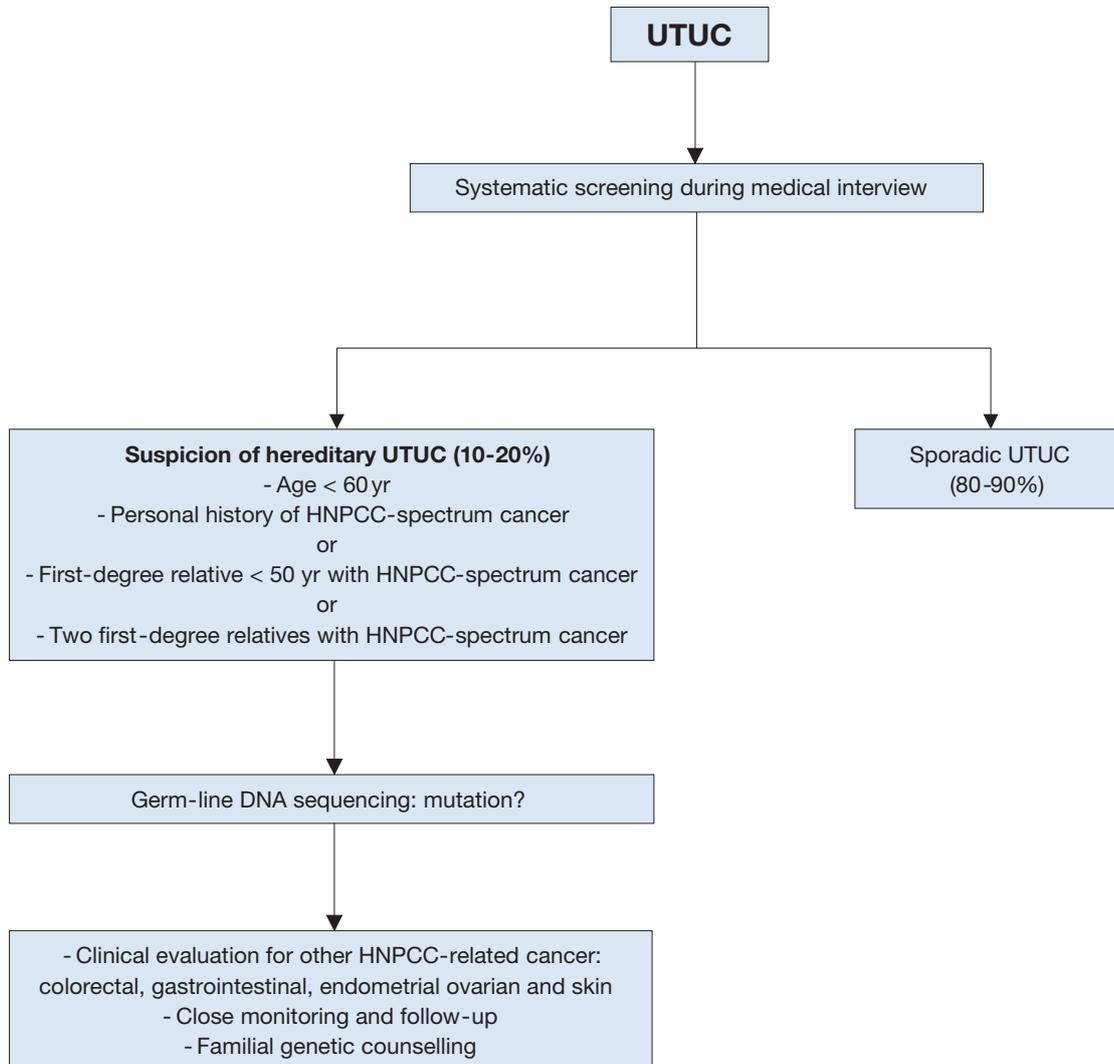

Urothelial carcinomas (UCs) are the fifth most common tumours [7]. They can be located in the lower (bladder and urethra) or upper (pyelocaliceal cavities and ureter) urinary tract. Bladder tumours account for 90-95% of UCs and are the most common malignancy of the urinary tract [8]. In contrast, UTUC are uncommon and account for only 5-10% of UCs [9, 10]. Pyelocaliceal tumours are about twice as common as ureteral tumours.

In 17% of cases, concurrent bladder cancer is present [11]. Recurrence in the bladder occurs in 22-47% of UTUC patients [12], compared with 2-6% in the contralateral upper tract [13, 14].

Approximately 60% of UTUC are invasive at diagnosis compared with 15-25% of bladder tumours [8, 15]. Upper tract urothelial carcinomas have a peak incidence in people aged 70 to 90 years and are three times more common in men [16, 17].

Familial/hereditary UTUC are linked to hereditary non-polyposis colorectal carcinoma (HNPCC) [18], which can be screened for during an interview (Figure 3.1) [19]. Patients should undergo DNA sequencing to identify hereditary cancers misclassified as sporadic if they fulfil the criteria for HNPCC [18, 20].

Figure 3.1: Selection of patients with UTUC for hereditary screening during the first medical interview

HNPCC = hereditary non-polyposis colorectal carcinoma.

3.2 Risk factors

Various environmental risk factors contribute to UTUC development [21, 22]. Tobacco exposure increases the relative risk from 2.5 to 7 [21, 23]. Historically, UTUC ‘amino tumours’ were related to occupational exposure to carcinogenic aromatic amines. The odds ratio of developing UC after exposure to aromatic amines is 8.3 [21, 22]. Upper tract urothelial carcinoma caused by phenacetin consumption almost disappeared after the product was banned in the 1970s [22].

Upper tract urothelial carcinoma often present after a bladder cancer. The average duration of exposure needed to develop UTUC is ~7 years, with a latency of ~20 years following termination of exposure.

Several studies have revealed the carcinogenic potential of aristolochic acid contained in *Aristolochia fangchi* and *Aristolochia clematis*. The aristolochic acid derivative dA-aristolactam causes a specific mutation in the p53 gene at codon 139, which occurs mainly in patients with nephropathy due to Chinese herbs or Balkan endemic nephropathy [22, 24, 25].

There is a high incidence of UTUC in Taiwan, especially on the South-west coast which represents 20-25% of UCs in the region [22, 25]. There is a possible association of UTUC with blackfoot disease and arsenic exposure in drinking water in this population [22, 25, 26].

Differences in the ability to counteract carcinogens may contribute to host susceptibility to UTUC. Some genetic polymorphisms are associated with an increased risk of cancer or faster disease progression, which introduces variability in the inter-individual susceptibility to the risk factors previously mentioned. Upper tract urothelial carcinoma may share some risk factors or molecular disruption pathways with bladder UC. Two UTUC-specific polymorphisms have been reported [27, 28].

3.3 Histology and classification

3.3.1 Histological types

Upper tract urothelial carcinoma with pure non-urothelial histology is an exception [29, 30] but variants are present in ~25% of cases [31, 32]. These variants always correspond to high-grade tumours with worse prognosis compared to pure UC. Squamous cell carcinoma of the upper urinary tract represents < 10% of pyelocaliceal tumours and is even rarer within the ureter. Squamous cell carcinoma of the urinary tract can be associated with chronic inflammatory and infectious diseases arising from urolithiasis [33, 34]. Other variants are: micropapillary, sarcomatoid carcinomas and lymphoepithelioma [33, 34].

3.3.1.1 Summary of evidence for histology and classification

Summary of evidence	LE
A small proportion of upper tract urothelial carcinoma belong to the tumour spectrum of the hereditary non-polyposis colorectal cancer.	3

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Classification

The classification and morphology of UTUC and bladder carcinoma are similar [8]. It is possible to distinguish between non-invasive papillary tumours (papillary urothelial tumours of low malignant potential, and low-grade and high-grade papillary UC), flat lesions (carcinoma *in situ* [CIS]), and invasive carcinoma. As in bladder tumours, non-urothelial differentiation has been identified as an adverse risk factor [35].

4.2 Tumour Node Metastasis staging

The Tumour Node Metastasis (TNM) classification is shown in Table 4.1 [36]. The regional lymph nodes that should be considered are the hilar, abdominal para-aortic, and paracaval nodes, and, for the ureter, the intrapelvic nodes. Laterality does not affect N classification.

A subclassification with pT3a and pT3b has been suggested, but is not in the officially accepted pTNM staging system [31, 37, 38]. Renal pelvic pT3 subclassification may discriminate between microscopic infiltration of the renal parenchyma (pT3a) and macroscopic infiltration or invasion of peripelvic adipose tissue. pT3b UTUC is more likely to be associated with aggressive pathologic features and disease recurrence [31, 37].

Table 4.1: TNM classification 2017 for upper tract urothelial carcinoma [36]

T - Primary tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Ta	Non-invasive papillary carcinoma
Tis	Carcinoma <i>in situ</i>
T1	Tumour invades subepithelial connective tissue
T2	Tumour invades muscularis
T3	(Renal pelvis) Tumour invades beyond muscularis into peripelvic fat or renal parenchyma (Ureter) Tumour invades beyond muscularis into periureteric fat
T4	Tumour invades adjacent organs or through the kidney into perinephric fat
N - Regional lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node 2 cm or less in the greatest dimension
N2	Metastasis in a single lymph node more than 2 cm, or multiple lymph nodes
M - Distant metastasis	
M0	No distant metastasis
M1	Distant metastasis

4.3 Histological grading

In 2004, the WHO and the International Society of Urological Pathology published a new histological classification of urothelial carcinomas which provides a different patient stratification between individual categories compared to the older 1973 WHO classification [39, 40]. Recently an update of the 2004 WHO grading classification was published [41], but the following guidelines are still based on the 1973 and 2004 WHO classifications [39, 40].

Only few tumours of low malignant potential are found in the upper urinary tract, [33, 34]. pT2 tumours should be treated as high-grade disease.

4.4 Guidelines for staging and classification systems

Recommendations	LE	GR
Classify the depths of invasion (staging) according to Tumour Node Metastasis classification, 8 th edition.	3	A
Classify flat, high-grade tumours, confined to the mucosa, as carcinoma <i>in situ</i> (Tis).	3	A
Use the World Health Organization 1973 and 2004 grading systems for the histological classification of upper tract urothelial carcinoma.	3	A

5. DIAGNOSIS

5.1 Symptoms

The most common symptom is visible- or non-visible haematuria (70-80%) [42, 43]. Flank pain occurs in 20-40% of cases, and a lumbar mass in 10-20% [44, 45]. Systemic symptoms (including anorexia, weight loss, malaise, fatigue, fever, night sweats, or cough) are associated with UTUC and should prompt more rigorous evaluation for metastatic disease [44, 45].

5.2 Diagnosis

5.2.1 Imaging

5.2.1.1 Computed tomography urography

Computed tomography (CT) urography has the highest diagnostic accuracy for UTUC of all the clinically available imaging techniques [45]. The sensitivity of CT urography for UTUC is 0.67-1.0 and the specificity is 0.93-0.99 according to the technique used [21, 46-51]. Epithelial 'flat lesions' without mass effect or urothelial thickening are not visible with CT [52].

Computed tomography urography is defined as CT examination of the kidneys, ureters and bladder following the administration of intravenous contrast material [21, 53]. Rapid acquisition of thin sections provides high-resolution isotropic images that can be viewed in multiple planes to assist with diagnosis without loss of resolution. Computed-tomography urography usually includes several phases of acquisition following administration of intravenous contrast media [21, 54].

The secondary sign of hydronephrosis is associated with advanced disease and poor oncological outcome [21, 53, 55, 56]. The presence of enlarged lymph nodes is highly predictive of metastasis in UTUC [21].

5.2.1.2 *Magnetic resonance imaging*

Magnetic resonance urography (MRU) is indicated in patients who cannot undergo CT urography, usually when radiation or iodinated contrast media are contraindicated [57]. The sensitivity of MRU is 0.75 after contrast injection for tumours < 2 cm [57]. The use of MRU with gadolinium-based contrast media should be limited in patients with severe renal impairment (< 30 mL/min creatinine clearance), due to the risk of nephrogenic systemic fibrosis. Computed tomography urography is generally preferred over MRU for diagnosing UTUC.

5.2.2 *Cystoscopy and urinary cytology*

Positive urine cytology is suggestive of UTUC when bladder cystoscopy is normal, provided that no CIS is detected in the bladder or prostatic urethra [8, 58]. Cytology is less sensitive for UTUC than for bladder tumours. It should be performed in the upper tract (*in situ* cytology) [59].

Retrograde ureteropyelography is an option to evaluate UTUC [21, 49, 60, 61] but is now mostly used in conjunction with ureteroscopy and not as a stand-alone diagnostic technique due to similar diagnostic accuracy when compared with CT urography for UTUC [49]. Urinary cytology of the renal cavities and ureteral lumina is preferable before application of contrast agent for retrograde ureteropyelography, because the latter may cause deterioration of cytological specimens [59, 60].

The sensitivity of fluorescence *in situ* hybridisation (FISH) for molecular abnormalities characteristic of UTUC parallels its performance in bladder cancer [62]. However, its use may be limited by the preponderance of low-grade recurrent disease in the population undergoing surveillance and kidney-sparing therapy for UTUC [63, 64]. FISH currently has limited value for the surveillance of UTUC [63, 64].

5.2.3 *Diagnostic ureteroscopy*

Flexible ureteroscopy is used to visualise the ureter, renal pelvis and collecting system and biopsy suspicious lesions. Ureteroscopic biopsies can determine tumour grade in 90% of cases with a low false-negative rate, regardless of sample size [65]. Under-grading may occur from diagnostic biopsy, making intensive follow-up necessary if a kidney-sparing treatment is chosen [66]. Ureteroscopy also facilitates selective ureteral sampling for cytology to detect carcinoma *in situ* [60, 67, 68].

Flexible ureteroscopy is especially useful for diagnostic uncertainty, if kidney-sparing treatment is considered, or in patients with a solitary kidney. Additional information can be provided by ureteroscopy with- or without biopsy. Combining ureteroscopic biopsy grade, imaging findings such as hydronephrosis, and urinary cytology, may help in the decision-making process between radical nephroureterectomy (RNU) and endoscopic treatment [67, 69].

Technical developments in flexible ureteroscopes and the use of novel imaging techniques improve visualisation and the diagnosis of flat lesions [70]. Narrow-band imaging is the most promising technique to date but the results are preliminary [69, 71]. Table 5.3 lists the recommendations for diagnosis.

5.3 Summary of evidence and guidelines for the diagnosis of upper tract urothelial carcinoma

Summary of evidence	LE
The diagnosis of upper tract urothelial carcinoma depends on computed tomography urography.	2
Selective urinary cytology has high sensitivity in high-grade tumours including carcinoma <i>in situ</i> .	3

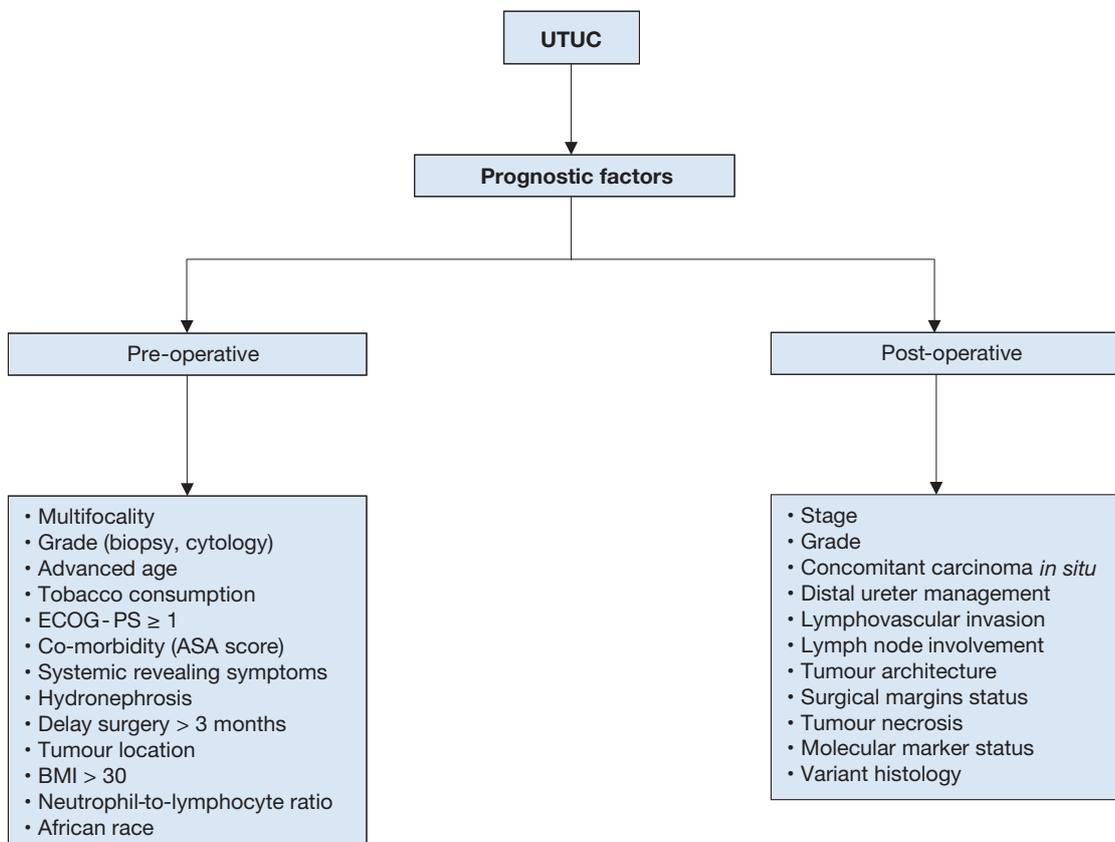

Recommendations	GR
Perform urinary cytology as part of a standard diagnostic work-up.	A
Perform a cystoscopy to rule out concomitant bladder tumour.	A
Perform a computed tomography urography for the diagnostic work-up.	A
Use diagnostic ureteroscopy and biopsy in cases where additional information will impact treatment decisions.	C

6. PROGNOSIS

6.1 Prognostic factors

Upper tract urothelial carcinomas that invade the muscle wall usually have a poor prognosis. The five-year specific survival is < 50% for patients with pT2/pT3 tumours and < 10% for those with pT4 [71-73]. The main prognostic factors are briefly listed below; Figure 6.1 presents a more exhaustive list.

Figure 6.1: Upper tract urothelial carcinoma - Prognostic factors

ASA = American Society of Anesthesiologists; BMI = body mass index;
ECOG = Eastern Cooperative Oncology Group; PS = performance score.

6.1.1 **Pre-operative factors**

6.1.1.1 *Age and sex*

Gender is no longer considered an independent prognostic factor influencing UTUC mortality [16, 73, 74]. Older age at the time of RNU is independently associated with decreased cancer-specific survival [73, 75] (LE: 3). Many elderly patients can be cured with RNU [76], suggesting that age alone is an inadequate indicator of outcome [75, 76]. Despite its association with survival, age alone should not prevent a potentially curable approach.

6.1.1.2 *Ethnicity*

One multicentre study did not show any difference between races [77] but population-based studies have indicated that African-American patients have worse outcomes compared to other ethnicities [76, 78] (LE: 3).

6.1.1.3 *Tobacco consumption*

Being a smoker at diagnosis increases the risk for disease recurrence and mortality after RNU [79, 80] as well as recurrence within the bladder [81] (LE: 3).

6.1.1.4 *Tumour location*

Initial location of the UTUC is a prognostic factor in some studies [82-84] (LE: 3). After adjustment for the effect of tumour stage, patients with ureteral and/or multifocal tumours seem to have a worse prognosis than those with renal pelvic tumours [73, 83-86].

6.1.1.5 *Surgical delay*

A delay between diagnosis of an invasive tumour and its removal may increase the risk of disease progression. Once a decision regarding RNU has been made the procedure should be carried-out within twelve weeks [87-90] (LE: 3).

6.1.1.6 *Other*

The American Society of Anesthesiologists (ASA) score significantly correlates with cancer-specific survival after RNU [91] (LE: 3). The Eastern Cooperative Oncology Group (ECOG) performance status correlates only with overall survival [92]. Obesity and higher body mass index adversely affect cancer-specific outcomes in UTUC [93, 94] (LE: 3). The pre-treatment derived neutrophil-lymphocyte ratio also correlates with higher cancer-specific mortality [95, 96] (LE: 3).

6.1.2 **Post-operative factors**

6.1.2.1 *Tumour stage and grade*

The primary recognised prognostic factors are tumour stage and grade [21, 67, 73, 97].

6.1.2.2 *Lymph node involvement*

Lymph node metastases and extranodal extension are powerful predictor of survival outcomes in UTUC [98]. Lymph node dissection (LND) performed at the time of RNU allows for optimal tumour staging [99, 100] (LE: 3). Its curative role remains debated.

6.1.2.3 *Lymphovascular invasion*

Lymphovascular invasion is present in ~20% of UTUC and is an independent predictor of survival [101, 102]. Lymphovascular invasion status should be specifically reported in the pathological reports of all UTUC specimens [101, 103] (LE: 3).

6.1.2.4 *Surgical margins*

Positive soft tissue surgical margin after RNU is a significant factor for developing UTUC recurrence. Pathologists should look for, and report, positive margins at the level of ureteral transection, bladder cuff, and around the tumour soft tissue margin [104] (LE: 3).

6.1.2.5 *Pathological factors*

Extensive tumour necrosis (> 10% of the tumour area) is an independent prognostic predictor in patients who undergo RNU [105, 106] (LE: 3). The architecture of UTUC is also a strong prognosticator with sessile growth pattern being associated with worse outcome [107, 108] (LE: 3). Concomitant CIS in organ-confined UTUC, and a history of bladder CIS are associated with a higher risk of disease recurrence and cancer-specific mortality [109-111] (LE: 3). Similar to lower tract UC, concomitant CIS is an independent predictor of worse outcomes in organ-confined disease [112].

6.2 Molecular markers

Several studies have investigated the prognostic impact of markers related to cell adhesion (E-cadherin and CD24), cell differentiation (Snail and epidermal growth factor receptor), angiogenesis (hypoxia-inducible factor-1 α and metalloproteinases), cell proliferation (Ki67), epithelial-mesenchymal transition (Snail), mitosis (Aurora-A), apoptosis (Bcl-2 and survivin), vascular invasion (RON), c-met protein (MET) and mTOR pathway [21, 73, 113-117]. Microsatellite instability (MSI) is an independent molecular prognostic marker [118] and can help detect germline mutations and hereditary cancers [18].

The rarity of UTUC means that the main limitations of the above studies were their retrospective nature and small sample size. None of the markers have fulfilled the criteria necessary to support their introduction in daily clinical decision-making.

6.3 Predictive tools

Accurate predictive tools are rare for UTUC. There are two models in a pre-operative setting: one in locally advanced cancer that can guide the extent of LND at the time of RNU [119]; and one for selection of non-organ-confined UTUC likely to benefit from RNU [120]. Four nomograms are available predicting survival rates post-operatively, based on standard pathological features [121-125].

6.4 Bladder recurrence

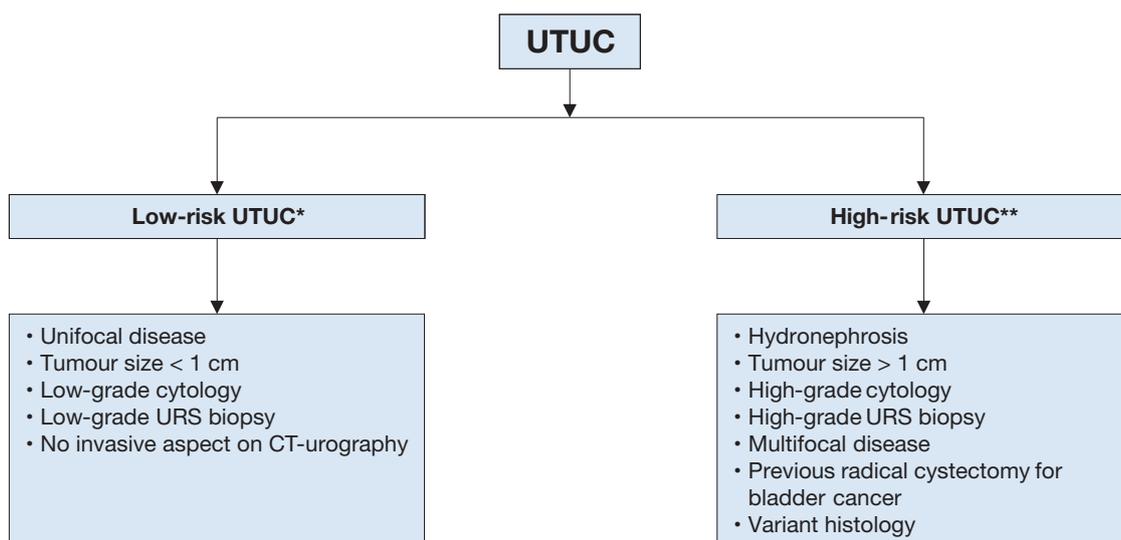

A recent meta-analysis of available data has identified significant predictors of bladder recurrence after RNU [12] (LE: 3). Three categories of predictors of increased risk for bladder recurrence were identified:

- patient-specific factors such as (male gender, previous bladder cancer, pre-operative chronic kidney disease);
- tumour-specific factors such as (positive pre-operative urinary cytology, ureteral location, multifocality, invasive pT stage, necrosis);
- treatment-specific factors such as (laparoscopic approach, extravesical bladder cuff removal, positive surgical margins) [12].

6.5 Risk stratification

As tumour stage is difficult to assert clinically in UTUC, It is useful to 'risk stratify' UTUC between low- and high-risk tumours to identify those that are more suitable for kidney-sparing treatment rather than radical extirpative surgery [126, 127] (Figure 6.2).

Figure 6.2: Pre-intervention risk stratification of upper tract urothelial carcinoma

*All of these factors need to be present

** Any of these factors need to be present

CTU = computed tomography urography; URS = ureterorenoscopy.

6.6 Summary of evidence and guidelines for prognosis

Summary of evidence	LE
Age, sex and ethnicity are no longer considered as independent prognostic factors.	3
The primary recognised post-operative prognostic factors are tumour stage and grade, extranodal extension and lymphovascular invasion.	3

Recommendations	LE	GR
Use microsatellite instability as an independent molecular prognostic marker to help detect germline mutations and hereditary cancers.	3	C
Use the American Society of Anesthesiologists score to assess cancer-specific survival following surgery.	3	C

7. DISEASE MANAGEMENT

7.1 Localised disease

7.1.1 Kidney-sparing surgery

Kidney-sparing surgery (KSS) for low-risk UTUC (Section 7.1.1.4) allows sparing the morbidity associated with radical surgery, without compromising oncological outcomes and kidney function [128]. In low-risk cancers it is the primary approach and survival is similar after KSS versus RNU [129]. This option should therefore be discussed in all low-risk cases, irrespective of the status of the contralateral kidney [21, 130, 131]. In high-risk tumours it can be considered in imperative cases (i.e. renal insufficiency or solitary functional kidney).

7.1.1.1 Ureteroscopy

Endoscopic ablation can be considered in patients with clinically low-risk cancer in the following situations [132, 133]:

- laser generator [134] and pliers are available for biopsies [133, 135] (LE: 3);
- in case a flexible ureteroscope is available (rather than a rigid ureteroscope);
- the patient is informed of the need for closer, more stringent, surveillance;
- complete tumour resection can be achieved.

Nevertheless, a risk of under-staging and under-grading remains with endoscopic management.

7.1.1.2 Percutaneous access

Percutaneous management can be considered for low-risk UTUC in the renal cavities [21, 133, 136] (LE: 3). This may be offered for low-risk tumours in the lower caliceal system that are inaccessible or difficult to manage by flexible ureteroscopy. However, this approach is being used less due to the availability of improved materials and advances in distal-tip deflection of recent ureteroscopes [21, 133, 136].

7.1.1.3 Surgical open approach

Segmental ureteral resection with wide margins provides adequate pathological specimens for staging and grading, while preserving the ipsilateral kidney. A lymphadenectomy can also be achieved during segmental ureteral resection.

Complete distal ureterectomy with neocystostomy are indicated for low-risk tumours in the distal ureter that cannot be removed completely endoscopically, and for high-risk tumours when kidney-sparing surgery for renal function preservation is necessary [21, 137, 138] (LE: 3).

Segmental resection of the iliac and lumbar ureter is associated with higher failure rates than for the distal pelvic ureter [21, 137, 138] (LE: 3).

Partial pyelectomy or partial nephrectomy is almost never indicated. Open resection of tumours of the renal pelvis or calices has almost disappeared.

7.1.1.4 Guidelines for kidney-sparing management of upper tract urothelial carcinoma

Recommendations	GR
Offer kidney-sparing management as primary treatment option to patients with low-risk tumour and two functional kidneys.	C
Offer kidney-sparing management in patients with solitary kidney and/or impaired renal function, providing it will not compromise the oncological outcome. This decision will have to be made on a case-by-case basis, engaging the patient in a shared decision-making process.	C
Offer a kidney-sparing approach in high-risk cancers for distal ureteral tumours and in imperative cases (solitary kidney and/or impaired renal function).	C
Use a laser for endoscopic treatment of upper tract urothelial carcinoma.	C

7.1.1.5 Adjuvant topical agents

The antegrade instillation of bacillus Calmette-Guérin (BCG) vaccine or mitomycin C in the upper urinary tract by percutaneous nephrostomy via a three-valve system open at 20 cm (after complete tumour eradication) is feasible after kidney-sparing management or for treatment of CIS [139] (LE: 3). Retrograde instillation through a ureteric catheter is also used. The reflux obtained from a double-J stent has been used, but is not advisable since it often does not reach the renal pelvis [140].

7.1.2 Radical nephroureterectomy

Open RNU with bladder cuff excision is the standard treatment for high-risk UTUC, regardless of tumour location [15] (LE: 3). Radical nephroureterectomy must comply with oncological principles, that is preventing tumour seeding by avoidance of entry into the urinary tract during resection [15].

Resection of the distal ureter and its orifice is performed because there is a considerable risk of tumour recurrence in this area. After removal of the proximal ureter, it is difficult to image or approach it by endoscopy [21, 137, 141].

Several techniques have been considered to simplify distal ureter resection, including pluck technique, stripping, transurethral resection of the intramural ureter, and intussusception [13, 21, 141]. Except for ureteral stripping, none of these techniques is inferior to bladder cuff excision [75-77, 83] (LE: 3).

7.1.2.1 Laparoscopic radical nephroureterectomy

Retroperitoneal metastatic dissemination and metastasis along the trocar pathway following manipulation of large tumours in a pneumoperitoneal environment have been reported in few cases [142, 143].

Several precautions may lower the risk of tumour spillage:

- avoid entering the urinary tract;
- avoid direct contact between instruments and the tumour;
- laparoscopic RNU must take place in a closed system. Avoid morcellation of the tumour and use an endobag for tumour extraction;
- the kidney and ureter must be removed *en-bloc* with the bladder cuff;
- invasive or large (T3/T4 and/or N+/M+) tumours are contraindications for laparoscopic RNU until proven otherwise.

Laparoscopic RNU is safe in experienced hands when adhering to strict oncologic principles. There is a tendency towards equivalent oncological outcomes after laparoscopic or open RNU [21, 143-147] (LE: 3).

Only one prospective randomised study has shown that laparoscopic RNU is not inferior to open RNU for non-invasive UTUC. In contrast, oncological outcomes were in favour of the open approach in pT3 and/or high-grade tumours [148] (LE: 2). Oncological outcomes after RNU have not changed significantly over the past three decades despite staging and refinements in staging and surgical technique [149] (LE: 3). A robot-assisted laparoscopic approach can be considered, but solid data are still lacking [150].

7.1.2.2 Lymph node dissection

The anatomic sites of lymph node drainage have not been clearly defined yet. The use of a LND template is likely to have a greater impact on patient survival than the number of removed lymph nodes [134].

Lymph node dissection appears to be unnecessary in cases of TaT1 UTUC because lymph node retrieval is reported in only 2.2% of T1 versus 16% of pT2-4 tumours [98]. An increase in the probability of lymph-node-positive disease is related to pT classification [100]. However, it is likely that the true rate of node-positive disease has been under-reported because these data are retrospective.

Despite available studies evaluating templates to date, it is not possible to standardise indication

or extent of LND [151, 152]. Lymph node dissection can be achieved following lymphatic drainage as follows: LND on the side of the affected ureter, retroperitoneal LND for higher ureteral tumour and/or tumour of the renal pelvis (i.e. right side: border vena cava or right side of the aorta; and left side: border aorta) [21, 98].

7.1.2.3 Adjuvant bladder instillation

The rate of bladder recurrence after RNU for UTUC is 22-47% [12, 153]. Two prospective randomised trials have demonstrated that a single post-operative dose of intravesical chemotherapy (mitomycin C, pirarubicin) immediately after surgery reduces the risk of bladder tumour recurrence within the first year post-RNU [154-156] (LE: 1b).

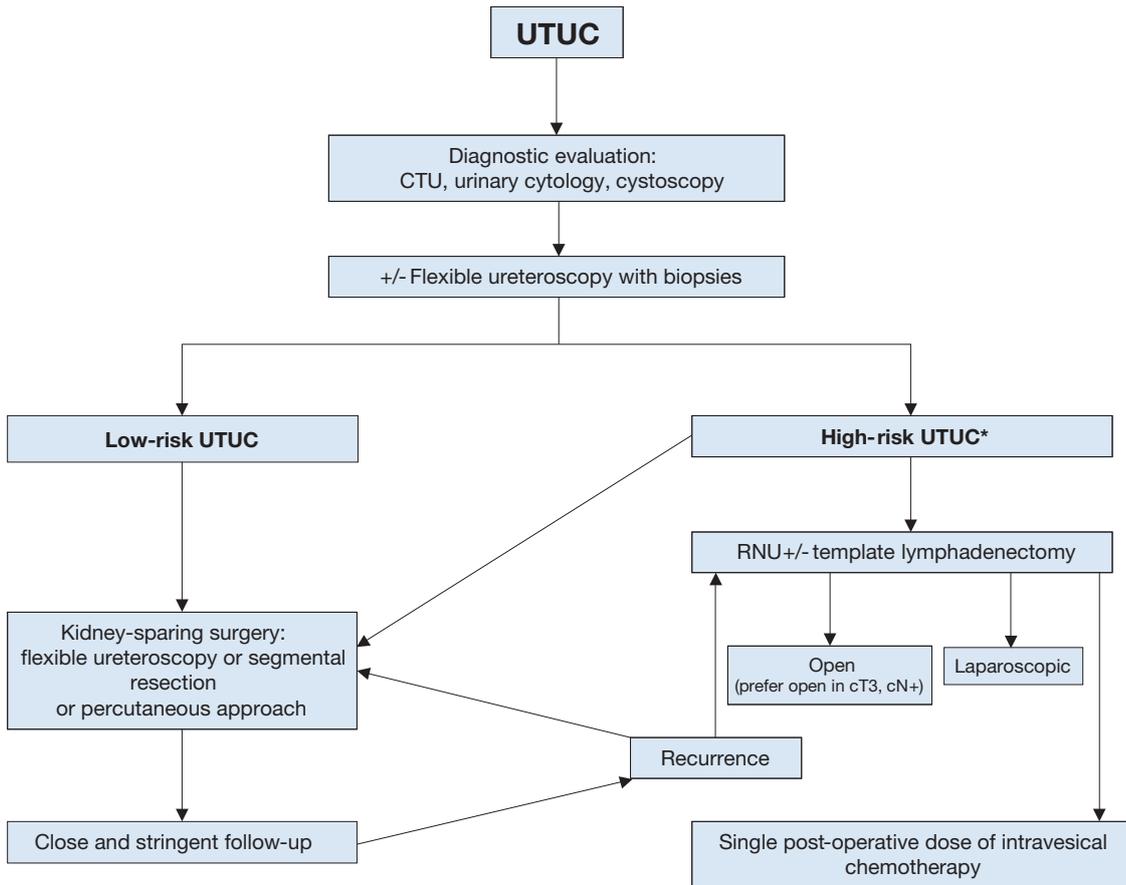

7.1.2.4 Summary of evidence and guidelines for radical nephroureterectomy

Summary of evidence	LE
Radical nephroureterectomy is the standard in high-risk upper tract urothelial carcinoma, regardless of tumour location.	2
Open and laparoscopic approaches have equivalent efficacy and safety in T1-2/N0 upper tract urothelial carcinoma.	2

Recommendations	GR
Perform radical nephroureterectomy in the following situations: <ul style="list-style-type: none"> suspicion of infiltrating upper tract urothelial carcinoma on imaging; high-grade tumour (urinary cytology); multifocality (with two functional kidneys); non-invasive but large (> 1 cm) upper tract urothelial carcinoma. 	B
Technical steps of radical nephroureterectomy:	
Remove the bladder cuff.	A
Perform a lymphadenectomy in invasive upper tract urothelial carcinoma.	C
Offer a post-operative bladder instillation to lower the bladder recurrence rate.	B

Management is outlined in Figures 7.1 and Figure 7.2.

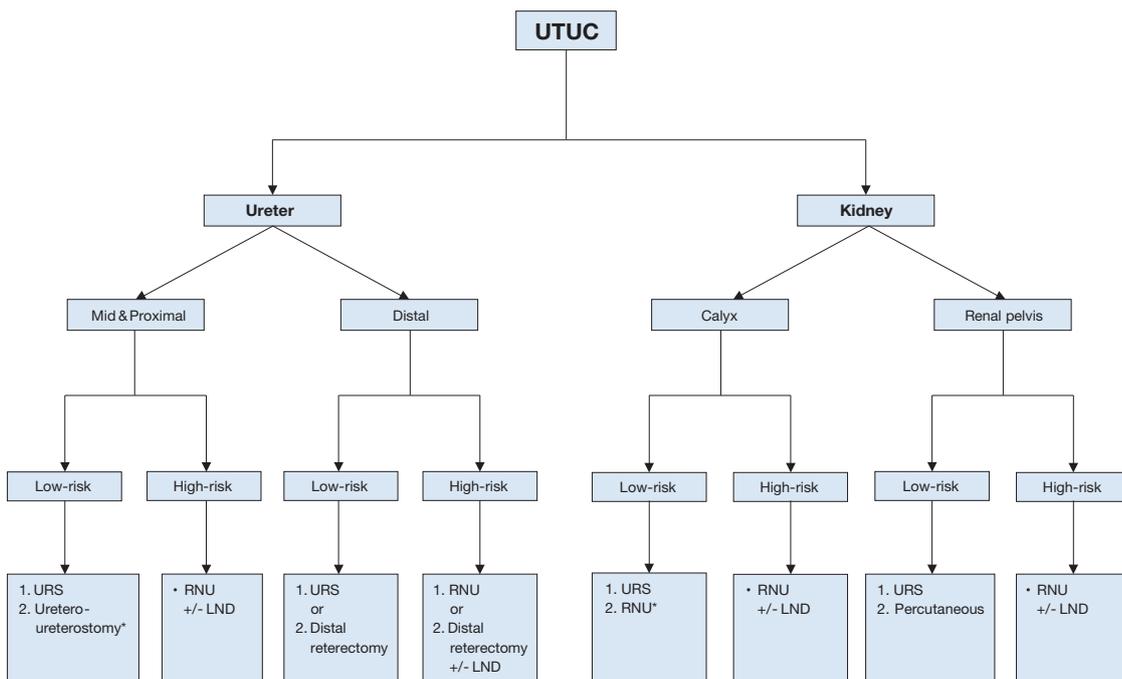

Figure 7.1: Proposed flowchart for the management of localised upper tract urothelial carcinoma

CTU = computed tomography urography; RNU = radical nephroureterectomy.

*In patients with a solitary kidney, consider a more conservative approach.

Figure 7.2: Surgical treatment according to location and risk status

1. First treatment option

2. Secondary treatment option

*In case not amendable to endoscopic management.

7.2 Advanced disease

7.2.1 Radical nephroureterectomy

There is no oncologic benefit for RNU in patients with metastatic UTUC except for palliative considerations [15, 100] (LE: 3).

7.2.2 Systemic chemotherapy

Extrapolating from the bladder cancer literature and small, single centre UTUC studies, platinum-based combination chemotherapy is expected to be efficacious in UTUC. However, there are currently insufficient data upon which to base recommendations.

There are several platinum-based regimens [157], but not all patients can receive adjuvant chemotherapy because of comorbidities and impaired renal function after radical surgery. Chemotherapy-related toxicity, particularly nephrotoxicity from platinum derivatives, may significantly affect survival in patients with post-operative renal dysfunction [158, 159].

There were no adverse effects of neoadjuvant chemotherapy for UTUC in the only study published to date [160], although survival data need to mature and longer follow-up is awaited. Adjuvant chemotherapy can achieve a recurrence-free rate of < 50% [161, 162].

After a recent comprehensive search of studies examining the role of peri-operative chemotherapy for UTUC, there appears to be an overall survival and disease-free survival benefit for cisplatin-based adjuvant chemotherapy [163] (LE: 3). However, there are currently insufficient data to base recommendations on until further evidence from an ongoing prospective trial is available [164].

7.2.3 Radiotherapy

The role of adjuvant radiotherapy is not well defined, neither alone, nor in combination with chemotherapy [21, 165] (LE: 3). It may be of benefit in terms of loco-regional and bladder control in selected patients but data are too scarce to give recommendations.

7.2.4 Summary of evidence and guideline for advanced disease

Summary of evidence	LE
Peri-operative systemic cisplatin-based chemotherapy may provide a survival benefit.	3

Recommendation	LE	GR
In case chemotherapy is offered, a neoadjuvant approach is recommended, as the renal function will decrease after radical nephroureterectomy.	3	C

8. FOLLOW-UP

The risk of disease recurrence and death evolves in the follow-up period after surgery and is less likely with time [166, 167]. Stringent follow-up (Section 8.1) is mandatory to detect metachronous bladder tumours [13], local recurrence, and distant metastases. When RNU is performed, local recurrence is rare and the risk of distant metastases is directly related to the risk factors listed previously.

Surveillance regimens are based on cystoscopy and urinary cytology for > 5 years [11-13]. Bladder recurrence is not a distant recurrence [12]. When kidney-sparing surgery is performed, the ipsilateral UUT requires careful follow-up due to the high risk of disease recurrence [130, 135, 168]. Despite endourological improvements, follow-up after kidney-sparing surgery is difficult; frequent and repeated endoscopic procedures are mandatory. As done in bladder cancer, a second look has been proposed after KSS but is not yet routine practice [169].

8.1 Summary of evidence and guidelines for follow-up of upper tract urothelial carcinoma patients after initial treatment

Summary of evidence	LE
Follow-up is more frequent and more strict in patients who have undergone kidney-sparing treatment compared to radical nephroureterectomy.	3

Recommendations	GR
After radical nephroureterectomy, > five years	
<i>Non-invasive tumour</i>	
Perform cystoscopy/urinary cytology at three months, and then annually.	C
Perform computed tomography urography every year.	C
<i>Invasive tumour</i>	
Perform cystoscopy/urinary cytology at three months, and then annually.	C
Perform computed tomography urography every six months for two years, and then annually.	C
After kidney-sparing management, > five years	
Perform urinary cytology and computed tomography urography at three and six months, and then annually.	C
Perform cystoscopy, ureteroscopy and cytology <i>in situ</i> at three and six months, and then every six months for two years, and then annually.	C

10. CONFLICT OF INTEREST

All members of the Non-Muscle-Invasive Bladder Cancer Guidelines working panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website: <http://uroweb.org/guideline/upper-urinary-tract-urothelial-cell-carcinoma/>. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

EAU Guidelines on Muscle-invasive and Metastatic Bladder Cancer

M. Rouanne, Y. Neuzillet, E. Veskimäe

TABLE OF CONTENTS	PAGE
1. INTRODUCTION	5
1.1 Aims and scope	5
1.2 Panel Composition	5
1.3 Available publications	5
1.4 Publication history and summary of changes	5
1.4.1 Publication history	5
1.4.2 Summary of changes	5
1.4.2.1 Change in summary of evidence	5
2. METHODS	6
2.1 Data identification	6
2.2 Review	6
2.3 Future goals	6
3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY	6
3.1 Epidemiology	6
3.2 Aetiology	6
3.2.1 Tobacco smoking	6
3.2.2 Occupational exposure to chemicals	7
3.2.3 Radiotherapy	7
3.2.4 Dietary factors	7
3.2.5 Bladder schistosomiasis and chronic urinary tract infection	7
3.2.6 Gender	7
3.2.7 Genetic factors	8
3.2.8 Summary of evidence and recommendations for epidemiology and risk factors	8
3.3 Pathology	8
3.3.1 Handling of transurethral resection and cystectomy specimens	8
3.3.2 Pathology of muscle-invasive bladder cancer	9
3.3.3 Recommendations for the assessment of tumour specimens	9
4. STAGING AND CLASSIFICATION SYSTEMS	9
4.1 Pathological staging	9
4.2 Tumour, node, metastasis classification	9
5. DIAGNOSTIC EVALUATION	10
5.1 Primary diagnosis	10
5.1.1 Symptoms	10
5.1.2 Physical examination	10
5.1.3 Bladder imaging	10
5.1.4 Urinary cytology and urinary markers	10
5.1.5 Cystoscopy	11
5.1.6 Transurethral resection of invasive bladder tumours	11
5.1.7 Second resection	11
5.1.8 Concomitant prostate cancer	11
5.1.9 Summary of evidence and specific recommendations for the primary assessment of presumably invasive bladder tumours	12
5.2 Imaging for staging of MIBC	12
5.2.1 Local staging of MIBC	12
5.2.1.1 MRI for local staging of invasive bladder cancer	12
5.2.1.2 CT imaging for local staging of MIBC	12
5.2.2 Imaging of lymph nodes in MIBC	13
5.2.3 Upper urinary tract urothelial carcinoma	13
5.2.4 Distant metastases at sites other than lymph nodes	13
5.2.5 Future developments	13
5.2.6 Summary of evidence and recommendations for staging in muscle-invasive bladder cancer	13

6.	PROGNOSIS	14
6.1	Introduction	14
6.2	MIBC and comorbidity	14
6.2.1	Evaluation of comorbidity	14
6.2.2	Comorbidity scales, anaesthetic risk classification and geriatric assessment	14
6.2.3	Summary of evidence and recommendations for comorbidity scales	15
6.2.4	Prognostic markers	16
6.2.4.1	Tumour location	16
6.2.4.2	Molecular markers	16
7.	DISEASE MANAGEMENT	16
7.1	Treatment failure of non-muscle invasive bladder cancer	16
7.1.1	High-risk non-muscle-invasive urothelial carcinoma	16
7.1.2	Recommendations for treatment failure of non-muscle-invasive bladder cancer	17
7.2	Neoadjuvant chemotherapy	17
7.2.1	Introduction	17
7.2.2	The role of imaging and biomarkers to identify responders	18
7.2.3	Summary of available data	18
7.2.4	Summary of evidence and recommendations for neoadjuvant chemotherapy	19
7.3	Pre- and post-operative radiotherapy in muscle-invasive bladder cancer	19
7.3.1	Post-operative radiotherapy	19
7.3.2	Pre-operative radiotherapy	19
7.3.2.1	Retrospective studies	19
7.3.2.2	Randomised studies	19
7.3.3	Summary of evidence and recommendations for pre- and post-operative radiotherapy	20
7.4	Radical surgery and urinary diversion	20
7.4.1	Removal of the tumour-bearing bladder	20
7.4.1.1	Introduction	20
7.4.2	Timing and delay of cystectomy	20
7.4.2.1	Indications	20
7.4.3	Radical cystectomy: technique and extent	21
7.4.3.1	Pelvic organ preservation techniques in men: oncological and functional outcomes	21
7.4.3.1.1	Summary of evidence and recommendations for sexual-preserving techniques in men	22
7.4.3.2	Pelvic organ preservation techniques in women: oncological and functional outcomes	23
7.4.3.2.1	Summary of evidence and recommendations for sexual-preserving techniques in women	23
7.4.3.3	Laparoscopic/robotic-assisted laparoscopic cystectomy	23
7.4.3.3.1	Summary of evidence and recommendations for laparoscopic/robotic-assisted laparoscopic cystectomy	25
7.4.4	Urinary diversion after radical cystectomy	25
7.4.4.1	Preparations for surgery	25
7.4.4.2	Patient selection for orthotopic diversion	26

1. INTRODUCTION

1.1 Aims and scope

The European Association of Urology (EAU) Guidelines Panel for Muscle-invasive and Metastatic Bladder Cancer (MIBC) have prepared these guidelines to help urologists assess the evidence-based management of MIBC and to incorporate guideline recommendations into their clinical practice.

Separate EAU guidelines documents are available addressing upper urinary tract tumours [1], non-muscle-invasive bladder cancer (TaT1 and carcinoma *in situ*) [2], and primary urethral carcinomas [3].

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel Composition

The EAU Guidelines Panel consists of an international multidisciplinary group of clinicians, including urologists, a pathologist, a radiologist and an oncologist.

All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website Uroweb: <http://uroweb.org/guideline/bladder-cancermuscle-invasive-and-metastatic/?type=panel>.

1.3 Available publications

A quick reference document (Pocket Guidelines) is available, both in print and in a number of versions for mobile devices. These are abridged versions which may require consultation together with the full text version.

Several scientific publications are available (the most recent paper dating back to 2016 [4]), as are a number of translations of all versions of the EAU MIBC Guidelines. All documents are accessible through the EAU website: <http://uroweb.org/guideline/bladder-cancer-muscle-invasive-and-metastatic/>.

1.4 Publication history and summary of changes

1.4.1 Publication history

The EAU published its first guidelines on bladder cancer in 2000. This document covered both superficial (non-muscle-invasive) bladder cancer and MIBC. Since these conditions require different treatment strategies, it was decided to give each condition its own guidelines, resulting in the first publication of the MIBC Guidelines in 2004. This 2017 document presents a limited update of the 2016 version.

1.4.2 Summary of changes

New relevant references have been identified through a structured assessment of the literature and incorporated in the various chapters of the 2017 EAU NMIBC Guidelines.

Key changes in the 2017 print are:

- Section 3.2.6 Gender - This section has been expanded with additional data.
- Section 5.1.4 Urinary cytology and urinary markers - This section has been expanded with additional data.
- Section 6.2.4 Prognostic markers - A new section has been included.
- Section 7.4.4.1 Preparations for surgery - A new section on pain management has been included as well as additional data on estimated glomerular filtration rate.
- Section 7.4.4.2.1 Ureterocutaneostomy - This section has been expanded with additional data.
- Table 7.6 Management of neobladder morbidity - Additional information has been added.
- Section 7.8.10 Role of immunotherapy - This is a new section.

1.4.2.1 Change in summary of evidence

7.8.11 Summary of evidence and recommendations for metastatic disease

7.8.11 Summary of evidence for metastatic disease	LE
PD-L1 inhibitor atezolizumab has been FDA approved for patients that have progressed during or after previous platinum-based chemotherapy based on the results of a phase-II trial.	2a

2. METHODS

2.1 Data identification

For the 2017 MIBC Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature.

A broad and comprehensive literature search, covering all sections of the MIBC Guideline was performed. The search was limited to English language publications. Databases searched included Medline, EMBASE and the Cochrane Libraries, covering a time frame between July 1st 2015 and April 5th 2016. A total of 2,298 unique records were identified, retrieved and screened for relevance. A detailed search strategy is available online: <http://uroweb.org/guideline/bladder-cancer-muscle-invasive-andmetastatic/?type=appendices-publications>.

References used in this text are assessed according to their level of evidence (LE) and Guidelines are given a grade of recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [5]. Additional methodology information can be found in the general Methodology section of this print, and online at the EAU website: <http://uroweb.org/guidelines/>.

A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review

No separate peer-review was done for the 2017 print of the MIBC Guidelines.

2.3 Future goals

Topics considered for inclusion in the 2018 update of the MIBC Guidelines:

- Diagnostics - haematuria

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Bladder cancer (BC) is the 7th most commonly diagnosed cancer in the male population worldwide, whilst it drops to 11th when both genders are considered [6]. The worldwide age-standardised incidence rate (per 100,000 person/years) is 9.0 for men and 2.2 for women [6]. In the European Union, the age-standardised incidence rate is 19.1 for men and 4.0 for women [6, 7]. In Europe, the highest age-standardised incidence rate has been reported in Belgium (31 in men and 6.2 in women) and the lowest in Finland (18.1 in men and 4.3 in women) [6, 7].

Worldwide, the BC age-standardised mortality rate (per 100,000 person/years) was 3.2 for men vs. 0.9 for women in 2012 [6, 7]. Bladder cancer incidence and mortality rates vary across countries due to differences in risk factors, detection and diagnostic practices, and availability of treatments. The variations are, however, also partly caused by the different methodologies used in the studies and the quality of data collection [8, 9].

The incidence and mortality of BC has decreased in some registries, possibly reflecting the decreased impact of causative agents [9, 10].

Approximately 75% of patients with BC present with a disease confined to the mucosa (stage Ta, carcinoma *in situ* [CIS]) or submucosa (stage T1). In younger patients (< 40) this percentage is even higher [11]. Patients with TaT1 and CIS have a high prevalence due to long-term survival in many cases and lower risk of cancer-specific mortality compared to T2-4 tumours [7, 8, 12].

3.2 Aetiology

3.2.1 Tobacco smoking

Tobacco smoking is the most well-established risk factor for BC, causing 50-65% of male cases and 20-30% of female cases [13]. A causal relationship has been established between exposure to tobacco and cancer in studies in which chance, bias and confounding can be discounted with reasonable confidence [14].

The incidence of BC is directly related to the duration of smoking and the number of cigarettes smoked per day [15]. A meta-analysis looked at 216 observational studies on cigarette smoking and cancer published between 1961 and 2003, and the pooled risk estimates for BC demonstrated a significant association for both current

and former smokers [16]. Recently, an increase in risk estimates for current smokers relative to never smokers has been described suggesting this could be due to changes in cigarette composition [13]. An immediate decrease in the risk of BC was observed in those who stopped smoking. The reduction was about 40% within one to four years of quitting smoking and 60% after 25 years of cessation [15]. Encouraging people to stop smoking would result in the incidence of BC decreasing equally in men and women.

3.2.2 **Occupational exposure to chemicals**

Occupational exposure is the second most important risk factor for BC. Work-related cases accounted for 20-25% of all BC cases in several series and it is likely to occur in occupations in which dyes, rubbers, textiles, paints, leathers, and chemicals are used [17]. The risk of BC due to occupational exposure to carcinogenic aromatic amines is significantly greater after ten years or more of exposure; the mean latency period usually exceeds 30 years [18, 19]. Population-based studies established the occupational attribution for BC in men to be 7.1%, while no such attribution was discernible for women [8, 20].

3.2.3 **Radiotherapy**

Increased rates of secondary bladder malignancies have been reported after external-beam radiotherapy (EBRT) for gynaecological malignancies, with relative risks of 2-4 [21]. In a population-based cohort study, the standardised incidence ratios for BC developing after radical prostatectomy (RP), EBRT, brachytherapy (BT), and EBRT-BT were 0.99, 1.42, 1.10, and 1.39, respectively, in comparison with the general U.S. population [22].

It has recently been proposed that patients who have received radiotherapy (RT) for prostate cancer with modern modalities such as intensity-modulated radiotherapy (IMRT) may have lower rates of in-field bladder- and rectal secondary malignancies [23]. Nevertheless, since longer follow-up data are not yet available, and as BC requires a long period to develop, patients treated with radiation and with a long life-expectancy are at a higher risk of developing BC [23].

3.2.4 **Dietary factors**

Several dietary factors have been considered to be related to BC; however, the links remain controversial. The European Prospective Investigation into Cancer and Nutrition (EPIC) study is an on-going multicentre cohort study designed to examine the association between diet, lifestyle, environmental factors and cancer. They found no links between BC and fluid intake, red meat, vegetable and fruit consumption, and only recently they have described an inverse association between dietary intake of flavonols and lignans and the risk of BC, in particular aggressive tumours [24].

3.2.5 **Bladder schistosomiasis and chronic urinary tract infection**

Bladder schistosomiasis (bilharzia) is the second most common parasitic infection after malaria, with about 600 million people exposed to infection in Africa, Asia, South America, and the Caribbean [25]. There is a well-established relationship between schistosomiasis and urothelial carcinoma of the bladder, which can progress to squamous cell carcinoma (SCC), however, a better control of the disease is decreasing the incidence of SCC of the bladder in endemic zones such as Egypt [26, 27].

Similarly, invasive SCC has been linked to the presence of chronic urinary tract infection (UTI) distinct from schistosomiasis. A direct association between BC and UTIs has been observed in several case-control studies, which have reported a two-fold increased risk of BC in patients with recurrent UTIs in some series. However, some of these results may be attributed to recall bias [28].

3.2.6 **Gender**

Although men are more likely to develop BC than women, women present with more advanced disease and have worse survival rates. A meta-analysis including nearly 28,000 patients shows that female gender was associated with a worse survival outcome (HR: 1.20; 95% CI: 1.09-1.32) compared to male gender after radical cystectomy (RC) [29]. This finding had already been presented in a descriptive Nation-Wide Analysis based on 27,773 Austrian patients. After their analysis the authors found that cancer-specific-survival (CSS) was identical for pT1-tumours in both sexes, while women had a worse CSS in both age cohorts (< 70 years and ≥ 70 years) with higher tumour stages [30]. However this higher mortality is questioned once both genders receive the same therapy. In the population-based study from the Ontario Cancer Registry analysing all patients with BC treated with cystectomy or radical RT between 1994 and 2008, no differences in overall survival (OS), mortality and outcomes were found between males and females following radical therapy [31].

A population-based study from the MarketScan databases suggests that a possible reason for worse survival in the female population may be that women experienced longer delays in diagnosis than men, as the differential diagnosis in women includes diseases that are more prevalent than BC [32].

Furthermore, differences in the gender prevalence of BC may be due to other factors besides tobacco and chemical exposure. In a large prospective cohort study, post-menopausal status was associated

with an increase in BC risk, even after adjustment for smoking status. This result suggests that the differences in oestrogen and androgen levels between men and women may be responsible for some of the difference in the gender prevalence of BC [33-35].

3.2.7 Genetic factors

There is growing evidence that genetic susceptibility factors and family association may influence the incidence of BC. The relationship between family history of cancer and risk of BC was examined in a Spanish BC study showing that family history of cancer in first-degree relatives was associated with an increased risk of BC; the association being stronger among younger patients. Shared environmental exposure was recognised as a potentially confounding factor [36]. Recent studies detected genetic susceptibility with independent loci, which are associated with BC risk [37].

Genome-wide association studies (GWAS) of BC identified several susceptibility loci associated with BC risk [38, 39].

3.2.8 Summary of evidence and recommendations for epidemiology and risk factors

Summary of evidence	LE
Worldwide, bladder cancer is the 11 th most commonly diagnosed cancer.	2a
Several risk factors connected with the risk of bladder cancer diagnosis have been identified.	3
Active and passive tobacco smoking continues to be the main risk factor, while the exposure-related incidence is decreasing.	2a
The increased risk of developing bladder cancer in patients undergoing external-beam radiotherapy (EBRT), brachytherapy (BT), or a combination of EBRT and BT, must be taken into account during patient follow-up. As bladder cancer requires time to develop, patients treated with radiation at a young age are at the greatest risk and should be followed up closely.	3

Recommendations	GR
The principal preventable risk factor for MIBC is active and passive smoking.	B
Notwithstanding stricter regulations, workers should be informed about the potential carcinogenic effects of a number of recognised substances, duration of exposure, and latency periods. Protective measures should be recommended.	A

3.3 Pathology

3.3.1 Handling of transurethral resection and cystectomy specimens

In transurethral resection (TUR), a snap frozen specimen from the tumour and normal looking bladder wall should be taken, if possible. Separate specimens should be taken from the superficial and deep areas of the tumour and sent to the pathology laboratory separately, in case the outcome will impact on treatment decisions. If random biopsies of the flat mucosa are taken, each biopsy specimen of the flat mucosa should also be sent separately.

In RC, bladder fixation must be carried out as soon as possible. The pathologist must open the specimen from the urethra to the bladder dome and fix the specimen. In some circumstances this procedure can also be performed by the urologist. In a female cystectomy specimen, the length of the urethral segment removed *en bloc* with the specimen should be checked, preferably by the urological surgeon [40].

Specimen handling should follow the general rules as published by a collaborative group of pathologists and urologists [41, 42]. It must be stressed that it may be very difficult to confirm the presence of a neoplastic lesion using gross examination of the cystectomy specimen after TUR or chemotherapy, so the entire retracted or ulcerated area should be included.

It is compulsory to study the urethra, the ureters, the prostate in men and the radial margins [43]. In urethra-sparing cystectomy; the level of urethral dissection, completeness of the prostate, specifically at the apex (in men), and the inclusion of the entire bladder neck and amount of adjacent urethra, uterus and vaginal top (in women) should be inked and documented.

All lymph node (LN) specimens should be provided in their totality, in clearly labelled containers. In case of doubt, or adipose differentiation of the LN, the entire specimen is to be included. LNs should be counted and measured on slides, capsular extension and percentage of LN invasion should be reported as well as vascular embols [44, 45]. In the case of metastatic spread in the perivesical fat without real LN structures (capsule, subcapsular sinus), this localisation should nevertheless be considered as N+.

A meta-analysis indicated that LN density is an independent predictor of clinical outcome (HR OS: 1.45; 95% CI: 1.11-1.90) [46].

Positive margins in the peripelvic fat tissue (soft tissue margins), should be inked by the pathologist for evaluation. Positive margins decrease CSS in cases of pN0M0 urothelial carcinomas [47].

In rare cases, fresh frozen sections may be helpful to determine treatment strategy. A recent study confirmed the reliability of fresh frozen sections of obturator LNs, but further studies are warranted to confirm these results [48].

3.3.2 Pathology of muscle-invasive bladder cancer

In MIBC all cases are high-grade urothelial carcinomas. For this reason, no prognostic information can be provided by grading MIBC [49]. However, identification of some morphological subtypes may be important for prognostic reasons and treatment decisions [50, 51]. Recently, an update of the World Health Organization (WHO) grading was published [52] however, the data presented in these guidelines are based on the 2004 WHO classification [53]. Currently the following differentiations are used:

1. urothelial carcinoma (more than 90% of all cases);
2. urothelial carcinomas with partial squamous and/or glandular differentiation [54, 55];
3. micropapillary and microcystic urothelial carcinoma;
4. nested variant [56] (including large nested variety);
5. lymphoepithelioma;
6. plasmocytoid, giant cell, signet ring, diffuse, undifferentiated;
7. some urothelial carcinomas with trophoblastic differentiation;
8. small-cell carcinomas [57];
9. sarcomatoid carcinomas.

3.3.3 Recommendations for the assessment of tumour specimens

Recommendations	GR
Record the depth of invasion (categories pT2a and pT2b, pT3a and pT3b or pT4).	A*
Record margins with special attention paid to the radial margin, prostate, ureter, urethra and peritoneal fat and uterus and vaginal top.	
Record the number of lymph nodes (LNs) and number of positive LNs.	
Record lymphatic or blood vessel invasion and extranodal extension.	
Record the presence of carcinoma <i>in situ</i> .	

*Upgraded following panel consensus.

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Pathological staging

For staging, the Tumour, Node, Metastasis (TNM) classification (2017, 8th edition) is recommended [58]. Blood and lymphatic vessel invasion and LN infiltration have an independent prognostic significance [59]. It seems that the pN category is closely related to the number of LNs studied by the pathologist [58]. New prognostic markers are under study (see Section 6.2.4 Prognostic Markers).

4.2 Tumour, node, metastasis classification

The TNM classification of malignant tumours is the method most widely used to classify the extent of cancer spread [50-52, 58, 60] (Table 4.1).

Table 4.1: TNM classification of urinary bladder cancer [58]

T - Primary Tumour	
Tx	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Ta	Non-invasive papillary carcinoma
Tis	Carcinoma <i>in situ</i> : “flat tumour”
T1	Tumour invades subepithelial connective tissue
T2	Tumour invades muscle
T2a	Tumour invades superficial muscle (inner half)
T2b	Tumour invades deep muscle (outer half)
T3	Tumour invades perivesical tissue:
T3a	microscopically
T3b	macroscopically (extravesical mass)
T4	Tumour invades any of the following: prostate stroma, seminal vesicles, uterus, vagina, pelvic wall, abdominal wall
T4a	Tumour invades prostate stroma, seminal vesicles, uterus, or vagina
T4b	Tumour invades pelvic wall or abdominal wall
N - Regional Lymph Nodes	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N2	Metastasis in multiple regional lymph nodes in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N3	Metastasis in a common iliac lymph node(s)
M - Distant Metastasis	
M0	No distant metastasis
M1a	Non-regional lymph nodes
M1b	Other distant metastasis

5. DIAGNOSTIC EVALUATION

5.1 Primary diagnosis

5.1.1 Symptoms

Painless haematuria is the most common presenting complaint. Other clinical signs include urgency, dysuria, increased frequency, and in more advanced tumours, pelvic pain and symptoms related to urinary tract obstruction.

5.1.2 Physical examination

Physical examination should include rectal and vaginal bimanual palpation. A palpable pelvic mass can be found in patients with locally advanced tumours. In addition, bimanual examination under anaesthesia should be carried out before and after transurethral resection of the bladder (TURB), to assess whether there is a palpable mass or if the tumour is fixed to the pelvic wall [61, 62]. However, considering the discrepancy between bimanual examination and pT stage after cystectomy (11% clinical overstaging and 31% clinical understaging), some caution is suggested with the interpretation of bimanual examination [63].

5.1.3 Bladder imaging

Patients with a bladder mass identified by any diagnostic imaging technique should undergo cystoscopy, biopsy and/or resection for histopathological diagnosis and staging.

5.1.4 Urinary cytology and urinary markers

Examination of voided urine or bladder washings for exfoliated cancer cells has high sensitivity in high-grade tumours (LE: 3) and is a useful indicator in cases of high-grade malignancy or CIS.

However, positive urinary cytology may originate from a urothelial tumour located anywhere in the urinary tract. Evaluation of cytology specimens can be hampered by low cellular yield, UTIs, stones or

intravesical instillations, but for experienced readers, specificity exceeds 90% [64, 65] (LE: 2b). However, negative cytology does not exclude a tumour. There is no known urinary marker specific for the diagnosis of invasive BC [66].

A standardised reporting system redefining urinary cytology diagnostic categories was published in 2016 by the Paris Working Group [67]:

- Adequacy of urine specimens (Adequacy);
- Negative for high-grade urothelial carcinoma (Negative);
- Atypical urothelial cells (AUC);
- Suspicious for high-grade urothelial carcinoma (Suspicious);
- High-grade urothelial carcinoma (HGUC);
- Low-grade urothelial neoplasia (LGUN).

5.1.5 **Cystoscopy**

Ultimately, the diagnosis of BC is made by cystoscopy and histological evaluation of resected tissue. In general, cystoscopy is initially performed in the office using a flexible instrument. If a bladder tumour has been visualised unequivocally in earlier imaging studies, such as computed tomography (CT), magnetic resonance imaging (MRI), or ultrasound (US), diagnostic cystoscopy may be omitted and the patient can proceed directly to TURB for histological diagnosis. Currently, there is no evidence for the role of photodynamic diagnosis (PDD) in the standard diagnosis of invasive BC.

A careful description of the cystoscopic findings is necessary. This should include documentation of the site, size, number, and appearance (papillary or solid) of the tumours, as well as a description of any mucosal abnormalities. The use of a bladder diagram is recommended.

The use of PDD could be considered if a T1 high-grade tumour is present, to identify associated CIS. Presence of CIS may lead to a modified treatment plan (see Section 7.1). Photodynamic diagnosis is highly sensitive for the detection of CIS, but in experienced hands, the rate of false-positive results may be similar to that with regular white-light cystoscopy [68].

5.1.6 **Transurethral resection of invasive bladder tumours**

The goal of TURB is to enable histopathological diagnosis and staging, which requires the inclusion of bladder muscle in the resection biopsies.

The strategy of resection depends on the size of the lesion. Small tumours (< 1 cm in diameter) can be resected *en bloc*, where the specimen contains the complete tumour plus a part of the underlying bladder wall including muscle. Larger tumours need to be resected separately in parts, which includes the exophytic part of the tumour, the underlying bladder wall with the detrusor muscle, and the edges of the resection area. At least the deeper part of the resection specimen must be referred to the pathologist in a separate labelled container to enable him/her to make a correct diagnosis. In cases in which RT is considered and CIS is to be excluded, PDD can be used [69].

The involvement of the prostatic urethra and ducts in men with bladder tumours has been reported. The exact risk is not known, but it seems to be higher if the tumour is located on the trigone or bladder neck, in the presence of bladder CIS, and in multiple tumours [70, 71] (LE: 3). Involvement of the prostatic urethra can be determined either at the time of primary TURB or by frozen section during the cystoprostatectomy procedure. A frozen section has a higher negative-predictive value and is more accurate [72-74].

5.1.7 **Second resection**

In the case of high-grade non-muscle-infiltrative tumour, residual disease is observed in 33-53% of patients [75-81]. In order to reduce the risk of understaging [76, 77], a second TURB resection is often required to determine the future treatment strategy.

Diagnosis of urethral tumour before cystectomy or positive urethral frozen section leads to urethrectomy and therefore excludes neobladder reconstruction. If indicated, in males, urethral frozen section has to be performed on the cystoprostatectomy specimen just below the verumontanum bladder neck and on the inferior limits of the bladder neck for females.

5.1.8 **Concomitant prostate cancer**

Prostate cancer is found in 25-46% of patients undergoing cystectomy for BC [82, 83]. The impact on survival is unknown but the impact on surgical treatment is limited.

5.1.9 Summary of evidence and specific recommendations for the primary assessment of presumably invasive bladder tumours

(For general information on the assessment of bladder tumours, see EAU Guidelines on Non-muscle-invasive Bladder Cancer [2]).

Summary of evidence	LE
Currently, treatment decisions cannot be based on molecular markers.	3

Recommendations	GR
During cystoscopy, describe all macroscopic features of the tumour (site, size, number and appearance) and mucosal abnormalities. A bladder diagram is recommended.	C
Take a biopsy of the prostatic urethra for cases of bladder neck tumour, when bladder carcinoma <i>in situ</i> is present or suspected, when there is positive cytology without evidence of tumour in the bladder, or when abnormalities of the prostatic urethra are visible.	C
Take a biopsy at the time of the second resection, if no biopsy was taken during the initial procedure.	C
In women undergoing subsequent orthotopic neobladder construction, obtain procedural information (including histological evaluation) of the bladder neck and urethral margin, either prior to or at the time of cystoscopy.	C
Specify the grade, depth of tumour invasion, and whether the lamina propria and muscle tissue are present in the specimen in the pathological report.	C

5.2 Imaging for staging of MIBC

The treatment and prognosis of MIBC is determined by tumour stage and grade [84, 85]. In clinical practice, CT and MRI are the imaging techniques used. The purpose of using imaging for staging MIBC is to determine prognosis and provide information to assist treatment selection. Tumour staging must be accurate to ensure that the correct choice of treatment is made. Imaging parameters required for staging MIBC are:

- extent of local tumour invasion;
- tumour spread to LNs;
- tumour spread to the upper urinary tract (UUT) and other distant organs (e.g., liver, lungs, bones, peritoneum, pleura, and adrenal glands).

5.2.1 Local staging of MIBC

Both CT and MRI may be used for assessment of local invasion, but they are unable to accurately diagnose microscopic invasion of perivesical fat (T2 vs. T3a) [86]. The principal aim of CT and MRI is therefore to detect T3b disease, or higher.

5.2.1.1 MRI for local staging of invasive bladder cancer

Magnetic resonance imaging has superior soft tissue contrast resolution compared with CT, but poorer spatial resolution. In studies performed before the availability of multidetector CT, MRI was reported as more accurate in local assessment. The accuracy of MRI for primary tumour staging varies from 73% to 96% (mean 85%). These values were 10-33% (mean 19%) higher than those obtained with CT [87]. Dynamic contrast-enhanced (DCE) MRI may help to differentiate bladder tumour from surrounding tissues or evaluate post-biopsy reaction, because enhancement of the tumour occurs earlier than that of the normal bladder wall, due to neovascularisation [88-90].

In 2006, a link was established between the use of gadolinium-based contrast agents and nephrogenic systemic fibrosis (NSF), which may result in fatal or severely debilitating systemic fibrosis. Patients with impaired renal function are at risk of developing NSF and the non-ionic linear gadolinium-based contrast agents should be avoided (gadodiamide, gadopentetate dimeglumine and gadoversetamide). A stable macrocyclic contrast agent should be used (gadobutrol, gadoterate meglumine or gadoteridol). Contrast-enhanced CT using iodinated contrast media should be considered as an alternative [91] (LE: 4).

5.2.1.2 CT imaging for local staging of MIBC

The advantages of CT include high spatial resolution, shorter acquisition time, wider coverage in a single breath hold, and lower susceptibility to variable patient factors. Computed tomography is unable to differentiate between stages from Ta to T3a tumours, but it is useful for detecting invasion into the perivesical fat (T3b) and adjacent organs. The accuracy of CT in determining extravesical tumour extension varies from 55% to 92% [92] and increases with more advanced disease [93].

5.2.2 **Imaging of lymph nodes in MIBC**

Assessment of LN metastases based solely on size is limited by the inability of both CT and MRI to identify metastases in normal-sized or minimally enlarged nodes. The sensitivity for detection of LN metastases is low (48-87%). Specificity is also low because nodal enlargement may be due to benign disease. Overall, CT and MRI show similar results in the detection of LN metastases in a variety of primary pelvic tumours [94-99]. Pelvic nodes > 8 mm and abdominal nodes > 10 mm in maximum short-axis diameter, detected by CT or MRI, should be regarded as pathologically enlarged [100, 101]. Currently, there is no evidence supporting the routine use of positron emission tomography (PET) in the nodal staging of BC, although the method has been evaluated with varying results in small prospective trials [102-105].

5.2.3 **Upper urinary tract urothelial carcinoma**

Excretory-phase CT urography is the imaging technique with the highest diagnostic accuracy for upper urinary tract urothelial carcinoma (UTUC) and has replaced conventional intravenous urography and US as the first-line imaging test for investigating high-risk patients [106]. The sensitivity of CT urography for UTUC is reported to range from 0.67 to 1.0 with a specificity from 0.93 to 0.99, depending on the technique used [107-114]. Attention to technique is therefore important for optimal results.

For UTUC detected by CT urography, a biopsy for histopathological confirmation of diagnosis is recommended to eliminate false-positive results and to provide information regarding the grade of the tumour to aid in the choice of treatment [108, 109, 115-117]. The biopsy is usually performed endoscopically.

5.2.4 **Distant metastases at sites other than lymph nodes**

Prior to any curative treatment, it is essential to evaluate the presence of distant metastases. Computed tomography and MRI are the diagnostic techniques of choice to detect lung [118] and liver metastases [119], respectively. Bone and brain metastases are rare at the time of presentation of invasive BC. A bone scan and additional brain imaging are therefore not routinely indicated unless the patient has specific symptoms or signs to suggest bone or brain metastases [120, 121]. Magnetic resonance imaging is more sensitive and specific for diagnosing bone metastases than bone scintigraphy [122, 123] (LE: 2b).

5.2.5 **Future developments**

Evidence is accruing in the literature suggesting that fluorodeoxyglucose (FDG)-PET/CT might have potential clinical use for staging metastatic BC [124, 125], but there is no consensus as yet. The results of further trials are awaited before a recommendation can be made. Recently, the first study was published showing the superior feasibility of diffusion-weighted imaging (DWI) over T2-weighted and DCE MRI for assessing the therapeutic response to induction chemotherapy against MIBC [126]. The high specificity of DWI indicates that it is useful for accurate prediction of a complete histopathological response, allowing better patient selection for bladder-sparing protocols. Results from prospective studies are awaited.

5.2.6 **Summary of evidence and recommendations for staging in muscle-invasive bladder cancer**

Summary of evidence	LE
Imaging as part of staging in muscle-invasive bladder cancer (MIBC) provides information about prognosis and assists in selection of the most appropriate treatment.	2b
There are currently insufficient data on the use of diffusion-weighted imaging (DWI) and fluorodeoxyglucose- positron emission tomography/computed tomography (FDG-PET/CT) in MIBC to allow a recommendation to be made.	

Recommendations	GR
In patients with confirmed MIBC, use computed tomography (CT) of the chest, abdomen and pelvis as the optimal form of staging. Include excretory-phase CT urography for complete examination of the upper urinary tract.	B
Diagnose upper urinary tract urothelial carcinoma (UTUC) using excretory-phase CT urography rather than magnetic resonance (MR) urography as excretory-phase CT urography has greater diagnostic accuracy and is associated with less cost, and greater patient acceptability.	C
Use MR urography when CT urography is contraindicated for reasons related to contrast administration or radiation dose.	C
Perform endoscopically-guided biopsy for histopathological confirmation of pre-operative diagnosis of UTUC.	C
Use CT or magnetic resonance imaging (MRI) for staging locally advanced or metastatic disease in patients in whom radical treatment is considered.	B
Use CT to diagnose pulmonary metastases. CT and MRI are generally equivalent for diagnosing local disease and distant metastases in the abdomen.	C

6. PROGNOSIS

6.1 Introduction

The treatment and prognosis for MIBC is mainly determined by tumour and nodal stage [85]. The pathological report will inform on histological type, lymphovascular invasion, presence of CIS, positive margins and extranodal extension. In clinical practice, CT and MRI are the imaging techniques used.

6.2 MIBC and comorbidity

Complications related to RC may be directly related to pre-existing comorbidity as well as the surgical procedure, bowel anastomosis, or urinary diversion. A significant body of literature has evaluated the usefulness of age as a prognostic factor for RC [127-129].

Advanced age has been identified as a risk factor for complications of RC, although chronological age is less important than biological age. Other risk factors for morbidity include prior abdominal surgery, extravesical disease, and prior RT [130]. Female gender, an increased body mass index (BMI) and lower pre-operative albumin levels are associated with a higher rate of parastomal hernias [131].

Low pre-operative serum albumin is also associated with impaired wound healing, gastrointestinal complications and a decrease of recurrence-free and OS after RC [132, 133]. Therefore, it could be used as a prognostic biomarker for patients undergoing RC.

6.2.1 Evaluation of comorbidity

Rochon *et al.* have shown that evaluation of comorbidity provides a better indicator of life expectancy in MIBC than patient age [134]. The evaluation helps to identify the medical conditions likely to interfere with, or have an impact on, treatment and the evolution and prognosis of MIBC [135].

The value of assessing overall health before recommending and proceeding with surgery was emphasised by Zietman *et al.*, who have demonstrated an association between comorbidity and adverse pathological and survival outcome following RC [136]. Similar results were found for the impact of comorbidity on cancer-specific and other-cause mortality in a population-based competing risk analysis of > 11,260 patients from the Surveillance, Epidemiology, and End Results (SEER) registries. Age carried the highest risk for other-cause mortality but not for increased cancer-specific death, while the stage of locally advanced tumour was the strongest predictor for decreased CSS [137]. Stratifying elderly patients according to their risk-benefit profile using a multidisciplinary approach will help to select patients most likely to benefit from radical surgery and to optimise treatment outcomes [138]. Unfortunately, most series evaluating RC do not include indices of comorbidity in the patient evaluation.

6.2.2 Comorbidity scales, anaesthetic risk classification and geriatric assessment

A range of comorbidity scales has been developed [139]; six of which have been validated [140-145] (LE: 3). The Charlson Comorbidity Index (CCI) ranges from 0 to 30 according to the importance of comorbidity described at four levels and is calculated by healthcare practitioners based on patients' medical records. The score has been widely studied in patients with BC and found to be an independent prognostic factor for peri-operative mortality [146, 147], overall mortality [148], and cancer-specific mortality [149-152]. Only the age-adjusted version of the CCI was correlated with both cancer-specific and other-cause mortality [153]. The age-

adjusted CCI (Table 6.1) is the most widely used comorbidity index in cancer for estimating long-term survival and is easily calculated [154].

Table 6.1: Calculation of the Charlson Comorbidity Index

Number of points	Conditions
1 point	50-60 years
	Myocardial infarction
	Heart failure
	Peripheral vascular insufficiency
	Cerebrovascular disease
	Dementia
	Chronic lung disease
	Connective tissue disease
	Ulcer disease
	Mild liver disease
	Diabetes
2 points	61-70 years
	Hemiplegia
	Moderate to severe kidney disease
	Diabetes with organ damage
	Tumours of all origins
3 points	71-80 years
	Moderate to severe liver disease
4 points	81-90 years
5 points	> 90 years
6 points	Metastatic solid tumours
	AIDS

Interpretation

Health assessment of oncology patients must be supplemented by measuring their activity level. Extermann *et al.* have shown that there is no correlation between morbidity and competitive activity level [155]. The Eastern Cooperative Oncology Group (ECOG) PS scores and Karnofsky index have been validated to measure patient activity [156] (LE: 3). Performance score is correlated with patient OS after RC [151] and palliative chemotherapy [157-159].

1. Calculate Charlson Comorbidity Score or Index = i
 - a. Add comorbidity score to age score
 - b. Total denoted as 'i' in the Charlson Probability calculation (see below). i = sum of comorbidity score to age score
2. Calculate Charlson Probability (10-year mortality = Y)
 - a. Calculate $Y = 10^{(i \times 0.9)}$
 - b. Calculate $Z = 0.983^Y$ (where Z is the 10-year survival)

According to a consensus conference of the National Institutes of Health, the aim of the Standardized Geriatric Assessment (SGA) is to discover, describe and explain the many problems of elderly people, to catalogue their resources and strengths, to assess individual service needs, and to develop a co-ordinated plan of care. The SGA can be carried out by means of several protocols. These protocols differ in the completeness of diagnostic research. The most complete protocol is the Comprehensive Geriatric Assessment (CGA) [160] which is tailored to the care of cancer patients [161]. In BC, the CGA has been used to adapt gemcitabine chemotherapy in previously untreated elderly patients with advanced BC [162].

6.2.3 Summary of evidence and recommendations for comorbidity scales

Summary of evidence	LE
Chronological age is of limited relevance.	3
A comorbidity score developed in particular for the assessment of patients diagnosed with bladder cancer would be helpful.	3

Recommendations	GR
Base the decision on bladder-sparing treatment or radical cystectomy in elderly/geriatric patients with invasive bladder cancer on tumour stage and comorbidity.	B
Assess comorbidity by a validated score, such as the Charlson Comorbidity Index. The American Society of Anesthesiologists (ASA) score should not be used in this setting (see section 7.4.4.1).	B

6.2.4 Prognostic markers

6.2.4.1 Tumour location

Location of the tumour at the bladder trigone has shown to be associated with an increased likelihood (OR 1.83 95% CI: 1.11-2.99) of nodal metastasis and decreased survival (OR 1.68; 95% CI: 1.11-2.55) [84].

6.2.4.2 Molecular markers

The performance of current commercially available pathological prognostic markers points to the relevance of including molecular prognostic markers into clinical practice [163], but so far very few studies have addressed this topic. At present, insufficient evidence exists to recommend the standard use of prognostic marker p53 in high-risk muscle-invasive disease, as it will not yield sufficient data upon which to base treatment in an individual patient [164].

Recent publications demonstrated four main molecular groups of BC:

- basal BC with the basal and claudin low-type group;
- luminal BC with luminal and p53-like subtype.

The basal group, which can have sarcomatoid aspects and shows an over-expression of epidermal growth factor receptor 3 (EGFR3), is chemosensitive, the luminal type displays an over-expression of fibroblast growth factor receptor 3 (FGFR3), epidermal growth factor receptor (ERBB2[↑] and ERBB3), and is chemotherapy resistant [50, 51, 165].

In 2014, the Cancer Genome Atlas (TCGA) project in BC reported on the integrated genomic analysis of the first 131 MIBC patients, identifying genes that are mutated in a significant proportion of BCs, several of which were not previously reported [166]. Profiling studies have also reported on validated biomarker panels that predict prognosis and can be used to identify patients who may benefit from more aggressive therapy [167]. In the coming years, expanding knowledge of BC carcinogenesis may change our management of the disease.

7. DISEASE MANAGEMENT

7.1 Treatment failure of non-muscle invasive bladder cancer

7.1.1 High-risk non-muscle-invasive urothelial carcinoma

The recurrence and progression rate of non-muscle invasive BC (NMIBC) strongly correlates with the factors as described in the European Organisation for Research and Treatment of Cancer (EORTC) risk calculator [168]. According to this calculator, the risk of progression after five years is 45% for high-risk tumours. In 2015, however, the EORTC group presented new nomograms based on two large phase III trials with a median follow up of 7.4 years. With one to three years of maintenance bacillus Calmette-Guérin (BCG), the risk for progression at five years was much lower: 19.3% for T1G3 tumours [169].

Meta-analyses have demonstrated that BCG-therapy prevents the risk of tumour recurrence [170] and the risk of tumour progression [171, 172] but so far, no significant overall- or disease-specific survival advantages have been shown, as compared to no intravesical therapy [171-173]. The EAU NMIBC Guidelines present data supporting cystectomy in selected patients with NMIBC.

Large cystectomy series show a risk of an understaging error in TaT1 tumours of 35-62%. This may be caused by the presence of persisting or recurrent tumours due to omission of a second TURB or re-TURB, and the absence of neoadjuvant therapy [174-176]. Second TURB identifies upstaging to > T2 tumours in 10-20% of patients [177, 178].

Progression to MIBC significantly decreases CSS. In a review of nineteen trials including 3,088 patients, CSS after progression from NMIBC to MIBC was 35%, which is significantly worse compared to patients with MIBC without a history of NMIBC. This underlines the need to recommend early radical treatment, such as RC, in case of intravesical therapy failure [2, 179, 180].

According to the EAU NMIBC Guidelines, it is reasonable to propose immediate RC to patients with non-muscle-invasive tumour who are at highest risk of progression [168, 181-183]. Risk factors are any of the following:

- T1 tumours;
- high-grade/G3 tumours;
- CIS;
- multiple and recurrent and large (> 3 cm) Ta G1G2 tumours (all conditions must be presented in this point).

Subgroup of highest-risk tumours:

- T1G3/high-grade associated with concurrent bladder CIS;
- multiple and/or large T1G3/HG and/or recurrent T1G3/high-grade;
- T1G3/high-grade with CIS in the prostatic urethra;
- unusual histology of urothelial carcinoma;
- lymphovascular invasion;
- BCG failures.

Although the percentage of patients with primary TaT1 tumours and the indication for cystectomy in TaT1 tumours is not specified in large cystectomy series, the ten-year recurrence-free survival rate is 80% and similar to that of TURB and BCG maintenance therapy [2, 175, 184, 185] (LE: 3).

Radical cystectomy is also strongly recommended in patients with BCG-refractory tumours, defined in the NMIBC guideline as:

- whenever muscle-invasive tumour is detected during follow-up;
- if high-grade, non-muscle-invasive papillary tumour is present at three months;
- if CIS (without concomitant papillary tumour) is present at both three and six months;
- if high-grade tumour appears during BCG therapy [186];
- high-grade recurrence after BCG (recurrence of high-grade/grade 3 [WHO 1973/2004] tumour after completion of BCG maintenance, despite an initial response).

Patients with disease recurrence within two years of initial TURB plus BCG therapy have a better outcome than patients who already have muscle-invasive disease, indicating that cystectomy should be performed at first recurrence, even in non-muscle-invasive disease [187] (LE: 3; GR: C).

There are now several bladder-preservation strategies available; immunotherapy, chemotherapy, device-assisted therapy, and combination therapy [188]. However, experience is limited and treatments other than RC must be considered oncologically inferior at the present time [188].

7.1.2 **Recommendations for treatment failure of non-muscle-invasive bladder cancer**

Recommendations	GR
Consider immediate radical treatment in all T1 tumours at high risk of progression (i.e., high grade, multifocality, carcinoma <i>in situ</i> , and tumour size, as outlined in the EAU Guidelines for Non-muscle-invasive Bladder Cancer).	C
Offer radical treatment to all T1 patients failing intravesical therapy.	B

7.2 **Neoadjuvant chemotherapy**

7.2.1 **Introduction**

The standard treatment for patients with MIBC is RC. However, RC only provides five-year survival in about 50% of patients [176, 189-192]. To improve these results, neoadjuvant chemotherapy (NAC) has been used since the 1980s [193, 194].

There are many advantages and disadvantages of administering chemotherapy before planned definitive surgery to patients with resectable muscle-invasive urothelial carcinoma of the bladder and cNOMO disease:

- Chemotherapy is delivered at the earliest time-point, when the burden of micrometastatic disease is expected to be low.
- Potential reflection of *in-vivo* chemosensitivity.
- Tolerability of chemotherapy and patient compliance are expected to be better pre-cystectomy.
- Patients might respond to NAC and reveal a favourable pathological status, determined mainly by achieving pT0, pN0 and negative surgical margins.
- Delayed cystectomy might compromise the outcome in patients not sensitive to chemotherapy [195, 196], although published studies on the negative effect of delayed cystectomy only include chemo-naïve patients. There are no trials indicating that delayed surgery, due to NAC, has a negative impact on survival.

- Neoadjuvant chemotherapy does not seem to affect the outcome of surgical morbidity. In one randomised trial the same distribution of grade 3-4 post-operative complications was seen in both treatment arms [197]. In the combined Nordic trials (n = 620), NAC did not have a major adverse effect on the percentage of performable cystectomies. The cystectomy frequency was 86% in the experimental arm and 87% in the control arm, 71% received all three chemotherapy cycles [198].
- Clinical staging using bimanual palpation, CT or MRI may often result in over- and understaging and have a staging accuracy of only 70% [199, 200]. Overtreatment is a possible negative consequence.
- Neoadjuvant chemotherapy should only be used in patients eligible for cisplatin combination chemotherapy; other combinations (or monotherapies) are inferior in metastatic BC and have not been fully tested in a neoadjuvant setting [197, 201-213].

7.2.2 *The role of imaging and biomarkers to identify responders*

Data from small imaging studies, aiming to identify responders in patients treated with NAC, suggest that response after two cycles of treatment is related to outcome. So far, neither PET, CT, nor conventional MRI or DCE MRI can accurately predict response [214-217]. In addition, the definition of stable disease after two cycles of NAC is still undefined. To identify progression during NAC, imaging is being used in many centres, notwithstanding the lack of supporting evidence.

For responders to NAC, especially in those with a complete response (pT0 N0), treatment has a major positive impact on OS [218]. The overtreatment of non-responders and patients in the non-target population (i.e. patients without micrometastatic disease) are major drawbacks. Pre-operative identification of responders based on molecular tumour profiling in TURB specimens might guide the use of NAC [219, 220] (see Section 7.8.12 - Biomarkers).

7.2.3 *Summary of available data*

Several randomised phase III trials addressed the potential survival benefit of NAC administration, with conflicting results [197, 201-210, 221-226]. The main differences in trial designs were the type of chemotherapy (i.e. single-agent cisplatin or combination chemotherapy) and the number of cycles provided. Patients had to be fit for cisplatin. Since these studies differed considerably for patient numbers, patient characteristics (e.g. clinical T-stages included) and the type of definitive treatment offered (cystectomy and/or RT), pooling of results was not possible.

Three meta-analyses were undertaken to establish if NAC prolongs survival [211-213]. In the most recent meta-analysis, published in 2005 [213], with updated patient data from 11 randomised trials (n = 3,005), a significant survival benefit was shown in favour of NAC. The results of this analysis confirmed the previously published data and showed a 5% absolute improvement in survival at five years.

The Nordic combined trial showed an absolute benefit of 8% survival at five years and 11% in the clinical T3 subgroup, translating into nine patients needed to treat [198]. Only cisplatin combination chemotherapy with at least one additional chemotherapeutic agent resulted in a meaningful therapeutic benefit [211, 213]; the regimens tested were methotrexate, vinblastine, adriamycin plus cisplatin (MVA(E)C), cisplatin, methotrexate plus vinblastine (CMV), cisplatin and methotrexate (CM), cisplatin/adriamycin, cisplatin/5-fluorouracil (5-FU), and carboplatin, methotrexate, vinblastine (CarboMV).

More modern chemotherapeutic regimens such as gemcitabine/cisplatin have shown similar pT0/pT1 rates as methotrexate, vinblastine, adriamycin plus cisplatin (MVAC) in the most recent retrospective series and pooled data analyses, but have not been used in randomised controlled trials (RCTs) [227-230]. The updated analysis of the largest randomised phase III trial [201] with a median follow-up of eight years confirmed previous results and provided some additional interesting findings:

- 16% reduction in mortality risk;
- improvement in ten-year survival from 30% to 36% with neoadjuvant CMV;
- benefit with regard to distant metastases;
- no benefit for locoregional control and locoregional disease-free survival, with the addition of neoadjuvant CMV independent of the definitive treatment.

The presence of micrometastases is postulated to be lower in smaller tumours (T2) compared to more extensive tumours (T3b-T4b). T4 stage tumours are prone to a higher degree of clinical understaging because macrometastatic nodal deposits are detected more often in post-cystectomy specimens [198]. Data support the use of NAC in the T2b-T3b tumour subgroup (former classification T3), and has shown a modest, but substantial, improvement in long-term survival as well as significant downstaging [218].

7.2.4 Summary of evidence and recommendations for neoadjuvant chemotherapy

Conclusions	LE
Neoadjuvant chemotherapy has its limitations regarding patient selection, current development of surgical techniques, and current chemotherapy combinations.	3
Neoadjuvant cisplatin-containing combination chemotherapy improves overall survival (OS) (5-8% at five years).	1a
Neoadjuvant treatment of responders and especially patients who show complete response (pT0 N0) has a major impact on OS.	2
Currently, no tools are available to select patients who have a higher probability of benefitting from neoadjuvant chemotherapy (NAC). In the future, genetic markers, in a personalised medicine setting, might facilitate the selection of patients for NAC and differentiate responders from non-responders.	

Recommendations	GR
Offer neoadjuvant chemotherapy (NAC) for T2-T4a, cN0M0 bladder cancer. In this case, always use cisplatin-based combination therapy.	A
Do not offer NAC to patients who are ineligible for cisplatin-based combination chemotherapy.	A

7.3 Pre- and post-operative radiotherapy in muscle-invasive bladder cancer

7.3.1 Post-operative radiotherapy

There are only very limited, old, data on adjuvant RT after RC. However, advances in targeting, and reducing the damage to surrounding tissue, may yield better results in the future [231]. A recent RCT in 100 patients, comparing pre-operative vs. post-operative RT and RC, showed comparable OS, DFS and complication rates [232]. Approximately half of these patients had urothelial cancer (UC), while the other half had SCC. In locally advanced BC (T3-T4, N0/N1, M0), the local recurrence rate seems to decrease with post-operative RT [233].

7.3.2 Pre-operative radiotherapy

7.3.2.1 Retrospective studies

Older data and retrospective studies alone cannot provide an evidence base for modern guideline recommendations due to the major study limitations, which include concomitant chemotherapy and differences between surgery and RT. This conclusion was supported by a 2003 systemic review [234]. A retrospective study from 2015 [235] did show a decreased cause-specific mortality and overall mortality for pre-operative RT in clinical T2b and T3 patients only. Another recent retrospective study with pre-operative RT in clinical T1-3 tumours showed that downstaging to T0 tumours occurs in > 50% of the irradiated patients, as compared to < 10% of patients without having received pre-operative RT [236]. Additionally, downstaging resulted in a longer progression-free survival (PFS).

7.3.2.2 Randomised studies

Six randomised studies have been published so far, investigating pre-operative RT, although all are from several decades ago. In the largest trial, pre-operative RT at a dose of 45 Gy was used in patients with muscle-invasive tumours resulting in a significant increase in pathological complete response (pCR) (9% to 34%) in favour of pre-operative RT, which was also a prognostic factor for survival [237]. The OS data were difficult to interpret since chemotherapy was used in a subset of patients only and more than 50% of patients (241/475) did not receive the planned treatment and were excluded from the final analyses. Two smaller studies using a dose of 20 Gy showed only a small survival advantage in \geq T3 tumours [238, 239]. Two other small trials confirmed downstaging after pre-operative RT [240, 241].

A meta-analysis of the five randomised trials showed a difference in five-year survival of (OR: 0.71; 95% CI: 0.48-1.06) in favour of pre-operative RT [242]. However, the meta-analysis was potentially biased by the patients in the data from largest trial who were not given the planned treatment. When the largest trial was excluded, the OR became 0.94 (95% CI: 0.57-1.55), which is not significant.

7.3.3 Summary of evidence and recommendations for pre- and post-operative radiotherapy

Summary of evidence	LE
No data exist to support that pre-operative radiotherapy (RT) for operable muscle-invasive bladder cancer (MIBC) increases survival.	2a
Pre-operative RT for operable MIBC, using a dose of 45-50 Gy in fractions of 1.8-2 Gy, results in downstaging after four-six weeks.	2
Limited high-quality evidence supports the use of pre-operative RT to decrease the local recurrence of MIBC after radical cystectomy.	3

Recommendations	GR
Do not offer pre-operative radiotherapy (RT) to improve survival.	A
Offer pre-operative RT for operable MIBC since it can result in tumour downstaging after four to six weeks.	C

7.4 Radical surgery and urinary diversion

7.4.1 Removal of the tumour-bearing bladder

7.4.1.1 Introduction

Radical cystectomy is the standard treatment for localised MIBC in most Western countries [176, 243]. Recent interest in patients' quality of life (QoL) has promoted the trend toward bladder-preserving treatment modalities, such as radio- and/or chemotherapy (see Sections 7.2 and 7.6). Performance status (PS) and age influence the choice of primary therapy, as well as the type of urinary diversion, with cystectomy being reserved for younger patients without concomitant disease and with a better PS. The value of assessing overall health before recommending and proceeding with surgery was emphasised in a multivariate analysis [149]. The analysis found an association between comorbidity and adverse pathological- and survival outcome following RC [149]. Performance status and comorbidity have a different impact on treatment outcomes and must be evaluated independently [155].

Controversy remains regarding age, RC and the type of urinary diversion. Cystectomy is associated with the greatest risk reduction in disease-related and non-disease-related death in patients aged > 80 years [149]. The largest, retrospective, single-institution study on cystectomy to date found that patients aged > 80 years had increased post-operative morbidity, but not increased mortality. Although some patients successfully underwent a neobladder procedure, most patients were treated with an ileal conduit diversion [244].

It is particularly important to evaluate functioning and QoL of elderly patients using a standardised geriatric assessment, as well as carrying out a standard medical evaluation (see Section 6.2) [245].

7.4.2 Timing and delay of cystectomy

Nielsen *et al.* reported that a delay of RC > 3 months in three American centres was not associated with a worse clinical outcome [246]. Ayres *et al.* investigated whether a delay > 3 months would have the same effect in the United Kingdom [247]. Initially they found, in agreement with Nielsen *et al.*, that cystectomy within 90 days of diagnosis had no effect on OS for MIBC (n = 955). However, analysis of T2 tumours showed a statistically significant survival benefit if patients had surgery within 90 days of diagnosis (n = 543; HR: 1.40; 95% CI: 1.10-1.79). A population-based study from the USA SEER database analysed patients who underwent a cystectomy between 1992 and 2001, also concluded that a delay of more than twelve weeks has a negative impact on outcome and should be avoided [248].

7.4.2.1 Indications

Traditionally, RC was recommended for patients with MIBC T2-T4a, N0-Nx, M0 [243]. Other indications include high risk and recurrent superficial tumours, BCG-resistant Tis, T1G3 (see Section 7.1), as well as extensive papillary disease that cannot be controlled with TURB and intravesical therapy alone.

Salvage cystectomy is indicated in non-responders to conservative therapy, recurrence after bladder-sparing treatment, and non-urothelial carcinoma (these tumours respond poorly to chemotherapy and RT). It is also used as a purely palliative intervention, including for fistula formation, pain and recurrent visible haematuria (macrohaematuria) (see Section 7.5.1 - Palliative cystectomy).

When there are positive LNs, in the case of N1 involvement (metastasis in a single node in the true pelvis) orthotopic neobladder can still be considered, but not in N2 or N3 tumours [249].

7.4.3 **Radical cystectomy: technique and extent**

In men, standard RC includes removal of the bladder, prostate, seminal vesicles, distal ureters, and regional LNs. Prostate-sparing cystectomy is an option in a subset of carefully selected patients with BC without involvement of the prostatic urethra and without prostate cancer. This procedure is oncologically safe with good functional results as long as it is performed in an experienced centre [250]. In women, standard RC includes removal of the bladder, entire urethra and adjacent vagina, uterus, distal ureters, and regional LNs [251]. Controversies in evaluating the clinical significance of lymphadenectomy are related to two main aspects of nodal dissection: therapeutic procedure and/or staging instrument.

Two important autopsy studies for RC have been performed so far. The first study showed that in 215 patients with MIBC and nodal dissemination, the frequency of metastasis was 92% in regional (perivesical or pelvic), 72% in retroperitoneal, and 35% in abdominal LNs. There was also a significant correlation between nodal metastases and concomitant distant metastases ($p < 0.0001$).

Approximately 47% of the patients had both nodal metastases and distant dissemination and only 12% of the patients had nodal dissemination as the sole metastatic manifestation [252]. The second autopsy study focused on the nodal yield when super-extended pelvic LN dissection (LND) was performed. Substantial inter-individual differences were found with counts ranging from 10 to 53 nodes [253]. These findings demonstrate the limited utility of node count as a surrogate for extent of dissection.

Regional LNs have been shown to consist of all pelvic LNs below the bifurcation of the aorta [254-258]. Mapping studies have also found that skipping lesions at locations above the bifurcation of the aorta, without more distally located LN metastases, is rare [258, 259].

The extent of LND has not been established to date. Standard lymphadenectomy in BC patients involves removal of nodal tissue cranially up to the common iliac bifurcation, with the ureter being the medial border, and including the internal iliac, presacral, obturator fossa and external iliac nodes [260]. Extended lymphadenectomy includes all LNs in the region of the aortic bifurcation, and presacral and common iliac vessels medial to the crossing ureters. The lateral borders are the genitofemoral nerves, caudally the circumflex iliac vein, the lacunar ligament and the LN of Cloquet, as well as the area described for standard lymphadenectomy [260-264]. A super-extended lymphadenectomy extends cranially to the level of the inferior mesenteric artery [265, 266].

In order to assess how and if cancer outcome is influenced by the extent of lymphadenectomy in patients with clinical N0M0 MIBC, a SR of the literature was undertaken [267]. Out of 1,692 abstracts retrieved and assessed, nineteen studies fulfilled the review criteria [260-264, 266, 268-280]. All five studies comparing LND vs. no LND reported a better oncological outcome for the LND group. Seven out of twelve studies comparing (super-)extended with limited or standard LND reported a beneficial outcome for (super)extended in at least a subset of patients which is in concordance with several other recently performed meta-analyses [281, 282]. No difference in outcome was reported between extended and super-extended LND in the two high-volume-centre studies identified [266, 278]. Further data from on-going randomised trials on the therapeutic impact of the extent of lymphadenectomy are awaited.

It has been suggested that PFS as well as OS might be correlated with the number of LNs removed during surgery, although there are no data from RCTs on the minimum number of LNs that should be removed. Nevertheless, survival rates increase with the number of dissected LNs [283]. Removal of at least ten LNs has been postulated as sufficient for evaluation of LN status, as well as being beneficial for OS in retrospective studies [284-286]. In conclusion, extended LND might have a therapeutic benefit compared to less-extensive LND, but due to study bias, no firm conclusions can be drawn [267].

7.4.3.1 *Pelvic organ preservation techniques in men: oncological and functional outcomes*

Different approaches have been described to improve voiding and sexual function in patients undergoing RC for BC. No consensus exists regarding which approach preserves function best. Concern remains regarding the impact of "sparing-techniques" on oncological outcomes.

To determine the effect of sexual function-preserving cystectomy (SPC) on functional and oncological outcomes a SR was undertaken [287].

Four main types of sexual-preserving techniques have been described:

1. **Prostate sparing cystectomy:** part or the whole prostate is preserved including seminal vesicles, vas deferens and neurovascular bundles.
2. **Capsule sparing cystectomy:** the capsule or peripheral part of the prostate is preserved with adenoma

(including prostatic urethra) removed by TURP or *en bloc* with bladder. Seminal vesicles, vas deferens and neurovascular bundles are also preserved.

3. **Seminal sparing cystectomy:** seminal vesicles, vas deferens and neurovascular bundles are preserved.
4. **Nerve sparing cystectomy:** the neurovascular bundles are the only tissue left in place.

Out of 8,517 screened abstracts twelve studies recruiting a total of 1,098 patients (823 in the intervention group vs. 275 in the control group) were identified, including nine comparative studies (one RCT and two retrospective non-RCTs with matched pair design [250, 288-297] and three single-arm case series [298-300]. Sexual function-preserving cystectomy described included prostate-, capsule-, seminal vesicle- and nerve-sparing techniques. In the majority of cases, the open surgical approach was used and the urinary diversion of choice was an orthotopic neobladder. Median follow-up was longer than three years in nine studies, with three studies presenting results at a median follow-up longer than five years.

The majority of the studies included patients who were potent pre-operatively with organ-confined disease without tumour in the bladder neck and/or prostatic urethra. Prostate cancer was ruled out in all of the SPC techniques, except in those performing nerve-sparing cystectomy.

Oncological outcomes did not differ between groups in any of the comparative studies that measured local recurrence, metastatic recurrence, DSS and OS, at a median follow-up of three to five years. Local recurrence after SPC was commonly defined as any urothelial cancer (UC) recurrence below the iliac bifurcation within the pelvic soft tissue and ranged from 1.2-61.1% vs. 16-55% in the control group. Metastatic recurrence ranged from 0-33.3%.

For those techniques preserving prostatic tissue (prostate or capsule sparing) rates of incidental prostate cancer in the intervention group ranged from 0 to 15%. In no case, incidental prostate cancer with Gleason score ≥ 8 was reported.

Sexual outcomes were evaluated using validated-questionnaires (International Index of Erectile Function [IIEF], Erection Hardness Scale [EHS], Bladder Cancer Index [BCI]) in eight studies. Post-operative potency was significantly better in patients who underwent any type of sexual-preserving technique compared to conventional RC ($p < 0.05$), ranging 80-90%, 50-100% and 29-78% for prostate-, capsule- or nerve-sparing techniques, respectively. Data did not show superiority of any sexual-preserving technique.

Urinary continence, defined as the use of no pads in the majority of studies, ranged from 88 to 100% (day-time continence) and from 31-96% (night-time continence) in the prostate-sparing cystectomy patients. No major impact was shown with regard to continence rates for any of the three approaches.

The evidence base suggests that these procedures may yield better sexual outcomes than standard cystectomy without compromising oncological outcomes. However, the overall quality of the evidence was moderate, and hence if a sexual-preserving technique is offered, patients must be carefully selected, counselled and closely monitored.

7.4.3.1.1 Summary of evidence and recommendations for sexual-preserving techniques in men

Summary of evidence	LE
The majority of patients motivated to preserve their sexual function will benefit from sexual-preserving techniques.	2
None of the sexual-preserving techniques (prostate/capsule/seminal/nerve sparing) have shown to be superior and no particular technique can be recommended.	

Recommendations	LE	GR
Offer sexual-preserving techniques to men motivated to preserve their sexual function since the majority will benefit.	2	B
Select patients based on: <ul style="list-style-type: none"> • organ-confined disease; • absence of any kind of tumour at the level of the prostate, prostatic urethra or bladder neck. 	2	A
Do not offer sexual-preserving cystectomy as standard therapy for muscle-invasive bladder cancer.		C

7.4.3.2 Pelvic organ preservation techniques in women: oncological and functional outcomes

Sexual and voiding dysfunction in female patients is prevalent after RC and orthotopic neobladder. Patients' QoL has promoted the trend toward pelvic organ-preserving techniques. Better imaging modalities, increased knowledge of the function of the pelvic structures and improved surgical techniques has enabled less destructive methods for treating high-risk BC. These techniques involve preserving the neurovascular bundle, vagina, uterus or variations of any of the stated techniques.

A SR was conducted to evaluate the advantages and disadvantages of sexual-function preserving RC and orthotopic neobladder for female patients [301].

After screening 11,941 abstracts, fifteen studies recruiting a total of 874 patients were eligible for inclusion. Three papers had a matched pair study design, and the remainder of the included studies were retrospective surgical series with small case numbers and a high risk of selection bias favouring less advanced cancers.

Sexual outcomes were reported in seven studies with 167/194 patients (86%) having resumed sexual activity within six months post-operatively, with median patients' sexual satisfaction scores of 88.5%, ranging from 80% to 100%.

Survival outcomes were reported in seven studies on 197 patients, with a mean follow-up of between 12 and 132 months. At three and five year, CSS was 70-100% and OS was 65-100%. Positive surgical margins were reported in six studies, ranging from 0 to 13.7%. Local and metastatic recurrence rates were reported as ranging between 0-13% and 0-16.7%, respectively. Mean time to local recurrence was seven months.

Eleven studies reported continence outcomes. Overall daytime and nighttime continence was 58-100% and 42-100%, respectively. Overall self-catheterisation rate was 9.5-78%.

Although, this SR provides the best evidence currently available, including basically all reported cases, the data remains immature. Most studies were retrospective and non-comparative with small numbers of patients included, meaning that any estimates are uncertain and likely to be biased. Heterogeneity in outcome definition, measurement and reporting hampers the usefulness of the current evidence base. The overall risk of bias was high across all studies. However, for well-selected patients, sparing female reproductive organs during RC appears to be oncologically safe and provides improved functional outcomes.

7.4.3.2.1 Summary of evidence and recommendations for sexual-preserving techniques in women

Summary of evidence	LE
Data regarding pelvic organ-preserving radical cystectomy for female patients remain immature.	3

Recommendations	LE	GR
Offer sexual-preserving techniques to female patients motivated to preserve their sexual function since the majority will benefit.	3	C
Select patients based on: <ul style="list-style-type: none"> • organ-confined disease; • absence of tumour in bladder neck or urethra. 		C
Do not offer pelvic organ-preserving radical cystectomy for female patients as standard therapy for muscle-invasive bladder cancer.		C

7.4.3.3 Laparoscopic/robotic-assisted laparoscopic cystectomy

Due to data limitations, until recently, laparoscopic radical cystectomy (LRC) and robot-assisted radical cystectomy (RARC) were considered as investigational procedures for which no advantages could be shown as compared to open surgery. Most of the available studies suffered from patient selection bias (age, stage).

A number of new publications have become available (cut-off date for the literature search was Oct 1st, 2015), in particular on RARC; a SR [302], a consensus panel report [303], an RCT from the Memorial Sloan Kettering Cancer Center (MSKCC) group [304] a SR on oncologic and functional outcomes after RARC [305] and a retrospective review on the recurrence patterns after open radical cystectomy (ORC) and RARC [306]. Since there is a continuous flow of reports on RARC, this text section and the recommendations will be subject to significant updates in the coming years.

For the methodology of the SR we refer to the manuscript [302]. In short, out of 1,071 abstracts assessed, 105 studies were selected as meeting the inclusion criteria. Of the 105 papers 102 had a level of evidence of 4, and only three publications had a level of evidence of 2b.

For RARC with urinary diversion, the mean operative time was six to seven hours. Although the intracorporeal technique is more demanding, operating times are comparable, most likely reflecting more experience with the procedure. The operation time decreased over time, but remained longer than for ORC. The average operative time for ORC is listed as 297 minutes in the three higher quality RCTs, which still seems relatively long.

In the comparative studies, mean length of hospital stay for RARC decreases with time and experience, and is 1 to 1.5 days shorter as compared to ORC. In the RCT's however, operative time and length of hospital stay showed no significant difference for either procedure. Blood loss and transfusion rate favour RARC. Intraoperative, 30-day complication rate and mortality were similar for RARC and ORC, but complication grade and grade 3, 90-day, complication rates favoured RARC. Overall complication rates were reported as > 50% which illustrates that cystectomy and diversion remains major surgery. Complication rates did not change with time or experience.

A major limitation of this review is the low level of evidence of the included studies. Of the three RCT's, only one was adequately powered and there was no correction for baseline characteristics (selection bias). In some of the larger series in the review 59-67% of tumours are < pT2 tumours. In the largest RCT 91.5% were clinically < T2 and 71.7% pathologically < T2 [304] compared to a large series of ORC (n = 1,054) 47% of included patients had a < pT2 tumour [176].

The Pasadena Consensus Panel (a group of experts on RC, lymphadenectomy and urinary reconstruction) reached similar conclusions as the Novara review based on the same methodology and literature [303]. They presented similar outcomes comparing RARC and ORC for operative endpoints, pathological and intermediate oncological endpoints (positive surgical margins and LN yield), functional endpoints and complication outcomes. Additionally, RARC was associated with increased costs, although there are ergonomic advantages for the surgeon, as compared to laparoscopic radical cystectomy (LRC). For both techniques surgeons' experience and institutional volume strongly predicted outcome. According to the literature, proficiency is reached after 20-250 cases. However, the Pasadena Consensus Panel performed statistical modelling and came to the conclusion that 30 cases should be enough to achieve proficiency in RARC, but they also concluded that challenging cases (high BMI, post chemo- or RT, pelvic surgery, T4 or bulky tumours or positive nodes) should be performed by experienced robotic surgeons only. Experience is defined as a high volume centre, > 30 RARCs/year and experience in ORC.

In the only sufficiently powered RCT, comparing ORC (n = 58) vs. RARC (n = 60) and open diversion, the primary endpoint was an advantage in 90 days grade 2-5 complications for RARC [304]. Since the complication rates were similar (62% for RARC vs. 66% for ORC), the trial was closed after a planned interim analysis. Robotic-assisted radical cystectomy resulted in less blood loss but had a longer operative time and higher costs. Length of hospital stay, pathology, and QoL were similar. Limitations of this study are lack of long-term outcomes and limited experience in RARC as compared to ORC in this group of patients. A similar health-related QoL (HRQoL) was also found in an initial report of a prospective RCT comparing ORC and RARC [307]. Similar functional and oncological outcomes with five years follow up were also reported by Yuh *et al.* [305]. Ngyuyen *et al.* also reported that RARC was not an independent predictor of recurrence after surgery in a retrospective review of 383 consecutive patients [306].

Most reviewed series used extracorporeal reconstruction which leaves room for improvement.

Although an intracorporeal neobladder is a very complex robotic procedure [308] the choice for neobladder or cutaneous diversion, must not depend on the surgical approach.

For LRC, a recent review came to similar conclusions as described for RARC [308]. The review included sixteen eligible studies on LRC. As compared to ORC, LRC had a significantly longer operative time, fewer overall complications, blood transfusions and analgesic use, less blood loss and a shorter length of hospital stay. However, the review was limited by the inherent limitations of the included studies. Although this review also showed better oncological outcomes, these appeared comparable to ORC series in the largest LRC multicentre study to date [308].

7.4.3.3.1 Summary of evidence and recommendations for laparoscopic/robotic-assisted laparoscopic cystectomy

Summary of evidence	LE
Robot-assisted radical cystectomy (RARC) provides longer operative time (1-1.5 hours), major costs, but shorter length of hospital stay (1-1.5 days) and less blood loss compared to open radical cystectomy (ORC).	1
RARC series suffer from a significant stage selection bias as compared to ORC.	1
Grade 3, 90-day complication rate is lower with RARC.	2
Most endpoints, if reported, including intermediate term oncological endpoint and quality of life are not different between RARC and ORC.	2
Surgeons experience and institutional volume are considered the key factor for outcome of both RARC and ORC, not the technique.	2
Recommendations on how to define challenging patients and an experienced RARC surgeon are still under discussion.	3
The use of neobladder after RARC still seems under-utilised, and functional results of intracorporeally constructed neobladders should be studied.	4

Recommendations	GR
Inform the patient of the advantages and disadvantages of open radical cystectomy (ORC) and robot-assisted radical cystectomy (RARC) to allow selection of the proper procedure.	C
Select experienced centres, not specific techniques, both for RARC and ORC.	B
Beware of neobladder under-utilisation and outcome after RARC.	C

7.4.4 Urinary diversion after radical cystectomy

From an anatomical standpoint, three alternatives are currently used after cystectomy:

- abdominal diversion, such as an ureterocutaneostomy, ileal or colonic conduit, and various forms of a continent pouch;
- urethral diversion, which includes various forms of gastrointestinal pouches attached to the urethra as a continent, orthotopic urinary diversion (neobladder, orthotopic bladder substitution);
- rectosigmoid diversions, such as uretero-(ileo-)rectostomy.

Different types of segments of the intestinal tract have been used to reconstruct the urinary tract, including the stomach, ileum, colon and appendix [309]. Several studies have compared certain aspects of HRQoL, such as sexual function, urinary continence and body image, in patient cohorts with different types of urinary diversion. However, further research is needed on pre-operative tumour stage and functional situation, socio-economic status, and time interval to primary surgery.

7.4.4.1 Preparations for surgery

The ASA score has been validated to assess the risk of post-operative complications prior to surgery. In the BC setting, ASA scores ≥ 3 are associated with major complications [132, 310], particularly those related to the type of urinary diversion (Table 7.4) [311]. However, the ASA score is not a comorbidity scale and should not be used as such.

Table 7.4: ASA score [312]

ASA	
1	No organic pathology, or patients in whom the pathological process is localised and does not cause any systemic disturbance or abnormality.
2	A moderate but definite systemic disturbance caused either by the condition that is to be treated or surgical intervention, or which is caused by other existing pathological processes.
3	Severe systemic disturbance from any cause or causes. It is not possible to state an absolute measure of severity, as this is a matter of clinical judgment.
4	Extreme systemic disorders that have already become an imminent threat to life, regardless of the type of treatment. Because of their duration or nature, there has already been damage to the organism that is irreversible.
5	Moribund patients not expected to survive 24 hours, with or without surgery.

In consultation with the patient, both an orthotopic neobladder and ileal conduit should be considered in case where reconstructive surgery exposes the patient to excessive risk (as determined by comorbidity and age).

Diagnosis of urethral tumour before cystectomy or positive urethral frozen section leads to urethrectomy and therefore excludes neobladder reconstruction. If indicated, in males, urethral frozen section has to be performed on the cystoprostatectomy specimen just under the verumontanum and on the inferior limits of the bladder neck for females.

When there are positive LNs, orthotopic neobladder can nevertheless be considered in the case of N1 involvement (metastasis in a single node in the true pelvis) but not for N2 or N3 tumours [313].

Oncological results after orthotopic neobladder substitution or conduit diversion are similar in terms of local or distant metastasis recurrence, but secondary urethral tumours seem less common in patients with neobladder compared to those with conduits or continent cutaneous diversions [314].

For cystectomy, general preparations are necessary as for any other major pelvic and abdominal surgery. If the urinary diversion is constructed from gastrointestinal segments, the length or size of the respective segments and their pathophysiology when storing urine must be considered [315]. Despite the necessary interruption and re-anastomosis of bowel, a formal bowel preparation may not be necessary [316]. Bowel recovery time can be reduced by the use of early mobilisation and early oralisation, gastrointestinal stimulation with metoclopramide and chewing gum [317]. Patients treated according to the “fast tract”/ERAS (Early Recovery After Surgery) protocol have shown to score better on the emotional and physical functioning scores and suffer less from wound healing disorders, fever and thrombosis [318].

A cornerstone of the ERAS protocol is post-operative pain management which involves significantly reducing the use of opioids; offering opioids mainly as breakthrough pain medication. Instead of patient-controlled analgesia (PCA) and epidural opioids, most patients receive high-dose acetaminophen and/or ketorolac, starting intra-operatively. Patients on ERAS experience more pain as compared to patients on a traditional protocol (VAS 3.1 vs. 1.1, $p < 0.001$), but post-operative ileus decreased from 22% to 7.3% ($p = 0.003$) [319].

A multicentre randomised placebo-controlled trial showed that patients receiving alvimopan, a peripherally acting μ -opioid receptor antagonist, experienced quicker bowel recovery compared to patients receiving placebo [320]. However, this drug is, as yet, not approved in Europe.

Patients undergoing continent urinary diversion must be motivated to learn about their diversion and to be manually skilful in manipulating their diversion. Contraindications to more complex forms of urinary diversion include:

- debilitating neurological and psychiatric illnesses;
- limited life expectancy;
- impaired liver or renal function;
- transitional cell carcinoma of the urethral margin or other surgical margins.

Relative contraindications specific for an orthotopic neobladder are high-dose pre-operative RT, complex urethral stricture disease, and severe urethral sphincter-related incontinence [321].

7.4.4.2 Patient selection for orthotopic diversion

Radical cystectomy and urinary diversion are the two steps of one operation. However, the literature uniformly reports complications of RC, while ignoring the fact that most complications are diversion related [322]. Age alone is not a criterion for offering continent diversion [321, 323]. Comorbidity, cardiac and pulmonary function, and cognitive function, are all important factors that should be considered, along with the patient's social support and preference.

Age > 80 years is often considered to be the threshold after which neobladder reconstruction is not recommended. However, there is no exact age for a strict contraindication. In most large series from experienced centres, the rate of orthotopic bladder substitution after cystectomy for bladder tumour is up to 80% in men and 50% in women [324-327]. Nevertheless, no RCTs comparing conduit diversion with neobladder or continent cutaneous diversion have been performed.

Recently, a retrospective study including 1,383 patients showed that the risk of a decline in estimated glomerular filtration rate (eGFR) did not significantly differ after ileal conduit vs. neobladder in patients with pre-operative chronic kidney disease 2 (eGFR 60-89 mL/min/1.73 m²) or 3a (eGFR 45-59 mL/min/1.73 m²) [328]. Only age and anastomotic strictures were found to be associated with a decline in eGFR.

7.4.4.2.1 Ureterocutaneostomy

Ureteral diversion to the abdominal wall is the simplest form of cutaneous diversion. Operating time, complication rate, stay at intensive care and length of hospital stay are lower in patients treated with

ureterocutaneostomy as compared to ileal conduit [329]. Therefore, in older, or otherwise compromised, patients who need a supravescical diversion, ureterocutaneostomy is the preferred procedure [330, 331]. Quality of life, which was assessed using the Bladder Cancer Index, showed equal urinary bother and function for patients treated with ileal conduit and ureterocutaneostomy [329].

However, others have demonstrated that, in carefully selected elderly patients, all other forms of wet and dry urinary diversions, including orthotopic bladder substitutions, are possible [244]. Technically, either one ureter, to which the other shorter one is attached end-to-side, is connected to the skin (transureteroureterocutaneostomy) or both ureters are directly anastomosed to the skin. Due to the smaller diameter of the ureters, stoma stenosis has been observed more often than in intestinal stomas [330].

In a retrospective multicentre study peri-operative morbidity was evaluated for urinary diversion using bowel as compared to ureterocutaneostomy. Patients selected for a ureterocutaneostomy were older and had a higher ASA score, while their mean Charlson score was lower (4.2 vs. 5.6, $p < 0.001$) [332].

Despite the limited comparative data available, it must be taken into consideration that older data and clinical experience suggest ureter stenosis at the skin level and ascending UTI are more frequent complications in ureterocutaneostomy compared to an ileal conduit diversion. In a retrospective study comparing various forms of intestinal diversion, ileal conduits had fewer late complications than continent abdominal pouches or orthotopic neobladders [333].

7.4.4.2.2 Ileal conduit

The ileal conduit is still an established option with well-known/predictable results. However, up to 48% of patients develop early complications including UTIs, pyelonephritis, ureteroileal leakage and stenosis [333]. The main complications in long-term follow-up studies are stomal complications in up to 24% of cases and functional and/or morphological changes of the UUT in up to 30% [334-336]. An increase in complications was seen with longer follow-up in the Berne series of 131 patients who were followed for a minimum of five years (median follow-up 98 months) [337]; the rate of complications increased from 45% at five years to 94% in those surviving > 15 years. In the latter group, 50% of patients developed UUT changes and 38% developed urolithiasis.

7.4.4.2.3 Continent cutaneous urinary diversion

A low-pressure detubularised ileal reservoir can be used as a continent cutaneous urinary diversion for self-catheterisation; gastric, ileocecal and sigma pouches have also been described [338-340]. Different anti-reflux techniques can be used [341]. Most patients have a well-functioning reservoir with day-time and night-time continence approaching 93% [342]. In a retrospective study of > 800 patients, stomal stenosis was seen in 23.5% of patients with an appendix stoma and 15% of those with an efferent intussuscepted ileal nipple [342]. Stone formation in the pouch occurred in 10% of patients [341-343]. In a small series of previously irradiated female patients, incontinence and stomal stenosis was seen in 8/44 patients (18%) [344].

7.4.4.2.4 Ureterocolonic diversion

The oldest and most common form of ureterocolonic diversion was primarily a refluxive and later an anti-refluxive connection of ureters to the intact rectosigmoid colon (uretero-rectosigmoidostomy) [345, 346]. Most indications for this procedure have become obsolete due to a high incidence of upper UTIs and the long-term risk of developing colon cancer [313, 314]. Bowel frequency and urge incontinence are additional adverse effects of this type of urinary diversion. However, it may be possible to circumvent the above-mentioned problems by interposing a segment of ileum between the ureters and rectum or sigmoid in order to augment capacity and avoid direct contact between the urothelium and colonic mucosa, as well as faeces and urine [347].

7.4.4.2.5 Orthotopic neobladder

An orthotopic bladder substitution to the urethra is now commonly used both in men and women. Contemporary reports document the safety and long-term reliability of this procedure. In several large centres, this has become the diversion of choice for most patients undergoing cystectomy [189, 243, 321]. In elderly patients (> 80 years), however, it is rarely performed, even in high-volume expert centres [348, 349]. The terminal ileum is the gastrointestinal segment most often used for bladder substitution. There is less experience with the ascending colon, including the caecum, and the sigmoid [243]. Emptying of the reservoir anastomosed to the urethra requires abdominal straining, intestinal peristalsis, and sphincter relaxation. Early and late morbidity in up to 22% of the patients is reported [350, 351]. In two studies with 1,054 and 1,300 patients [321, 352], long-term complications included diurnal (8-10%) and nocturnal (20-30%) incontinence, ureterointestinal stenosis (3-18%), metabolic disorders, and vitamin B12 deficiency. In a recent study that compared cancer control and patterns of disease recurrence in patients with neobladder and ileal conduit, there was no

difference in CSS between the two groups when adjusting for pathological stage [353]. Urethral recurrence in neobladder patients seems rare (1.5-7% for both male and female patients) [321, 354]. These results indicate that neobladder in male and female patients does not compromise the oncological outcome of cystectomy. It remains debatable whether neobladder is better for QoL compared to non-continent urinary diversion [355-357].

Various forms of UUT reflux protection, including a simple isoperistaltic tunnel, ileal intussusception, tapered ileal prolongation implanted subserosally, and direct (sub)mucosal or subserosal ureteral implantation, have been described [341, 351]. According to the long-term results, the UUT is protected sufficiently by either method.

In conclusion, standard RC in male patients with bladder neoplasms includes removal of the entire bladder, prostate, seminal vesicles, distal ureters (segment length undefined), and corresponding LNs (extent undefined) (LE: 2b). In female patients, standard RC includes removal of the entire bladder, urethra and adjacent vagina, uterus, distal ureters, and corresponding LNs.

A detailed investigation of the bladder neck prior to RC is important for women who are scheduled for an orthotopic bladder substitute [358]. In women undergoing RC the rate of concomitant urethral malignancy has been reported to range from 12-16% [359]. Localisation of the primary tumour at the bladder neck correlated strongly with concomitant urethral malignancy. Additionally, the tumours were at higher risk of advanced stage and nodal involvement [360].

Currently, it is not possible to recommend a particular type of urinary diversion. However, most institutions prefer ileal orthotopic neobladders and ileal conduits, based on clinical experience [361, 362]. In selected patients, such as patients with a single kidney, ureterocutaneostomy is surgically the least burdensome type of diversion (LE: 3). Recommendations related to RC and urinary diversions are listed in section 7.5.

7.4.5 **Morbidity and mortality**

In three long-term studies, and one population-based cohort study, the peri-operative mortality was reported as 1.2-3.2% at 30 days and 2.3-8.0% at 90 days [189, 322, 324, 363, 364]. In a large single-centre series, early complications (within three months of surgery) were seen in 58% of patients [322]. Late morbidity was usually linked to the type of urinary diversion (see also above) [325, 365]. Early morbidity associated with RC for NMIBC (at high risk for disease progression) is similar and no less than that associated with muscle-invasive tumours [366]. In general, lower morbidity and (peri-operative) mortality have been observed by surgeons and in hospitals with a higher case load and therefore more experience [363, 367-371].

Table 7.6: Management of neobladder morbidity (30-64%) [372].

CLAVIEN System		Morbidity	Management
Grade I	Any deviation from the normal post-operative course without the need for pharmacological treatment or surgical, endoscopic and radiological interventions. Allowed therapeutic regimens are: drugs such as antiemetics, antipyretics, analgetics, diuretics and electrolytes and physiotherapy. This grade also includes wound infections opened at the bedside.	Immediate complications:	
		Post-operative ileus	Nasogastric intubation (usually removed at J1) Chewing gum Avoid fluid excess and hypovolemia (provoke splanchnic hypoperfusion)
		Post-operative nausea and vomiting	Antiemetic agent (decrease opioids) Nasogastric intubation
		Urinary infection	Antibiotics (ATB), no ureteral catheter removal Check the 3 drainages (ureters and neobladder)
		Ureteral catheter obstruction	Inject 5cc saline in the ureteral catheter to resolve the obstruction Increase volume infusion to increase diuresis
		intra-abdominal urine leakage (anastomosis leakage)	Check drainages and watchful waiting
		Anaemia well tolerated	Martial treatment (give iron supplement)
		Late complications:	
		Non compressive lymphocele	Watchful waiting
		Mucus cork	Cough Indwelling catheter to remove the obstruction
		Incontinence	Urine analysis (infection), echography (post-void residual) Physiotherapy
		Retention	Drainage and self-catheterisation education
		Grade II	Requiring pharmacological treatment with drugs other than those allowed for grade I complications. Blood transfusions and total parenteral nutrition are also included.
Pulmonary embolism	Heparinotherapy ³		
Pyelonephritis	ATB and check kidney drainage (nephrostomy if necessary)		
Confusion or neurological disorder	Neuroleptics and avoid opioids		
Grade III	Requiring surgical, endoscopic or radiological intervention	Ureteral catheter accidentally dislodged	Indwelling leader to raise the ureteral catheter
		Anastomosis stenosis (7%)	Renal drainage (ureteral catheter or nephrostomy)
		Ureteral reflux	No treatment if asymptomatic
III-a	Intervention not under general anaesthesia	Compressive lymphocele	Transcutaneous drainage or intra-operative marsupialisation (cf grade III)
III-b	Intervention under general anaesthesia	Ileal anastomosis leakage	Ileostomy, as soon as possible
		Evisceration	Surgery in emergency
		Compressive lymphocele	Surgery (marsupialisation)

Grade IV	Life-threatening complication (including central nervous system complications: brain haemorrhage, ischaemic stroke, subarachnoid bleeding, but excluding transient ischaemic attacks) requiring intensive care/intensive care unit management.	Rectal necrosis	Colostomy
		Neobladder rupture	Nephrostomy and indwelling catheter/surgery for repairing neobladder
		Severe sepsis	ATB and check all the urinary drainages and computed tomography scan in emergency
IV-a	Single organ dysfunction (including dialysis)	Non-obstructive renal failure	Bicarbonate/aetiology treatment
IV-b	Multi-organ dysfunction	Obstructive pyelonephritis and septicaemia	Nephrostomy and ATB
Grade V	Death of a patient		
Suffix 'd'	If the patient suffers from a complication at the time of discharge, the suffix "d" (for 'disability') is added to the respective grade of complication. This label indicates the need for a follow-up to fully evaluate the complication.		

¹ A recent SR showed that peri-operative blood transfusion (PBT) in patients who undergo RC correlates with increased all-cause mortality, cancer specific mortality and cancer recurrence. The authors hypothesised that this may be caused by the suggested immunosuppressive effect of PBT. The foreign antigens in transfused blood induce immune suppression, which may lead to tumour cell spread, tumour growth and reduced survival in already immunosuppressed cancer patients. As other possible causes for this finding increased post-operative infections and blood incompatibility were mentioned [373].

² Intraoperative tranexamin acid infusion reduces peri-operative blood transfusion rates from 57.7% to 31.1%. There was no increase seen in peri-operative venous thromboembolism [374].

³ Hammond and co-workers reviewed 20,762 cases of venous thromboembolism (VTE) after major surgery and found cystectomy patients to have the second highest rate of VTE among all cancers studied [375]. These patients benefit from 30 days low-molecular-weight heparin prophylaxis. Subsequently, it was demonstrated that BMI > 30 and non-urothelial BCs are independently associated with VTE after cystectomy. In these patients extended (90 days) heparin prophylaxis should be considered [376].

7.4.6 Survival

According to a multi-institutional database of 888 consecutive patients undergoing RC for BC, the five-year recurrence-free survival was 58% and the CSS was 66% [377]. Recent external validation of post-operative nomograms for BC-specific mortality showed similar results, with bladder-CSS of 62% [378].

Recurrence-free survival and OS in a large single-centre study of 1,054 patients was 68% and 66% at five years and 60% and 43%, at ten years, respectively [176]. However, the five-year recurrence-free survival in node-positive patients who underwent cystectomy was considerably less at 34-43% [175, 176, 379]. In a surgery-only study, the five-year recurrence-free survival was 76% in patients with pT1 tumours, 74% for pT2, 52% for pT3, and 36% for pT4 [176].

A trend analysis according to the five-year survival and mortality rates of BC in the U.S.A., between 1973 and 2009 with a total of 148,315 BC patients, revealed an increased stage-specific five-year survival rate for all stages, except for metastatic disease [380].

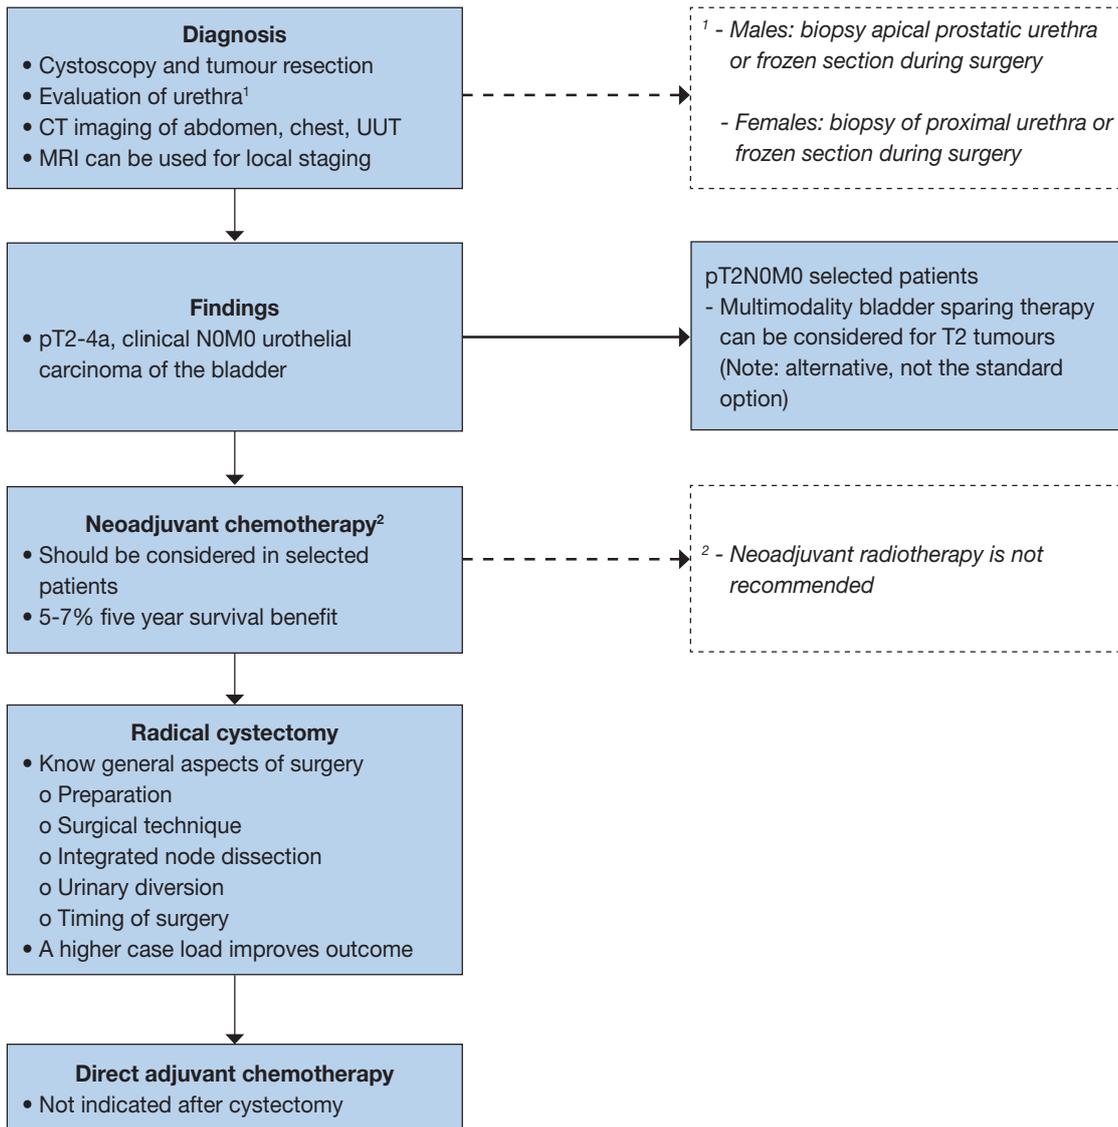

7.4.7 **Summary of evidence and recommendations for radical cystectomy and urinary diversion**

Summary of evidence	LE
For muscle-invasive bladder cancer, offer radical cystectomy as the curative treatment of choice.	3
A higher case load reduces morbidity and mortality of cystectomy.	3
Radical cystectomy includes removal of regional lymph nodes.	3
There are data to support that extended lymph node dissection (LND) (vs. standard or limited LND) improves survival after radical cystectomy.	3
Radical cystectomy in both sexes must not include removal of the entire urethra in all cases, which may then serve as the outlet for an orthotopic bladder substitution. The terminal ileum and colon are the intestinal segments of choice for urinary diversion.	3
The type of urinary diversion does not affect oncological outcome.	3
Laparoscopic cystectomy and robotic-assisted laparoscopic cystectomy are feasible but still investigational. Current best practice is open radical cystectomy.	3
In patients aged > 80 years with MIBC, cystectomy is an option.	3
Surgical outcome is influenced by comorbidity, age, previous treatment for bladder cancer or other pelvic diseases, surgeon and hospital volumes of cystectomy, and type of urinary diversion.	2
Surgical complications of cystectomy and urinary diversion should be reported using a uniform grading system. Currently, the best-adapted, graded system for cystectomy is the Clavien grading system.	2
No conclusive evidence exists as to the optimal extent of LND.	2a

Recommendations	GR
Do not delay cystectomy for > 3 months as it increases the risk of progression and cancer-specific mortality.	B
Before cystectomy, fully inform the patient about the benefits and potential risks of all possible alternatives. The final decision should be based on a balanced discussion between the patient and the surgeon.	B
Offer an orthotopic bladder substitute or ileal conduit diversion to male and female patients lacking any contraindications and who have no tumour in the urethra or at the level of urethral dissection.	B
Do not offer pre-operative radiotherapy when subsequent cystectomy with urinary diversion is planned.	A
Pre-operative bowel preparation is not mandatory. "Fast track" measurements may reduce the time of bowel recovery.	C
Offer radical cystectomy in T2-T4a, N0M0, and high-risk non-MIBC (as outlined above).	A*
Perform a lymph node dissection as an integral part of cystectomy.	A
Preserve the urethra if margins are negative.	B
Check the urethra regularly if no bladder substitution is attached.	B

*Upgraded following EAU Working Panel consensus.

7.1: Flow chart for the management of T2-T4a N0M0 urothelial bladder cancer

CT = computed tomography; MRI = magnetic resonance imaging; UUT = upper urinary tract.

7.5 Unresectable tumours

7.5.1 Palliative cystectomy for muscle-invasive bladder carcinoma

Locally advanced tumours (T4b, invading the pelvic or abdominal wall) may be accompanied by several debilitating symptoms, including bleeding, pain, dysuria and urinary obstruction. These patients are candidates for palliative treatments, such as palliative RT. Palliative cystectomy with urinary diversion carries the greatest morbidity and should be considered for symptom relief only if there are no other options [381-383].

Locally advanced MIBC can be associated with ureteral obstruction due to a combination of mechanical blockage by the tumour and invasion of ureteral orifices by tumour cells. In a series of 61 patients with obstructive uraemia, RC was not an option in 23 patients, and obstruction was relieved using permanent nephrostomy tubes [384]. Another ten patients underwent palliative cystectomy, but local pelvic recurrence occurred in all ten patients within the first year of follow-up. Another small study (n = 20) showed that primary cystectomy for T4 BC was technically feasible and associated with a very tolerable therapy-related morbidity and mortality [385].

7.5.1.1 *Recommendations for unresectable tumours*

Recommendations	GR
Offer radical cystectomy as a palliative treatment to patients with inoperable locally advanced tumours (T4b).	B
Offer palliative cystectomy in patients with symptoms.	B

7.5.2 **Supportive care**7.5.2.1 *Obstruction of the UUT*

Unilateral (best kidney) or bilateral nephrostomy tubes provide the easiest solution for UUT obstruction, but patients find the tubes inconvenient and prefer ureteral stenting. However, stenting can be difficult to achieve, stents must be regularly replaced and there is the risk of stent obstruction or displacement. Another possible solution is a urinary diversion with, or without, a palliative cystectomy.

7.5.2.2 *Bleeding and pain*

In the case of bleeding, the patient must be screened first for coagulation disorders or the patient's use of anticoagulant drugs must be reviewed. Transurethral (laser) coagulation may be difficult in a bladder full of tumour or with a bleeding tumour. Intravesical rinsing of the bladder with 1% silver nitrate or 1-2% alum can be effective [386]. It can usually be done without any anaesthesia. The instillation of formalin (2.5-4% for 30 minutes) is a more aggressive and painful procedure, requiring anaesthesia. Formalin instillation has a higher risk of side-effects, e.g. bladder fibrosis, but is more likely to control the bleeding [386]. Vesicoureteral reflux should be excluded to prevent renal complications.

Radiation therapy is another common strategy for control of bleeding, and is also used to control pain. An older study reported control of haematuria in 59% of patients and pain control in 73% [387]. Irritative bladder and bowel complaints due to irradiation are possible, but are usually mild. Non-conservative options are embolisation of specific arteries in the small pelvis, with success rates as high as 90% [386]. Radical surgery is a last resort and includes cystectomy and diversion (see above Section 7.5.1).

7.6 **Bladder-sparing treatments for localised disease**7.6.1 ***Transurethral resection of bladder tumour (TURB)***

Transurethral resection of bladder tumour alone in patients with muscle-invasive bladder tumours is only possible as a therapeutic option if tumour growth is limited to the superficial muscle layer and if re-staging biopsies are negative for residual (invasive) tumour [388]. In general, about half will still have to undergo RC for recurrent muscle-invasive cancer with a disease-specific mortality rate of up to 47% within this group [389]. A disease-free status at re-staging TURB appears to be crucial in making the decision not to perform RC [390, 391]. A prospective study by Solsona *et al.*, which included 133 patients with radical TURB and re-staging negative biopsies, reported a fifteen-year follow-up [391]. Thirty per cent had recurrent NMIBC and went on to intravesical therapy, and 30% (n = 40) progressed, of which 27 died of BC. After five, ten and fifteen years the results showed a CSS of 81.9%, 79.5%, and 76.7%, respectively and PFS rates with an intact bladder of 75.5%, 64.9%, and 57.8%, respectively.

In conclusion, TURB alone should only be considered as a therapeutic option for muscle-invasive disease after radical TURB, when the patient is unfit for cystectomy or a multimodality bladder-preserving approach, or refuses open surgery [392].

7.6.1.1 *Recommendation for transurethral resection of bladder tumour*

Recommendation	LE	GR
Do not offer transurethral resection of bladder tumour alone as a curative treatment option as most patients will not benefit.	2a	B

7.6.2 ***External beam radiotherapy (EBRT)***

Current RT techniques with soft-tissue matching result in superior bladder coverage and a reduced integral dose to the surrounding tissues. The target dose for curative RT in BC is 60-66 Gy, with a subsequent boost using external RT or interstitial RT. The use of modern standard RT techniques results in major, related, late morbidity of the urinary bladder or bowel in less than 5% of tumour-free patients [393]. Acute diarrhoea is even more reduced with intensity-modulated RT [394]. Important prognostic factors for outcome include response to

RT, tumour size, hydronephrosis and completeness of the initial TURB. Additional prognostic factors reported were age and stage [395].

In 2007 long-term results were reported by Chung *et al.* [396]. A total of 340 patients with MIBC were treated with EBRT alone, EBRT with concurrent chemotherapy, or NAC followed by EBRT. The overall CR was 55% and the ten-year DSS and OS were 35% and 19%, respectively. Complete response was 64% after EBRT alone, 79% after concurrent chemotherapy (n = 36), and 52% after NAC (n = 57). Younger age, lower tumour stage and absence of CIS were associated with a significant improvement in survival.

A 2002 Cochrane analysis demonstrated that RC has an OS benefit compared to RT [397], although this was not the case in a 2014 retrospective review using a propensity score analysis [398].

In conclusion, EBRT can be an alternative treatment in patients unfit for radical surgery.

7.6.2.1 Summary of evidence and recommendation for external beam radiotherapy

Summary of evidence	LE
External beam radiotherapy alone should only be considered as a therapeutic option when the patient is unfit for cystectomy or a multimodality bladder-preserving approach.	3
Radiotherapy can also be used to stop bleeding from the tumour when local control cannot be achieved by transurethral manipulation because of extensive local tumour growth.	3

Recommendation	GR
Do not offer radiotherapy alone as primary therapy for localised bladder cancer.	B

7.6.3 Chemotherapy

Chemotherapy alone rarely produces durable complete remissions. In general, a clinical CR rate of up to 56%, as reported in some series, which must be weighed against a staging error of > 60% [399, 400]. Response to chemotherapy is a prognostic factor for treatment outcome and eventual survival [199], though it may be confounded by patient selection.

Several groups have reported the effect of chemotherapy on resectable tumours (neoadjuvant approach), as well as unresectable primary tumours [197, 226, 401, 402]. Neoadjuvant chemotherapy with 2-3 cycles of MVAC or CMV has led to a downstaging of the primary tumour in different prospective series [197, 226, 401]. Pathological complete responses of primary bladder tumours were reached in 12-50% of patients after MVAC and in 12-22% of patients after gemcitabine/cisplatin (GC) in phase II and phase III trials [197, 226, 401, 403-410].

Contemporary series with GC followed by RC reported inferior pT0 rates, which may have been related to a lack of dose density and inappropriate delay of surgery [230].

For highly selected patients, a bladder-conserving strategy with TURB and systemic cisplatin-based chemotherapy, preferably with MVAC, may allow long-term survival with intact bladder [199]. However, this approach cannot be recommended for routine use.

7.6.3.1 Summary of evidence and recommendation for chemotherapy for muscle-invasive bladder tumours

Summary of evidence	LE
With cisplatin-based chemotherapy as primary therapy for locally advanced tumours in highly selected patients, complete and partial local responses have been reported.	2b

Recommendation	GR
Do not offer chemotherapy alone as primary therapy for localised bladder cancer.	A

7.6.4 Multimodality bladder-preserving treatment

Multimodality treatment (MMT) or trimodality treatment combines TURB, chemotherapy and radiation. The rationale for performing TURB and radiation is to achieve local tumour control. The addition of systemic chemotherapy or other radiosensitisers (mentioned below) aims at the potentiation of RT. Micrometastases

are targeted by platinum-based combination chemotherapy and this topic is covered in the section on NAC (see Section 7.2). The aim of multimodality therapy is to preserve the bladder and QoL, without compromising outcome. A collaborative review addressed this approach [411].

There are no completed RCTs to compare the outcome of MMT with the gold standard, RC, but this approach has been shown to be superior to RT alone [412, 413]. Many of the reported series have differing characteristics as compared to the large surgical series which typically have median ages in the mid-late 60s compared to mid-70s for some large RT series (reviewed in [412]). In the case of MMT, two distinct patterns of care may be distinguished: treatment aimed at patients fit for cystectomy and treatment aimed at older, less fit patients. For the former category MMT presents selective bladder preservation. In that case, the initial step is a radical TURB, where as much tumour as possible should be resected. This implies that proper patient selection (T2 tumours, no CIS) is critical [414]. For patients who are not candidates for cystectomy, less stringent criteria can be applied, though extensive CIS and poor bladder function should both be regarded as strong contraindications.

Following TURB and staging, treatment comprises EBRT with concurrent radiosensitising drugs. Two schedules are in common use worldwide: a split dose format with interim cystoscopy is used in North America [414] whilst single-phase treatment is more commonly used elsewhere [412]. For radiosensitising chemotherapy, cisplatin [415] or mitomycin C plus 5-fluorouracil (5-FU) can be used [412], but also other schedules have been used. In particular, hypoxic cell sensitisation with nicotinamide and carbogen has been evaluated in a large phase III trial [416]. In a recent phase I trial gemcitabine was used [417]. The regimen was well tolerated with promising results.

With MMT, five-year CSS and OS rates are achieved from 50-82% and from 36-74% respectively [393, 412, 415, 416, 418-420]. Salvage cystectomy rates are 10-30% [412, 415, 420]. There are data that major complication rates are similar for salvage and primary cystectomy [421]. The majority of recurrences post-MMT are non invasive and can be managed conservatively [412]. The collaborative review comes to the conclusion that there are accumulating data suggesting that bladder preservation with MMT leads to acceptable outcomes and therefore may be considered a reasonable treatment option in well-selected patients as compared to RC [422]. It should also be considered in all patients where surgery is contraindicated, either relatively or absolutely as the factors that determine fitness for surgery and chemoradiotherapy differ.

A bladder-preserving multimodality strategy requires very close multidisciplinary co-operation and a high level of patient compliance. Even if a patient has shown a CR to a multimodality bladder-preserving strategy, the bladder remains a potential source of recurrence, hence long-term bladder monitoring is essential and patients should be counselled that this will be required. A recent subanalysis from two RTOG trials looked at CR (T0) and near CR (Ta or Tis) after MMT [423]. After a median follow up of 5.9 years 41/119 (35%) of these patients experienced a bladder recurrence, and fourteen required a salvage cystectomy. There was no difference between complete and near-complete responders.

7.6.4.1 Summary of evidence and recommendations for multimodality treatment in muscle-invasive bladder cancer

Summary of evidence	LE
In a highly selected patient population, long-term survival rates of multimodality treatment are comparable to those of early cystectomy.	2b

Recommendations	GR
Offer surgical intervention or multimodality treatments as primary curative therapeutic approaches since they are more effective than radiotherapy alone.	B
Offer multimodality treatment as an alternative in selected, well-informed and compliant patients, especially for whom cystectomy is not an option.	B

7.7 Adjuvant chemotherapy

Adjuvant chemotherapy after RC for patients with pT3/4 and/or LN positive (N+) disease without clinically detectable metastases (M0) is still under debate [421, 424] and is still infrequently used [193].

The general benefits of adjuvant chemotherapy include:

- chemotherapy is administered after accurate pathological staging, therefore treatment in patients at low risk for micrometastases is avoided;
- no delay in definitive surgical treatment.

The drawbacks of adjuvant chemotherapy are:

- assessment of *in vivo* chemosensitivity of the tumour is not possible and overtreatment is an unavoidable problem;
- delay or intolerance of chemotherapy, due to post-operative morbidity [425].

There is limited evidence from adequately conducted and accrued randomised phase III trials in favour of the routine use of adjuvant chemotherapy [424, 426-431]. Individual patient data from six randomised trials [420, 432-435] of adjuvant chemotherapy were included in one meta-analysis [426] with 491 patients for survival analysis (unpublished data from Otto *et al.*, were included in the analysis). All these trials were suboptimal with serious deficiencies, including small sample size (underpowered), early cessation of patient entry, and flaws in design and statistical analysis, including irrelevant endpoints or a lack of recommendations concerning salvage chemotherapy for relapse or metastases [424]. In these trials, three or four cycles of CMV, cisplatin, cyclophosphamide, and adriamycin (CISCA), methotrexate, vinblastine, adriamycin or epirubicin, and cisplatin (MVA(E)C) and cisplatin and methotrexate (CM) were used [436], and one trial used cisplatin monotherapy [434]. These data were not convincing enough to give an unequivocal recommendation for the use of adjuvant chemotherapy.

In a 2014 meta-analysis [427], an additional three studies were included [428-430]. However, only 945 patients were included in this meta-analysis of nine trials, and none of the trials were fully accrued and no individual patient data were used [427]. For one trial, only an abstract was available at the time of the meta-analysis [429], and none of the included trials by themselves were significantly positive for OS in favour of adjuvant chemotherapy. In two of the trials, more modern chemotherapy regimens were used (gemcitabine/ cisplatin and paclitaxel/gemcitabine and cisplatin) [428, 429]. The HR for OS was 0.77 and there was a trend towards an OS benefit when including all nine trials. The effect was stronger for DFS (HR: 0.66; 95% CI: 0.48-0.92) and when stratified for the ratio of nodal positivity (HR: 0.64; 95% CI: 0.45- 0.91). The background of this finding was heterogeneity in outcomes observed between the included studies. After stratification of the studies by the ratio of node positivity, no further heterogeneity was identified. The HR for DFS associated with adjuvant cisplatin-based chemotherapy in studies with higher nodal involvement was 0.39 (95% CI: 0.28-0.54), compared with 0.89 (95% CI: 0.69-1.15) in studies with less nodal involvement.

Furthermore, a retrospective cohort analysis that included 3,974 patients after cystectomy and LND showed an OS benefit in high-risk subgroups (extravesical extension and nodal involvement) [HR: 0.75; CI: 0.62-0.90] [437]. The most recent publication of the so far largest RCT (EORTC 30994), although not fully accrued, showed a significant improvement of PFS for immediate compared with deferred treatment (HR: 0.54; 95% CI: 0.4-0.73, $p < 0.0001$), there was, however, no significant OS benefit [438].

From the currently available evidence, it is still unclear whether immediate adjuvant chemotherapy or chemotherapy at the time of relapse is superior, or if the two approaches are equivalent with respect to the endpoint of OS. Cisplatin-based combination chemotherapy results in long-term DFS, even in metastatic disease, mainly in patients with LN metastases only, and with a good PS [407, 439, 440]. In the most recent meta-analysis, the positive role of adjuvant chemotherapy for BC has been strengthened, however, still with a poor level of evidence [427]. Patients should be informed about potential chemotherapy options before RC, including neoadjuvant and adjuvant chemotherapy, and the limited evidence for adjuvant chemotherapy.

7.7.1 Recommendation for adjuvant chemotherapy

Recommendation	GR
Offer adjuvant cisplatin-based combination chemotherapy to patients with pT3/4 and/or pN+ disease if no neoadjuvant chemotherapy has been given.	B

7.8 Metastatic disease

7.8.1 Introduction

Half of the patients with muscle-invasive UC relapse after RC, depending on the pathological stage of the primary tumour and the nodal status. Local recurrence accounts for 30% of relapses, whereas distant metastases are more common. Ten to fifteen percent of patients are already metastatic at diagnosis [441]. Before the development of effective chemotherapy, patients with metastatic UC rarely had a median survival that exceeded three-six months [442].

7.8.1.1 Prognostic factors and treatment decisions

Prognostic factors are crucial for assessing phase II study results and stratifying phase III trials [405, 409].

In a multivariate analysis, Karnofsky PS of $\leq 80\%$ and presence of visceral metastases were independent prognostic factors of poor survival after treatment with MVAC [409]. They have also been validated for newer combination chemotherapy regimens [443-445].

For patients refractory to, or progressing shortly after, platinum-based combination chemotherapy, four prognostic groups have been established, based on three adverse factors that have been developed in patients treated with vinflunine and that have been validated in an independent data set: Hb < 10 g/dL; presence of liver metastases; and ECOG PS ≥ 1 [446]. Cisplatin, has also been administered in patients with a GFR as low as 40 mL/min., using different schedules. The respective studies were mostly small size phase I and II trials [447-450]. In one phase III trial the cut off for cisplatin eligibility was ≥ 50 mL/min [451].

7.8.1.2 *Comorbidity in metastatic disease*

Comorbidity is defined as “the presence of one or more disease(s) in addition to an index disease” (see Section 6.2.1). Comorbidity increases with age. However, chronological age does not necessarily correlate with functional impairment. Different evaluation systems are being used to screen patients as potentially fit or unfit for chemotherapy, but age alone should not be used to base treatment selection on [452].

7.8.1.3 *Not eligible for cisplatin (unfit)*

The EORTC conducted the first randomised phase II/III trial for urothelial carcinoma patients who were unfit for cisplatin chemotherapy [453]. The EORTC definitions were GFR < 60 mL/min and/or PS 2.

An international survey among BC experts [454] was the basis for a consensus statement on how to classify patients unfit for cisplatin-based chemotherapy. At least one of the following criteria has to be present: PS > 1 ; GFR ≤ 60 mL/min; grade ≥ 2 audiometric loss; peripheral neuropathy; and New York Heart Association (NYHA) class III heart failure [455].

More than 50% of patients with UC are not eligible for cisplatin-based chemotherapy [456-459].

Renal function assessment in UC is of utmost importance for treatment selection. Calculation of creatinine clearance (CrCl) (24-h urine collection) with current formulae tend to underestimate clearance in patients aged > 65 years compared to measured CrCl [456, 460].

7.8.2 *Single-agent chemotherapy*

Response rates to single-agent, first-line chemotherapy vary. The most robust data have shown a response rate of about 25% for first- and second-line gemcitabine in several phase II trials [461, 462]. Responses with single agents are usually short-lived, complete responses are rare and no long-term DFS has been reported. The median survival in such patients is only six-nine months.

7.8.3 *Standard first-line chemotherapy for fit patients*

Cisplatin-containing combination chemotherapy has been the standard of care since the late 1980s (for a review see [463]). Methotrexate, vinblastine, adriamycin plus cisplatin MVAC and GC prolonged survival to up to 14.8 and 13.8 months, respectively, compared to monotherapy and older combinations. Neither of the two combinations is superior to the other, but equivalence has not been tested. Response rates were 46% and 49% for MVAC and GC, respectively. The long-term survival results have confirmed the anticipated equivalence of the two regimens [439]. The major difference between the above-mentioned combinations is toxicity. The lower toxicity of GC [158] has resulted in it becoming a new standard regimen [464]. Methotrexate, vinblastine, adriamycin plus cisplatin is better tolerated when combined with granulocyte colony-stimulating factor (G-CSF) [464, 465].

High-dose intensity MVAC (HD-MVAC) combined with G-CSF is less toxic and more efficacious than standard MVAC in terms of dose density, complete response, and two-year survival rate. However, there is no significant difference in median survival between the two regimens [466, 467]. In general, all disease sites have been shown to respond to cisplatin-based combination chemotherapy. A response rate of 66% and 77% with MVAC and HD-MVAC, respectively, has been reported in retroperitoneal LNs vs. 29% and 33% at extranodal sites [466]. The disease sites also have an impact on long-term survival. In lymph-node-only disease, 20.9% of patients were alive at five years compared to only 6.8% of patients with visceral metastases [439].

Further intensification of treatment using the new paclitaxel, cisplatin and gemcitabine (PCG) triple regimen did not result in a significant improvement in OS in the intent-to-treat (ITT) population of a large randomised phase III trial, comparing PCG triple regimen to GC [468]. However, the overall response rate (ORR) was higher with the triple regimen (56% vs. 44%; $p = 0.0031$), and the trend for OS improvement in the ITT population (15.8 vs. 12.7 months; HR = 0.85, $p = 0.075$) became significant in the eligible population. Adding paclitaxel to GC did not induce major additional side effects. Grade 4 neutropenia was more common (35.8% vs. 20% for GC), as

was febrile neutropenia (13.2% vs. 4.3%), and the need for G-CSF was higher (17% vs. 11%). Gemcitabine/cisplatin alone caused more G4 thrombocytopenia and thrombocytopenia-induced bleeding (11.4% vs. 6.8%). Paclitaxel, cisplatin and gemcitabine is an additional option for first-line treatment of UC.

7.8.4 **Carboplatin-containing chemotherapy for fit patients**

Carboplatin-containing chemotherapy is not equivalent to cisplatin combinations, and should not be considered interchangeable or standard. Several randomised phase II trials of carboplatin vs. cisplatin combination chemotherapy have produced lower CR rates and shorter OS for the carboplatin arms [469].

7.8.5 **Non-platinum combination chemotherapy**

Different combinations of gemcitabine and paclitaxel have been studied as first- and second-line treatments. Apart from severe pulmonary toxicity with a weekly schedule of both drugs, this combination is well tolerated and produces response rates between 38% and 60% in both lines. Non-platinum combination chemotherapy has not been compared to standard cisplatin chemotherapy in randomised trials, therefore, it is not recommended for first-line use in cisplatin-eligible patients [470-477].

7.8.6 **Chemotherapy in patients unfit for cisplatin**

Up to 50% of patients are ineligible for cisplatin-containing chemotherapy [455]. The first randomised phase II/III trial in this setting was conducted by the EORTC and compared methotrexate/carboplatin/vinblastine (M-CAVI) and carboplatin/gemcitabine (GemCarbo) in patients unfit for cisplatin. Both regimens were active. Severe acute toxicity (SAT) was 13.6% in patients treated with GemCarbo vs. 23% with M-CAVI, while the ORR was 42% for GemCarbo and 30% for M-CAVI. Further analysis showed that in patients with PS 2 and impaired renal function, combination chemotherapy provided limited benefit [453]. The ORR and SAT were both 26% for the former group, and 20% and 24%, respectively, for the latter group [453]. Phase III data have confirmed these results [445].

7.8.7 **Second-line treatment**

Second-line chemotherapy data are highly variable and prognostic factors have been established recently (see Section 7.8.1.1) [446]. A reasonable strategy may be to re-challenge former cisplatin-sensitive patients if progression occurs at least six to twelve months after first-line cisplatin-based combination chemotherapy. Second-line response rates of paclitaxel (weekly), docetaxel, nab-paclitaxel [478] oxaliplatin, ifosfamide, topotecan, pemetrexed, lapatinib, gefitinib and bortezomib have ranged between 0% and 28% in small phase II trials [462, 479, 480]. Although gemcitabine has also shown excellent response rates in second-line use, most patients already receive this drug as part of their front-line treatment [461].

Paclitaxel/gemcitabine studies have shown response rates of 38-60%. No randomised phase III trial with an adequate comparator arm has been conducted to assess the true value and OS benefit of this second-line combination [442, 476, 481].

Vinflunine, a novel third-generation vinca alkaloid, provided promising results in phase II trials [482]. A randomised phase III trial compared vinflunine plus best supportive care (BSC) against BSC alone in patients progressing after first-line treatment with platinum-containing combination chemotherapy for metastatic disease [483]. The results showed a modest ORR (8.6%), a clinical benefit with a favourable safety profile and, most importantly, a survival benefit in favour of vinflunine, which was statistically significant in the eligible patient population (not in the ITT population). For second-line treatment of advanced or metastatic UC, this trial reached the highest level of evidence ever reported. Currently, in Europe, vinflunine is the only approved second-line treatment. Vinflunine has not been approved for this indication in the United States.

7.8.8 **Low-volume disease and post-chemotherapy surgery**

With cisplatin-containing combination chemotherapy, excellent response rates may be obtained in patients with LN but no other metastases, good PS, and adequate renal function, including a high number of CRs, with up to 20% of patients achieving long-term DFS [439, 467, 484, 485]. The role of surgery after chemotherapy is still unclear. Although some studies suggest a survival benefit and QoL improvement, the level of evidence supporting this practice is very limited [486-500]. A retrospective study of post-chemotherapy surgery after a partial or complete response has indicated that surgery may contribute to long-term DFS in selected patients [410, 501, 502].

7.8.9 **Treatment of bone metastases**

The prevalence of metastatic bone disease (MBD) in patients with advanced/metastatic UC is 30-40% [503]. Skeletal complications due to MBD have a detrimental effect on pain and QoL and are also associated with increased mortality [504]. Bisphosphonates reduce and delay skeletal-related events (SREs) due to bone metastases by inhibiting bone resorption. In a small pilot study in patients with BC, SREs caused by bone metastases were delayed [505]. Denosumab is a fully human monoclonal antibody that binds to and neutralises RANKL (receptor activator of nuclear factor- κ B ligand), thereby inhibiting osteoclast function and preventing generalised bone resorption and local bone destruction. Denosumab is not inferior to zoledronic acid (ZA) in preventing or delaying SREs in patients with advanced MBD, including patients with UC [506]. Denosumab has recently been approved by the European Medicines Agency (EMA) for treatment of patients with bone metastases from solid tumours. Patients with MBD, irrespective of the cancer type, should be considered for bone-targeted treatment [504].

Patients treated with ZA or denosumab should be informed about possible side effects and receive prophylactic treatment for jaw osteonecrosis and hypocalcaemia, which is more common with denosumab. Aggressive calcium and vitamin D supplementation is recommended. Dosing regimens of ZA should follow regulatory recommendations and should be adjusted according to pre-existing medical conditions [507]. For denosumab, no dose adjustments are required for variations in renal function.

7.8.10 **Role of immunotherapy**

Immunomodulatory therapies using checkpoint inhibition, particularly with antibodies directed against the programmed cell death-1 (PD-1) protein or its ligand (PD-L1) have been tested. Atezolizumab, the first PD-L1 inhibitor was approved by the US Food and Drug Administration (FDA) in May 2016 for patients that have progressed during or after previous platinum-based chemotherapy. In a phase-II two-cohort study including 310 patients, the objective response rate was 15% independent of the expression of PD-L1. Progression-free survival was 2.1 and OS was 7.9 months. According to the expression level of PD-L1 numbers for response rate, PFS and OS were greater for patients with high expression but responses occurred also in patients with no expression of PD-L1. The toxicity profile of atezolizumab was favourable. Results of the phase III trial (NCT02302807) comparing atezolizumab with second-line chemotherapy are pending [508, 509].

7.8.11 **Summary of evidence and recommendations for metastatic disease**

Summary of evidence	LE
In a first-line setting, performance status (PS) and the presence or absence of visceral metastases are independent prognostic factors for survival.	1b
In a second-line setting, negative prognostic factors are: liver metastasis, PS \geq 1 and low haemoglobin (< 10 g/dL)	1b
Cisplatin-containing combination chemotherapy can achieve median survival of up to 14 months, with long-term disease-free survival reported in ~15% of patients with nodal disease and good PS.	1b
Single-agent chemotherapy provides low response rates of usually short duration.	2a
Carboplatin combination chemotherapy is less effective than cisplatin-based chemotherapy in terms of complete response and survival.	2a
Non-platinum combination chemotherapy produces substantial responses in first- and second-line settings.	2a
Non-platinum combination chemotherapy has not been tested against standard chemotherapy in patients who are fit or unfit for cisplatin combination chemotherapy.	4
There is no defined standard chemotherapy for unfit patients with advanced or metastatic urothelial cancer (UC).	2b
Vinflunine reaches the highest level of evidence ever reported for second-line use.	1b
Post-chemotherapy surgery after partial or complete response may contribute to long-term disease-free survival in selected patients.	3
Zoledronic acid and denosumab have been approved for all cancer types including UC, because they reduce and delay skeletal related events in metastatic bone disease.	1b
PD-L1 inhibitor atezolizumab has been FDA approved for patients that have progressed during or after previous platinum-based chemotherapy based on the results of a phase-II trial.	2a

Recommendations	GR
First-line treatment for fit patients:	
Use cisplatin-containing combination chemotherapy with GC, MVAC, preferably with G-CSF, HD-MVAC with G-CSF or PCG.	A
Do not use carboplatin and non-platinum combination chemotherapy.	B
First-line treatment in patients ineligible (unfit) for cisplatin:	
Use carboplatin combination chemotherapy or single agents.	C
For cisplatin-ineligible (unfit) patients, with performance status 2 or impaired renal function, as well as those with 0 or 1 poor Bajorin prognostic factors and impaired renal function, offer carboplatin-containing combination chemotherapy, preferably with gemcitabine/carboplatin.	B
Second-line treatment:	
Offer vinflunine to patients progressing after platinum-based combination chemotherapy for metastatic disease. Alternatively, offer treatment within a clinical trial setting.	A*
Offer zoledronic acid or denosumab to treat bone metastases.	B

* Grade A recommendation is weakened since the key studies did not reach statistical significance.

GC = gemcitabine plus cisplatin; G-CSF = granulocyte colony-stimulating factor; MVAC = methotrexate, vinblastine, adriamycin plus cisplatin; HD MVAC = high-dose methotrexate, vinblastine, adriamycin plus cisplatin; PCG = paclitaxel, cisplatin, gemcitabine.

7.8.12 Biomarkers

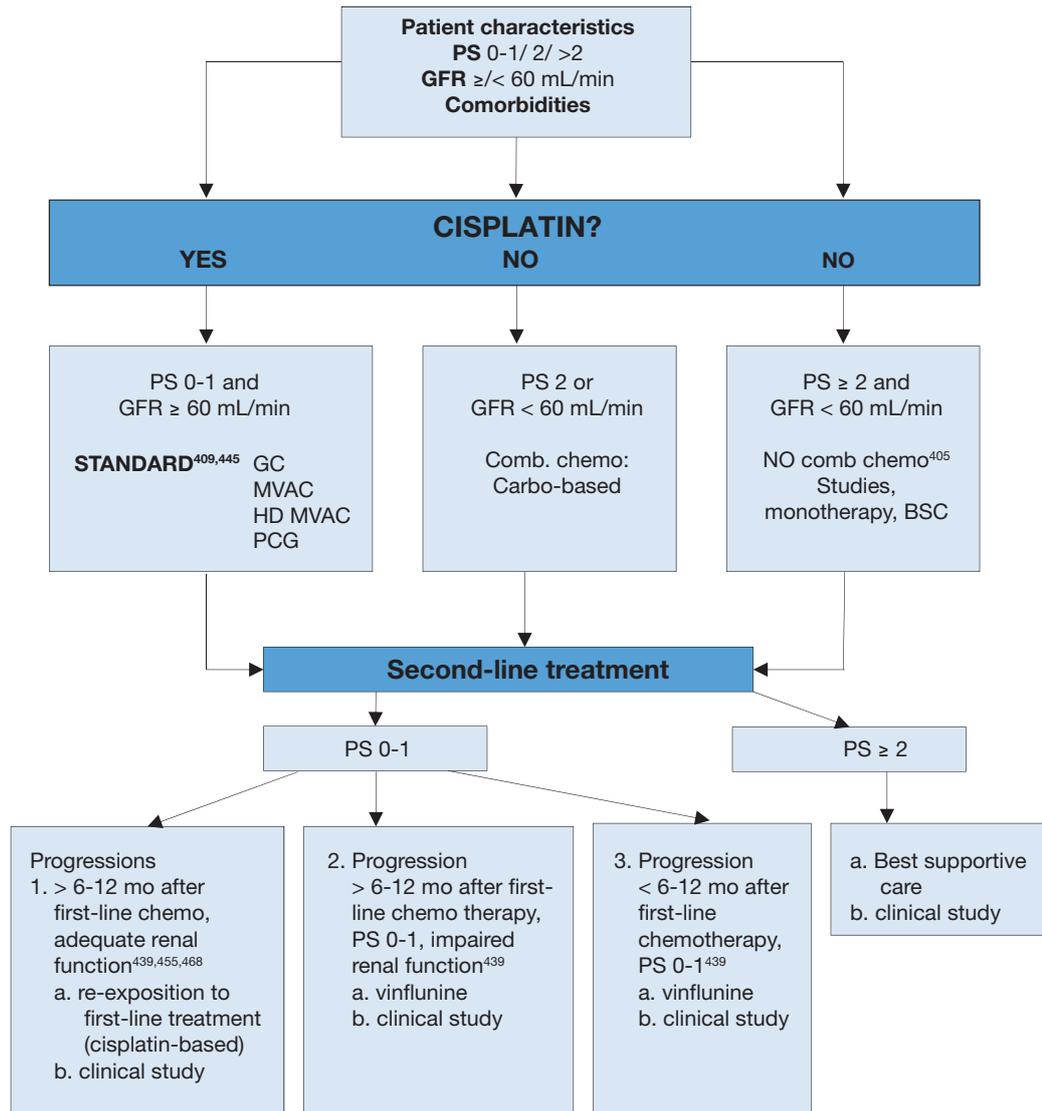

Modest disease control rates, with sporadic marked responses, in some patients with UC have led to the investigation of biomarkers for assessment of post-operative prognosis and the potential value of peri-operative chemotherapy, and as predictors of response to chemotherapy or its monitoring. Most of the biomarkers are associated with tumour angiogenesis. Small studies, usually retrospective, have investigated microvessel density, altered p53 tumour expression [510], serum vascular endothelial growth factor [511], urinary and tissue basic fibroblast growth factor [512], urinary (wild-type and mutant) and tissue fibroblast growth factor receptor-3 [513], and more recently, thrombospondin-1 [514], circulating tumour cells [515, 516], and multidrug resistance gene expression [517]. Although a few biomarkers have shown potential, as yet, there is insufficient evidence to support their routine clinical use (LE: 3).

7.8.12.1 Recommendation for the use of biomarkers

Recommendation	GR
Do not use biomarkers in daily clinical practice since they have no impact on predicting outcome, treatment decisions, or monitoring therapy in muscle-invasive bladder cancer.	A*

*Upgraded following panel consensus.

Figure 7.2: Flow chart for the management of metastatic urothelial cancer

BSC = best supportive care; GC = gemcitabine plus cisplatin; GFR = glomerular filtration rate; MVAC = methotrexate, vinblastine, adriamycin plus cisplatin; HD MVAC = high-dose methotrexate, vinblastine, adriamycin plus cisplatin; PS = performance status; PCG = paclitaxel, cisplatin, gemcitabine.

7.9 Quality of life

7.9.1 Introduction

The evaluation of HRQoL considers physical, psychological, emotional and social functioning.

Several questionnaires have been validated for assessing HRQoL in patients with BC, including FACT (Functional Assessment of Cancer Therapy)-G [518], EORTC QLQ-C30 [519], EORTC QLQ-BLM (muscle-invasive BC module) [520], and SF (Short Form)-36 [521, 522] and recently the BCI questionnaire specifically designed and validated for BC patients [523].

A psychometric test, such as the FACT-BL, should be used for recording BC morbidity. New intensive interviewing techniques have added valuable information to our knowledge of HRQoL, which greatly depends on patients' individual preferences [524].

7.9.2 Choice of urinary diversion

There is controversy about which type of urinary diversion is best for a patient's HRQoL [243]. Most patients stated that, given a choice, they would still opt for an orthotopic diversion rather than an ileal conduit [525]. Another study reported that, although urinary function is better in conduit patients, at long-term follow up (> 1 year) the urinary bother is the same in both diversion groups .

A SR based on 18 studies showed a slight, but not significant, better QoL in patients with an orthotopic diversion [526]. However, analysing only the studies comparing exclusively ileal conduit vs. ileal orthotopic neobladder, the advantage in QoL of the latter group was significant.

Due to improved surgical techniques in orthotopic bladder substitution, some recent studies are supportive of continent bladder substitutes [362, 520, 527]. Patients with an orthotopic substitution had significantly better physical function and a more active lifestyle compared to patients with an ileal conduit. It is important to note that HRQoL parameters are independent prognostic factors for OS [528]. Patients with a continent bladder-substitute generally scored more favourably than those with an incontinent diversion, as judged by body image, social activity and physical function [527, 529]. Note that all studies investigated mostly male patients. Also of interest is the urinary bother in female neobladder. Bartsch and co-workers found in 56 female patients day-time and night-time incontinence rates of respectively 29.6% and 35.2%. Thirty-five patients (62.5%) performed clean intermittent catheterisation, which is much worse compared to male neobladder patients. Moreover, patients with non-organ-confined disease ($p = 0.04$) and patients with a college degree ($p = 0.001$) showed worse outcome on HRQoL scores [530].

Nevertheless, the HRQoL outcome is most likely a result of good patient selection. An older more isolated patient is probably better served with an ileal conduit whereas a younger patient with more interest in body image and sexuality is better off with an orthotopic diversion.

7.9.3 *Non-curative or metastatic bladder cancer*

In non-curative or metastatic BC, HRQoL is reduced because of associated micturition problems, bleeding, pain and therefore disturbance of social and sexual life [531]. There is limited literature describing HRQoL in BC patients receiving palliative care [532], but there are reports of bladder-related symptoms relieved by palliative surgery [385], RT [533], and/or chemotherapy [534].

Alternative definitive treatments of MIBC, e.g. trimodality bladder-sparing procedures, have shown similar survival times compared to cystectomy. However, the impact on HRQoL has been controversial [136, 393, 535-538].

7.9.4 *Summary of evidence and recommendations for health-related quality of life*

Summary of evidence	LE
No randomised, prospective health-related quality of life (HRQoL) study has evaluated the different forms of definitive treatment for MIBC.	2b
In most patient groups studied, the overall HRQoL after cystectomy remains good, irrespective of the type of urinary diversion used. The suggestion that continent diversions are associated with a better HRQoL has not been sufficiently substantiated.	
Important determinants of (subjective) quality of life are a patient's personality, coping style and social support.	

Recommendations	GR
Use validated questionnaires to assess HRQoL in patients with MIBC.	B
Offer a continent urinary diversion unless a patient's comorbidities, tumour variables and coping abilities present clear contraindications.	C
Pre-operative patient information, patient selection, surgical techniques, and careful post-operative follow-up are the cornerstones for achieving good long-term results.	C
Encourage patients to actively participate in the decision-making process.	
Provide clear and exhaustive information on all potential benefits and side-effects, allowing patients to make informed decisions.	A

8. FOLLOW-UP

8.1 Introduction

An appropriate schedule for disease monitoring should be based on:

- natural timing of recurrence;
- probability and site of recurrence;
- functional monitoring after urinary diversion;
- possible treatment of recurrence [539].

Nomograms on CSS following RC have been developed and externally validated. However, their wider use cannot be recommended until further data becomes available [540, 541].

Surveillance protocols are commonly based on patterns of recurrence observed from retrospective series. Diagnosis of asymptomatic recurrence based on routine oncological follow-up and results from retrospective studies are controversial [542, 543]. Importantly, these retrospective studies use different follow-up regimens and imaging techniques that make final analysis and conclusive recommendations difficult. Prospective trials demonstrating the effectiveness of follow up after RC and its impact on OS are lacking [544].

8.2 Site of recurrence

8.2.1 Local recurrence

Local recurrence takes place in soft tissues at the original surgical site or LNs in the area of LND. Lymph node involvement above the aortic bifurcation can be considered metastatic recurrence [542].

Contemporary cystectomy has a 5-15% probability of pelvic recurrence. Most recurrence manifests during the first 24 months, often within six to eighteen months after surgery. However, late recurrence can occur up to five years after cystectomy. Pathological stage and LN status are predictive for pelvic recurrence, as well as positive margins, extent of LND, and peri-operative chemotherapy [545].

Patients have poor prognosis after pelvic recurrence. Even with treatment, the median survival ranges from four to eight months following diagnosis. Definitive therapy can prolong survival, but mostly provides significant palliation of symptoms. Treatment comprises systemic chemotherapy, local surgery, or RT [544].

8.2.2 Distant recurrence

Distant recurrence is seen in up to 50% of patients treated with cystectomy. Stage and nodal involvement are risk factors [546]. Systemic recurrence is more common in locally advanced disease (pT3/4), ranging from 32 to 62%, and in patients with LN involvement (range 52-70%) [547].

The most likely sites for distant recurrence are LNs, lungs, liver and bone. Nearly 90% of distant recurrence appears within the first three years after RC, mainly in the first two years, although late recurrence has been described after > 10 years. Median survival of patients with progressive disease treated with platinum-based chemotherapy is 9-26 months [548-550].

Despite periodic monitoring, > 50% of metastases are diagnosed after symptom appearance.

The value of monitoring in diagnosis of asymptomatic metastases and its impact on survival is questionable. Some studies have demonstrated no impact on survival despite using routine monitoring, although others have suggested that diagnosis of asymptomatic metastases, especially in the lungs, improves survival [542, 543]. Consideration must also be given to the possibility of longer survival in patients with minimal metastatic disease undergoing multimodal treatment, including metastasectomy. There are reports of survival rates of 28-33% at five years in patients undergoing resection of metastases after objective response to chemotherapy [495, 502].

The incidence of new urethral tumours after RC is 1.5-6.0% in men, with a mean recurrence-free interval of 13.5-39.0 months and median survival of 28-38 months, of which > 50% die from systemic disease.

Secondary urethral tumours are likely to occur at one to three years after surgery. Prophylactic urethrectomy at cystectomy is no longer justified in most patients. Independent predictors for urethral recurrence are: cystectomy for NMIBC, prostate involvement, and history of recurrent NMIBC [544].

In women, the main risk factor is bladder neck disease. Many studies have demonstrated that the risk of urethral recurrence after orthotopic diversion (0.9-4.0%) [551-554] is significantly less than after non-orthotopic diversion (6.4-11.1%) [545, 551, 553].

There is limited data and agreement about urethral follow-up, with some recommending routine surveillance with urethral wash and urine cytology [554], and others doubting the need for routine urethral surveillance [552, 555, 556]. Urethral washes and urine cytology do not appear to affect survival [555, 557]. However, there is a significant survival advantage in men with urethral recurrence diagnosed asymptotically vs. symptomatically, so follow-up of the male urethra is indicated in patients at risk of urethral recurrence [544].

Treatment is influenced by local stage and grade of urethral occurrence:

- in urethral CIS, BCG instillations have success rates of 83% [554];
- in invasive disease, urethrectomy should be performed if the urethra is the only site of disease;
- in distant disease, systemic chemotherapy is indicated [558].

Upper urinary urothelial carcinomas occur in 1.8-6.0% of cases and represent the most common sites of late recurrence (three years DFS following RC). Median OS is 10-55 months, and 60-67% of patients die of metastatic disease [544].

A meta-analysis found that 38% of UTUC recurrence was diagnosed by follow-up investigation, whereas in the remaining 62%, diagnosis was based on symptoms. When urine cytology was used in surveillance, the rate of primary detection was 7% and 29.6% with UUT imaging [559]. This meta-analysis concluded that patients with non-invasive cancer are twice as likely to have UTUC as patients with invasive disease. Multifocality increases the risk of recurrence by three-fold, while positive ureteral or urethral margins increase the risk by seven-fold. Radical nephroureterectomy can prolong survival [560].

8.2.3 Summary of evidence and recommendations for specific recurrence sites

Site of recurrence	Summary of evidence	LE	Recommendation	GR
Local recurrence	Poor prognosis. Treatment should be individualised depending on the local extent of tumour.	2b	Offer radiotherapy, chemotherapy and possibly surgery as options for treatment, either alone or in combination.	C
Distant recurrence	Poor prognosis.	2b	Offer chemotherapy as the first option, and consider metastasectomy in case of unique metastasis site.	C
Upper urinary tract recurrence	Multifocal disease (non-muscle-invasive bladder cancer/carcinoma <i>in situ</i> or positive ureteral margins).		See EAU guidelines on Upper Urinary Tract Urothelial Carcinomas.	
Secondary urethral tumour	Staging and treatment should be done as for primary urethral tumour.	3	Use local conservative treatment for non-invasive tumour.	C
			Offer urethrectomy in isolated invasive disease.	B
			Do not use urethral washes and cytology.	A

Although general recommendations are not advised based on high level of evidence, closer follow-up could be considered in patients with locally advanced disease or LN involvement. The suggested follow-up includes four-monthly CT scans during the first year, six-monthly until the third year, and annual imaging thereafter.

Patients with multifocal disease, NMIBC with CIS or positive ureteral margins are at higher risk of developing UTUC which can develop late (> 3 years). In those cases, monitoring of the UUT is mandatory during follow-up. Computed tomography is to be used to assess the UUT [559].

8.3 Follow-up of functional outcomes and complications

Apart from oncological surveillance, patients having undergone a urinary diversion deserve functional follow up. Complications related to urinary diversion are detected in 45% of patients during the first five years of follow up.

This rate increases over time, and exceeds 54% after fifteen years of follow up. Therefore, long-term follow up of functional outcomes is desirable [544] (LE: 3), and may stop after fifteen years.

The functional complications are diverse and include: vitamin B12 deficiency, metabolic acidosis, worsening of

renal function, urinary infections, urolithiasis, stenosis of uretero-intestinal anastomosis, stoma complications in patients with ileal conduit, neobladder continence problems, and emptying dysfunction [544]. Especially in women, approximately two-thirds need to catheterise their neobladder, while almost 45% do not void spontaneously at all [530]. Recently a 21% increased risk of fractures was described as compared to no cystectomy, due to chronic metabolic acidosis and subsequent long-term bone loss [561].

10. CONFLICT OF INTEREST

All members of the Muscle-invasive and Metastatic Bladder Cancer Guidelines Working Group have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publicly accessible through the European Association of Urology website: <https://uroweb.org/guideline/bladder-cancer-muscle-invasive-and-metastatic/?type=panel>.

This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

1. INTRODUCTION

1.1 Aims and scope

The aim of these guidelines is to deliver current evidence-based information on the diagnosis and treatment of patients with primary urethral carcinoma (UC). When the first carcinoma in the urinary tract is detected in the urethra, this is defined as primary UC, in contrast to secondary UC, which presents as recurrent carcinoma in the urethra after prior diagnosis and treatment of carcinoma elsewhere in the urinary tract. Most often, secondary UC is reported after radical cystectomy for bladder cancer [1, 2] (see Chapter 7.4 of the EAU Guidelines on Muscle-invasive and Metastatic Bladder Cancer (MIBC) [2]).

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account.

Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Guidelines Panel on MIBC is responsible for this publication. This is an international multidisciplinary group of clinicians, including urologists, a pathologist, an oncologist and a radiologist. Members of this panel have been selected based on their expertise to represent the professionals treating patients suspected of suffering from urethral carcinoma. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU Website Uroweb: www.uroweb.org/guidelines/primary-urethral-carcinoma/.

1.3 Publication history and summary of changes

The Primary Urethral Carcinoma Guidelines were first published in 2013 [3]. This is the third update of this document.

1.3.1 Summary of changes

The literature for the complete document has been assessed and updated, where relevant.

2. METHODS

2.1 Data identification

For the 2017 Primary urethral Carcinoma Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature. An updated systematic literature search was performed to identify studies reporting data on urethral malignancies since the prior search, covering a time frame between January 1st 2014 and September 20th, 2016. Databases searched included Ovid (Medline), EMBASE and the Cochrane Central Register of Controlled Trials and Cochrane Database of Systematic Reviews. A total of 309 records were identified, retrieved and screened for relevance. A detailed search strategy is available online:

<https://uroweb.org/guideline/primary-urethral-carcinoma/?type=appendices-publications>.

Recommendations in this text are assessed according to their level of evidence (LE) and Guidelines are given a grade of recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [4]. Additional methodology information can be found in the general Methodology section of this print, and online at the EAU website: <http://uroweb.org/guidelines/>.

A list of Associations endorsing the EAU Guidelines can also be viewed on line at the above address.

2.2 Review

This document was peer-reviewed prior to publication in 2015.

2.3 Future goals

The MIBC Guidelines Panel aims to systematically address the following key clinical topics for future updates of the Primary Urethral Carcinoma Guidelines:

- assessment of the accuracy of radiological imaging (MRI) for local staging of primary UC and its predictive value on clinical decision-making;
- the (long-term) efficacy of urethral-sparing surgery and radiochemotherapy for genital preservation in localised tumours;
- the prognostic impact of neoadjuvant and adjuvant treatment modalities in locally advanced disease.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Primary UC is considered a rare cancer, accounting for < 1% of all malignancies [5] (ICD-O3 topography code: C68.0 [6]). In early 2008, the prevalence of UC in the 27 European Union countries was 4,292 cases with an estimated annual incidence of 655 new cases [7]. The age-standardised ratio was 1.1 per million inhabitants (1.6/million in men and 0.6/million in women; with a male to female ratio of 2.9) [7]. There were differences between European regions; potentially caused by registration or classification [7]. Likewise, in an analysis of the Surveillance, Epidemiology and End Results (SEER) database, the incidence of primary UC peaked in the > 75 years age group (7.6/million). The age-standardised rate was 4.3/million in men and 1.5/million in women, and was almost negligible in those aged < 55 years (0.2/million) [8].

3.2 Aetiology

For male primary UC, various predisposing factors have been reported, including urethral strictures [9, 10], chronic irritation after intermittent catheterisation/urethroplasty [11-13], external beam irradiation therapy [14], radioactive seed implantation [15], and chronic urethral inflammation/urethritis following sexually transmitted diseases (i.e. condylomata associated with human papilloma virus 16) [16, 17]. In female UC, urethral diverticula [18-20] and recurrent urinary tract infections [21] have been associated with primary UC. Clear cell adenocarcinoma (AC) may also have a congenital origin [22, 23].

3.3 Histopathology

Both the Surveillance of Rare Cancers in Europe (RARECARE) project and SEER database have reported that urothelial carcinoma of the urethra is the predominant histological type of primary urethral cancer (54-65%), followed by squamous cell carcinoma (SCC) (16-22%) and AC (10-16%) [7, 8]. A recent SEER analysis of 2,065 men with primary UC (mean age: 73 years) found that UC was most common (78%), and SCC (12%) and AC (5%) were significantly less frequent [24]. In women, a recent report of the Dutch National Cancer Registry on primary urethral cancer reported that UC occurred in 45% of cases, followed by AC in 29%, SCC in 19%, and other histological entities in 6% [25].

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Tumour, Node, Metastasis (TNM) staging system

In men and women, UC is classified according to the 8th edition of the TNM classification [6] (Table 4.1). It should be noted that there is a separate TNM staging system for prostatic UC [6]. Of note, for cancers occurring in the urethral diverticulum, stage T2 is not applicable as urethral diverticula are lacking periurethral muscle [26].

Table 4.1: TNM classification (8th edition) for urethral carcinoma (UC) [6]
Primary tumour stage is separated into UC and UC of the prostate

T - Primary Tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Urethra (male and female)	
Ta	Non-invasive papillary, polypoid, or verrucous carcinoma
Tis	Carcinoma <i>in situ</i>
T1	Tumour invades subepithelial connective tissue
T2	Tumour invades any of the following structures: corpus spongiosum, prostate, periurethral muscle
T3	Tumour invades any of the following structures: corpus cavernosum, beyond prostatic capsule, anterior vagina, bladder neck (extraprostatic extension)
T4	Tumour invades other adjacent organs (invasion of the bladder)
Urothelial (transitional cell) carcinoma of the prostate	
Tis pu	Carcinoma <i>in situ</i> , involvement of prostatic urethra
Tis pd	Carcinoma <i>in situ</i> , involvement of prostatic ducts
T1	Tumour invades subepithelial connective tissue (for tumours involving prostatic urethra only)
T2	Tumour invades any of the following: prostatic stroma, corpus spongiosum, periurethral muscle
T3	Tumour invades any of the following: corpus cavernosum, beyond prostatic capsule, bladder neck (extraprostatic extension)
T4	Tumour invades other adjacent organs (invasion of the bladder or rectum)
N - Regional Lymph Nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node
N2	Metastasis in multiple lymph nodes
M - Distant Metastasis	
M0	No distant metastasis
M1	Distant metastasis

4.2 Tumour grade

The former World Health Organization (WHO) grading system of 1973 which differentiated urothelial carcinomas into three different grades (G1-G3) has been replaced by the grading system of 2004 that differentiates urothelial UC into papillary urothelial neoplasm of low malignant potential (PUNLMP), low grade and high grade. Non-urothelial UC is graded by a trinomial system that differentiates between well-differentiated (G1), moderately-differentiated (G2), and poorly-differentiated tumours (G3). Table 4.2 lists the different grading systems according to the WHO 1973 and 2004 systems [27]. The 2004 classification corresponds to the new 2016 WHO classification [28].

Table 4.2: Histopathological grading of urothelial and non-urothelial primary urethral carcinoma [27]

PUNLMP	Papillary urothelial neoplasm of low malignant potential
Low grade	Well differentiated
High grade	Poorly differentiated

Non-urothelial urethral carcinoma	
Gx	Tumour grade not assessable
G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated

Recommendation	LE	GR
Use the 2017 TNM classification and 2004/2016 WHO grading systems for pathological staging and grading of primary urethral carcinoma.	3	B

5. DIAGNOSTIC EVALUATION AND STAGING

5.1 History

When becoming clinically apparent, most patients (45-57%) with primary UC present with symptoms associated with locally advanced disease (T3/T4) [26, 27, 29]. At initial presentation visible haematuria or bloody urethral discharge is reported in up to 62% of the cases. Further symptoms of locally advanced disease include; an extraurethral mass (52%), bladder outlet obstruction (48%), pelvic pain (33%), urethrocutaneous fistula (10%), abscess formation (5%) or dyspareunia [29].

5.2 Clinical examination

In men, physical examination should comprise palpation of the external genitalia for suspicious indurations or masses and digital rectal examination [30]. In women, further pelvic examination with careful inspection and palpation of the urethra should be performed, especially in those with primary onset of irritative or obstructive voiding. In addition, bimanual examination, when necessary under general anaesthesia, should be performed for local clinical staging and to exclude the presence of colorectal or gynaecological malignancies. Bilateral inguinal palpation should be conducted to assess the presence of enlarged lymph nodes (LNs), describing location, size and mobility [31].

5.3 Urinary cytology

Cytological assessment of urine specimens in suspect cases of primary UC should be conducted according to the Paris system [32]. The role of urinary cytology in primary UC is limited since its sensitivity ranges between 55% and 59% [33]. Detection rates depend on the underlying histological entity. In male patients, the sensitivity for UC and SCC was reported to be 80% and 50%, respectively, whereas in female patients, sensitivity was found to be 77% for SCC and 50% for UC [32].

5.4 Diagnostic urethrocystoscopy and biopsy

Diagnostic urethrocystoscopy and biopsy enables primary assessment of a urethral tumour in terms of tumour extent, location and underlying histology [30]. To enable accurate pathological assessment of surgical margins, biopsy sites (proximal/distal end) should be marked and sent together with clinical information to the pathologist.

Careful cystoscopic examination is necessary to exclude the presence of concomitant bladder tumours [3, 34]. A cold-cup biopsy enables accurate tissue retrieval for histological analysis and avoids artificial tissue damage. In patients with larger lesions, transurethral resection (optionally in men under penile blood arrest using a tourniquet) can be performed for histological diagnosis. In patients with suspected UC of the prostatic urethra or ducts, resectoscope loop biopsy of the prostatic urethra (between the five and seven o'clock position from the bladder neck and distally around the area of the verumontanum) can contribute to an improved detection rate [35].

5.5 Radiological imaging

Radiological imaging of UC aims to assess local tumour extent and to detect lymphatic and distant metastatic spread. For local staging, there is increasing evidence that magnetic resonance imaging (MRI) is an accurate tool for monitoring tumour response to neoadjuvant chemoradiotherapy and evaluating the extent of local disease prior to exenterative surgery [36]. Imaging for regional LN metastases should concentrate on inguinal and pelvic LNs, using either MRI or computed tomography (CT). Distant staging should concentrate on chest and liver, with CT of the thorax and abdomen in all patients with invasive disease (> cT1N0M0) [36-40]. If imaging of the remainder of the urothelium is required, then CT should include CT urography with an excretory phase [41].

5.6 Regional lymph nodes

Enlarged LNs in UC often represent metastatic disease [42, 43]. In men, lymphatics from the anterior urethra drain into the superficial- and deep inguinal LNs and subsequently to the pelvic (external, obturator and internal iliac) LNs. Conversely, lymphatic vessels of the posterior urethra drain into the pelvic LNs. In women, the lymph of the proximal third drains into the pelvic LN chains, whereas the distal two-thirds initially drain into the superficial- and deep inguinal nodes [44, 45].

Nodal control in UC can be achieved either by regional LN dissection [30], radiotherapy [46] or chemotherapy [42]. Currently, there is still no clear evidence supporting prophylactic bilateral inguinal and/or pelvic lymphadenectomy in all patients with UC. However, in patients with clinically enlarged inguinal/pelvic LNs or invasive tumours, regional lymphadenectomy should be considered as initial treatment since cure might still be achievable with limited disease [30].

Summary of evidence	LE
Patients with clinically enlarged inguinal or pelvic lymph nodes often exhibit pathological lymph node metastasis.	3

Recommendations	LE	GR
Use urethrocytostcopy with biopsy and urinary cytology to diagnose urethral carcinoma.	3	B
Assess the presence of distant metastases by computed tomography of the thorax and abdomen.	3	B
Use pelvic magnetic resonance imaging to assess the local extent of urethral tumour (mapping tumour extension).	3	B

6. PROGNOSIS

6.1 Long-term survival after primary urethral carcinoma

According to the RARECARE project, the mean one- and five-year overall survival (OS) in patients with UC in Europe is 71% and 54%, respectively [7]. With longer follow-up, a SEER analysis of 1,615 cases reported median five- and ten-year OS rates of 46% and 29%, respectively. Cancer-specific survival (CSS) at five and ten years was 68% and 60%, respectively [8].

6.2 Predictors of survival in primary urethral carcinoma

In Europe, mean five-year OS does not substantially differ between the sexes [7]. Predictors of decreased survival in patients with primary UC are:

- advanced age (> 65 years) and black race [7, 47];
- stage, grade, nodal involvement [43] and metastasis [24];
- tumour size and proximal tumour location [24];
- extent of surgical treatment and treatment modality [24, 47];
- underlying histology [7, 25, 47];
- presence of concomitant bladder cancer [34];
- location of recurrence (urethral vs. non-urethral) [48].

Some limitations have to be taken into account in the interpretation of these results. In the Dutch study, the numbers were low (n = 91) [26]. In the large SEER database (n = 2,046), therapy is not well specified in relation to survival [25]. Finally, in contrast to the RARECARE project [7], the opposite findings were reported in the SEER database in relation to the role of histology on survival in male patients [47].

Summary of evidence	LE
Risk factors for survival in primary urethral carcinoma are: age, race, tumour stage and grade, nodal stage, presence of distant metastasis, histological type, tumour size, tumour location, concomitant bladder cancer and type and modality of treatment.	3

7. DISEASE MANAGEMENT

7.1 Treatment of localised primary urethral carcinoma in males

Previously, treatment of male anterior UC has followed the procedure for penile cancer, with aggressive surgical excision of the primary lesion with a wide safety margin [30]. Distal urethral tumours exhibit significantly improved survival rates compared with proximal tumours [49]. Therefore, optimising treatment of distal UC has become the focus of clinicians to improve functional outcome and quality of life, while preserving oncological safety. A retrospective series found no evidence of local recurrence, even with < 5 mm resection margins (median follow-up: 17-37 months), in men with pT1-3N0-2 anterior UC treated with well-defined penis-preserving surgery and additional iliac/inguinal lymphadenectomy for clinically suspected LN disease [50]. This suggests that prognosis is mainly determined by nodal stage. Similar results for the feasibility of penile-preserving surgery have also been reported in recent series [51, 52].

Summary of evidence	LE
In distal urethral tumours performing a partial urethrectomy with a minimal safety margin does not increase the risk of local recurrence.	3

Recommendation	LE	GR
Offer distal urethrectomy as an alternative to penile amputation in localised anterior urethral tumours, if surgical margins are negative.	3	B

7.2 Treatment of localised urethral carcinoma in females

7.2.1 Urethrectomy and urethra-sparing surgery

In women with localised UC, to provide the highest chance of local cure, primary radical urethrectomy should remove all the periurethral tissue from the bulbocavernosus muscle bilaterally and distally, with a cylinder of all adjacent soft tissue up to the pubic symphysis and bladder neck. Bladder neck closure and appendicovesicostomy for primary anterior urethral lesions has been shown to provide satisfactory functional results in women [30].

Recent series have reported outcomes in women with mainly anterior UC undergoing primary treatment with urethra-sparing surgery or radiotherapy, compared to primary urethrectomy, with the aim of maintaining integrity and function of the lower urinary tract [53-55]. In long-term series with a median follow-up of 153-175 months, local recurrence rates in women undergoing partial urethrectomy with intra-operative frozen section analysis were 22-60%, and distal sleeve resection of > 2 cm resulted in secondary urinary incontinence in 42% of patients who required additional reconstructive surgery [54].

Ablative surgical techniques, i.e., transurethral resection (TUR) or laser, used for small distal UC, have also resulted in considerable local failure rates of 16%, with a CSS rate of 50%. This emphasises the critical role of local tumour control in women with distal UC to prevent local and systemic progression [53].

7.2.2 Radiotherapy

In women, radiotherapy was investigated in several older long-term series with a medium follow up of 91-105 months [46, 50]. With a median cumulative dose of 65 Gy (range: 40-106 Gy), the five year local control rate was 64% and seven year CSS was 49% [46]. Most local failures (95%) occurred within the first two years after primary treatment [50]. The extent of urethral tumour involvement was found to be the only parameter independently associated with local tumour control but the type of radiotherapy (external beam radiotherapy [EBRT] vs. interstitial brachytherapy) was not [46]. In one study, the addition of brachytherapy to EBRT reduced the risk of local recurrence by a factor of 4.2 [56]. Of note, pelvic toxicity in those achieving local control was considerable (49%), including urethral stenosis, fistula, necrosis, and cystitis and/or haemorrhage, with 30% of the reported complications graded as severe [46].

Summary of evidence	LE
In anterior tumours, urethra-sparing surgery and local radiotherapy represent alternatives to primary urethrectomy but are associated with increased risk of tumour recurrence and local toxicity.	3

Recommendations	LE	GR
Offer urethra-sparing surgery as an alternative to primary urethrectomy to women with anterior urethral tumours, if negative surgical margins can be achieved intra-operatively.	3	B
Offer local radiotherapy as an alternative to urethral surgery to women with localised urethral tumours, but discuss local toxicity.	3	C

7.3 Multimodal treatment in advanced urethral carcinoma in both genders

7.3.1 Preoperative platinum-based chemotherapy

Recent retrospective studies have reported that modern platinum-based polychemotherapeutic regimens are effective in advanced primary UC, providing prolonged survival even in LN-positive disease. Moreover, they have emphasised the critical role of surgery after chemotherapy to achieve long-term survival in patients with locally advanced UC.

In a series of 39 patients treated with perioperative platinum-based chemotherapy for advanced primary UC, preoperative chemotherapy was found to be associated with improved progression-free and OS compared to surgery followed by adjuvant chemotherapy [57]. Another series reported outcomes in 44 patients with advanced primary UC treated with specific cisplatin-based polychemotherapeutic regimens according to the underlying histology. The overall response rate for the various regimens was 72% and the median OS 32 months. Patients who underwent surgery after chemotherapy had a significantly improved OS compared with those who were managed with chemotherapy alone [42].

7.3.2 Preoperative chemoradiotherapy in locally advanced squamous cell carcinoma of the urethra

The clinical feasibility of preoperative local radiotherapy with concurrent radiosensitising chemotherapy as an alternative to surgery in locally advanced SCC has been reported in several recent series. This approach offers a potential for genital preservation [57-62]. The largest and recently updated series reported outcomes in 25 patients with primary locally advanced SCC of the urethra treated with two cycles of 5-fluorouracil and mitomycin C with concurrent EBRT. A complete response to primary chemoradiotherapy was observed in ~80%. The five-year OS and DSS survival was 52% and 68%, respectively. In this updated series, salvage surgery initiated only in non-responders or in case of local failure was not reported to be associated with improved survival [58].

Summary of evidence	LE
In locally advanced urethral carcinoma, cisplatin-based chemotherapy with curative intent prior to surgery improves survival compared to chemotherapy alone, or surgery followed by chemotherapy.	4
In locally advanced squamous cell carcinoma (SCC) of the urethra, the prognostic role and timing of surgery after completion of chemoradiotherapy is unclear.	4

Recommendations	LE	GR
Discuss treatment of patients with locally advanced urethral carcinoma within a multidisciplinary team of urologists, radio-oncologists and oncologists.	4	A
Use cisplatin-based chemotherapeutic regimens with curative intent prior to surgery.	4	C
In locally advanced SCC of the urethra, offer the combination of curative radiotherapy with radiosensitising chemotherapy for genital preservation.	4	C

7.4 Treatment of urothelial carcinoma of the prostate

Local conservative treatment with extensive TUR and subsequent Bacillus-Calmette-Guérin (BCG) instillation is effective in patients with Ta or Tis prostatic UC [63, 64]. Likewise, patients undergoing TUR of the prostate prior to BCG experience improved complete response rates compared with those who do not (95% vs. 66%) [65]. Risk of understaging local extension of prostatic urethral cancer at TUR is increased, especially in patients with ductal or stromal involvement [66]. In smaller series, response rates to BCG in patients with prostatic duct involvement have been reported to vary between 57 and 75% [63, 67]. Some earlier series have reported superior oncological results for the initial use of radical cystoprostatectomy as a primary treatment option in patients with ductal involvement [68, 69]. In 24 patients with prostatic stromal invasion treated with radical cystoprostatectomy, a LN mapping study found that twelve patients had positive LNs, with an increased proportion located above the iliac bifurcation [70].

Summary of evidence	LE
Patients undergoing transurethral resection of the prostate for prostatic urothelial carcinoma (UC) prior to bacillus-Calmette-Guérin (BCG) treatment show superior complete response rates compared to those who do not.	3

Recommendations	LE	GR
Offer a urethra-sparing approach with transurethral resection (TUR) and BCG to patients with non-invasive urethral carcinoma or carcinoma <i>in situ</i> of the prostatic urethra and prostatic ducts.	3	C
In patients with non-invasive UC or carcinoma <i>in situ</i> , perform a prior TUR of the prostate to improve response to BCG.	3	C
In patients not responding to BCG, or in patients with extensive ductal or stromal involvement, perform a cystoprostatectomy with extended pelvic lymphadenectomy.	3	C

8. FOLLOW-UP

Given the low incidence of primary urethral cancer, follow-up has not been investigated systematically so far. Therefore, it seems reasonable to tailor surveillance regimens according to patients' individual risk factors (see Chapter 6.2). In patients undergoing urethra-sparing surgery, it seems prudent to advocate a more extensive follow-up with urinary cytology, urethrocystoscopy and cross-sectional imaging despite the lack of specific data.

10. CONFLICT OF INTEREST

All members of the Muscle-invasive and Metastatic Bladder Cancer Guidelines Panel have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website: <http://www.uroweb.org/guidelines/primary-urethral-carcinoma/>. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

TABLE OF CONTENTS	PAGE
1. INTRODUCTION	9
1.1 Aims and scope	9
1.2 Panel composition	9
1.2.1 Acknowledgement	9
1.3 Available publications	9
1.4 Publication history and summary of changes	9
1.4.1 Publication history	9
1.4.2 Summary of changes	9
2. METHODS	11
2.1 Data identification	11
2.2 Review	12
2.3 Future goals	12
3. EPIDEMIOLOGY AND AETIOLOGY	12
3.1 Epidemiology	12
3.2 Aetiology	13
3.2.1 Family history/genetics	13
3.2.2 Risk factors	13
3.2.2.1 Metabolic syndrome (MetS)	13
3.2.2.1.1 Diabetes/metformin	13
3.2.2.1.2 Cholesterol/statins	13
3.2.2.1.3 Obesity	13
3.2.2.2 Dietary factors	13
3.2.2.3 Hormonally active medication	14
3.2.2.3.1 5-alpha-reductase inhibitors (5-ARIs)	14
3.2.2.3.2 Testosterone	14
3.2.2.4 Other risk factors	14
3.2.3 Summary of evidence and guidelines for epidemiology and aetiology	14
4. CLASSIFICATION AND STAGING SYSTEMS	15
4.1 Classification	15
4.2 Gleason score and International Society of Urological Pathology 2014 grade groups	15
4.3 Prognostic relevance of stratification	16
5. DIAGNOSTIC EVALUATION	16
5.1 Screening and early detection	16
5.1.1 Guidelines for screening and early detection	18
5.2 Clinical diagnosis	18
5.2.1 Digital rectal examination	18
5.2.2 Prostate-specific antigen	18
5.2.2.1 PSA density	19
5.2.2.2 PSA velocity and doubling time	19
5.2.2.3 Free/total PSA ratio	19
5.2.2.4 Additional serum testing	19
5.2.2.5 PCA3 marker	19
5.2.2.6 Guidelines for risk-assessment of asymptomatic men	20
5.2.3 Prostate biopsy	20
5.2.3.1 Baseline biopsy	20
5.2.3.2 Repeat biopsy after previously negative biopsy	20
5.2.3.3 Saturation biopsy	21
5.2.3.4 Sampling sites and number of cores	21
5.2.3.5 Diagnostic transurethral resection of the prostate	21
5.2.3.6 Seminal vesicle biopsy	21
5.2.3.7 Transition zone biopsy	21
5.2.3.8 Antibiotics prior to biopsy	21
5.2.3.9 Local anaesthesia prior to biopsy	21
5.2.3.10 Fine-needle aspiration biopsy	21

	5.2.3.11	Complications	21		
5.2.4		The role of imaging	22		
	5.2.4.1	Transrectal ultrasound (TRUS) and ultrasound-based techniques	22		
	5.2.4.2	Multiparametric magnetic resonance imaging	22		
	5.2.4.3	Guidelines for imaging	23		
5.2.5		Pathology of prostate needle biopsies	23		
	5.2.5.1	Processing	23		
	5.2.5.2	Microscopy and reporting	23		
	5.2.5.3	Tissue-based prognostic biomarker testing	24		
5.2.6		Histopathology of radical prostatectomy specimens	24		
	5.2.6.1	Processing of radical prostatectomy specimens	24		
		5.2.6.1.1 Guidelines for processing prostatectomy specimens	24		
	5.2.6.2	Radical prostatectomy specimen report	24		
		5.2.6.2.1 Gleason score in prostatectomy specimens	25		
		5.2.6.2.2 Definition of extraprostatic extension	25		
	5.2.6.3	PCa volume	26		
	5.2.6.4	Surgical margin status	26		
5.2.7		Guidelines for the clinical diagnosis of prostate cancer	26		
5.3		Diagnosis: Clinical staging	26		
	5.3.1	T-staging	26		
		5.3.1.1 Definitions	26		
		5.3.1.2 DRE, PSA level and biopsy findings	26		
		5.3.1.3 Transrectal ultrasound	27		
		5.3.1.4 Multiparametric magnetic resonance imaging	27		
	5.3.2	N-staging	27		
		5.3.2.1 Computed tomography and magnetic resonance imaging	27		
		5.3.2.2 Choline PET/CT	28		
		5.3.2.3 New methods	28		
	5.3.3	M-staging	28		
		5.3.3.1 Bone scan	28		
		5.3.3.2 Other modalities	28		
5.4		Guidelines for staging of prostate cancer	29		
6.		DISEASE MANAGEMENT	29		
	6.1	Treatment: Deferred treatment (active surveillance/watchful waiting)	29		
		6.1.1 Introduction	29		
			6.1.1.1 Definition	29	
				6.1.1.1.1 Active surveillance	29
				6.1.1.1.2 Watchful waiting	30
		6.1.2 Deferred treatment of localised PCa (stage T1/T2, Nx/N0, M0)	30		
			6.1.2.1 Active surveillance	30	
			6.1.2.2 Watchful waiting	32	
				6.1.2.2.1 Patient selection for watchful waiting	32
				6.1.2.2.2 Outcome of watchful waiting compared to active treatment	32
			6.1.2.3 The ProtecT study	33	
		6.1.3 Deferred treatment for locally advanced PCa (stage T3-T4, Nx-N0, M0)	33		
		6.1.4 Deferred treatment for metastatic PCa (stage M1)	33		
		6.1.5 Guidelines for active surveillance and watchful waiting	34		
	6.2	Treatment: Radical prostatectomy	34		
		6.2.1 Introduction	34		
		6.2.2 Low-risk PCa	34		
		6.2.3 Intermediate-risk, localised PCa	35		
		6.2.4 High-risk and locally advanced PCa	35		
			6.2.4.1 High-risk PCa	35	
				6.2.4.1.1 Gleason score 8-10	35
				6.2.4.1.2 Prostate-specific antigen > 20 ng/mL	35
			6.2.4.2 Locally advanced PCa	36	
		6.2.5 Indication and extent of pelvic lymph node dissection	36		
			6.2.5.1 Technique of lymph node dissection	36	

	6.2.5.1.1	Sentinel node biopsy analysis	36
6.2.6		Radical prostatectomy in cN0 patients who are found to have pathologically confirmed lymph node invasion (pN1)	36
	6.2.6.1	Outcome of pN1 disease	36
	6.2.6.1.1	Prognostic indicators	36
6.2.7		Adjuvant treatment	36
	6.2.7.1	Adjuvant treatment after RP	36
	6.2.7.2	Adjuvant androgen ablation in men with pN1 disease	36
	6.2.7.3	Adjuvant radiotherapy in men with pN1 disease	37
	6.2.7.4	Adjuvant chemotherapy	37
	6.2.7.5	Guidelines for extended lymph node dissection in prostate cancer and pN+ patients	37
6.2.8		Comparing RP surgical approaches	37
6.2.9		Indications for nerve-sparing surgery	37
6.2.10		Guidelines for radical prostatectomy	38
6.3		Treatment: definitive radiotherapy	38
	6.3.1	Introduction	38
	6.3.2	Technical aspects: three-dimensional conformal radiotherapy and intensity-modulated external-beam radiotherapy	38
	6.3.3	Radiotherapy for localised PCa	39
	6.3.3.1	Dose escalation	39
	6.3.3.2	Hypofractionation	40
	6.3.3.3	Neoadjuvant or adjuvant hormone therapy plus radiotherapy	42
	6.3.3.4	Neoadjuvant chemotherapy plus radiotherapy	44
	6.3.3.5	Combined dose-escalated radiotherapy and androgen-deprivation therapy	44
	6.3.3.6	Recommended external beam radiation therapy treatment policy for localised PCa	44
	6.3.3.6.1	Low-risk PCa	44
	6.3.3.6.2	Intermediate-risk PCa	44
	6.3.3.6.3	Localised high-risk PCa	44
	6.3.3.6.4	Locally advanced PCa: T3-4 N0, M0	44
	6.3.3.6.5	MRC PR3/PR07 study - The National Cancer Institute of Canada (NCIC)/UK Medical Research Council (MRC)/ Southwest Oncology Group (SWOG) intergroup PR3/PR07 study	44
	6.3.3.7	Lymph node irradiation	45
	6.3.3.7.1	Prophylactic LN irradiation in clinically N0 prostate cancer (estimated cN0)	45
	6.3.3.7.2	Clinical, or pathological node positive, M0 disease	45
	6.3.4	Proton beam therapy	45
	6.3.5	Low-dose rate and high-dose rate brachytherapy	46
	6.3.5.1	Low-dose rate (LDR) brachytherapy	46
	6.3.5.2	High-Dose Rate (HDR) brachytherapy	46
	6.3.6	Immediate (adjuvant) post-operative external irradiation after RP (cN0 or pN0)	47
	6.3.6.1	EORTC 22911	47
	6.3.6.2	ARO trial	47
	6.3.6.3	SWOG 8794 trial	47
	6.3.6.4	Conclusion	47
	6.3.7	Summary of evidence and guidelines for definitive radiotherapy	48
6.4		Treatment: Options other than surgery and radiotherapy for the primary treatment of localised prostate cancer	49
	6.4.1	Background	49
	6.4.2	Cryosurgery	49
	6.4.2.1	Results of cryosurgery for PCa	49
	6.4.3	High-intensity focused ultrasound of the prostate	49
	6.4.3.1	Results of high-intensity focused ultrasound in PCa	50
	6.4.4	Focal therapy of PCa	50

6.4.5	Summary of evidence and guidelines for experimental therapeutic options to treat clinically localised prostate cancer	51
6.5	Treatment: Hormonal therapy - rationale and available drugs	51
6.5.1	Introduction	51
6.5.1.1	Different types of hormonal therapy	51
6.5.2	Testosterone-lowering therapy (castration)	51
6.5.2.1	Castration level	51
6.5.2.2	Bilateral orchiectomy	51
6.5.3	Oestrogens	51
6.5.4	Luteinising-hormone-releasing hormone agonists	51
6.5.4.1	Achievement of castration levels	51
6.5.4.2	'Flare-up' phenomenon	52
6.5.5	Luteinising-hormone-releasing hormone antagonists	52
6.5.6	Anti-androgens	52
6.5.6.1	Steroidal anti-androgens	52
6.5.6.1.1	Cyproterone acetate	52
6.5.6.2	Non-steroidal anti-androgens	52
6.5.6.2.1	Nilutamide	52
6.5.6.2.2	Flutamide	52
6.5.6.2.3	Bicalutamide	53
6.5.7	New compounds (for castrate-resistant patients only)	53
6.5.7.1	Abiraterone acetate	53
6.5.7.2	Enzalutamide	53
6.5.8	Cost-effectiveness of hormonal therapy options	53
6.6	Treatment: Metastatic prostate cancer	53
6.6.1	Introduction	53
6.6.2	Prognostic factors	53
6.6.3	First-line hormonal treatment	53
6.6.3.1	Prevention of 'flare-up'	54
6.6.4	Combination therapies	54
6.6.4.1	Complete androgen blockade	54
6.6.4.2	Non-steroidal anti-androgen monotherapy	54
6.6.4.3	Intermittent versus continuous androgen deprivation therapy	54
6.6.4.4	Immediate versus deferred androgen deprivation therapy	55
6.6.5	Hormonal treatment combined with chemotherapy	55
6.6.6	Prostate targeted therapy in newly diagnosed metastatic disease	56
6.6.7	Metastasis-directed therapy	56
6.6.8	Imaging as marker of response in metastatic prostate cancer	56
6.6.9	Guidelines for the first-line treatment of metastatic prostate cancer	56
6.6.10	Guidelines for hormonal treatment of metastatic prostate cancer	57
6.7	Management of prostate cancer in older men	57
6.7.1	Evaluating health status in senior adults	57
6.7.1.1	Introduction	57
6.7.1.2	Evaluation of life expectancy, comorbidity and health status	57
6.7.1.2.1	Comorbidity	57
6.7.1.2.2	Dependence in daily activities	58
6.7.1.2.3	Malnutrition	58
6.7.1.2.4	Cognitive impairment	58
6.7.1.2.5	Baseline screening using the G8 screening tool	59
6.7.1.2.6	Conclusions	61
6.7.1.3	Guidelines for the evaluation of health status in elderly men	62
6.7.2	Specific aspects of PCa treatment in older men	62
6.7.2.1	Localised PCa	62
6.7.2.1.1	Deferred treatment (active surveillance, watchful waiting)	62
6.7.2.1.2	Radical prostatectomy	63
6.7.2.1.3	External beam radiotherapy	63
6.7.2.1.4	Minimally invasive therapies	63
6.7.2.1.5	Androgen deprivation therapy	63
6.7.2.2	Advanced PCa	63
6.7.2.2.1	Hormone-naïve metastatic PCa	63

	6.7.2.2.2	Metastatic CRPC	63
	6.7.3	Guidelines for the treatment of senior adults (> 70 years of age)	63
6.8		Summary of guidelines for the primary treatment of prostate cancer	64
6.9		Treatment - Management of PSA-only recurrence after treatment with curative intent	67
	6.9.1	Background	67
	6.9.2	Definitions	68
	6.9.2.1	Definition of biochemical recurrence	68
	6.9.3	Natural history of biochemical recurrence	68
	6.9.3.1	Post-radical prostatectomy biochemical recurrence	68
	6.9.3.2	Post-radiotherapy biochemical recurrence	68
	6.9.4	Assessment of metastases	68
	6.9.4.1	Bone scan and abdominopelvic computed tomography	68
	6.9.4.2	Choline PET/CT	69
	6.9.4.3	Other radionuclide techniques	69
	6.9.4.4	Whole-body and axial magnetic resonance imaging	69
	6.9.4.5	Assessment of local recurrences	69
	6.9.4.5.1	Local recurrence after radical prostatectomy	69
	6.9.4.5.2	Local recurrence after radiation therapy	70
	6.9.4.6	Guidelines for imaging in patients with biochemical recurrence	70
	6.9.5	Treatment of PSA-only recurrences	70
	6.9.5.1	Radiotherapy (salvage radiotherapy - with or without androgen-deprivation therapy for PSA-only recurrence after radical prostatectomy)	71
	6.9.5.1.1	Dose and toxicity	71
	6.9.5.1.2	Comparison of adjuvant radiotherapy (ART) and salvage radiotherapy	72
	6.9.5.2	Hormonal therapy	72
	6.9.5.3	Observation	73
	6.9.6	Management of PSA failures after radiation therapy	73
	6.9.6.1	Salvage radical prostatectomy	73
	6.9.6.1.1	Oncological outcomes	73
	6.9.6.1.2	Morbidity	73
	6.9.6.2	Summary of salvage radical prostatectomy	74
	6.9.7	Salvage cryoablation of the prostate	74
	6.9.7.1	Oncological outcomes	74
	6.9.7.2	Morbidity	74
	6.9.7.3	Summary of salvage cryoablation of the prostate	75
	6.9.8	Salvage brachytherapy for radiotherapy failure	75
	6.9.9	Salvage high-intensity focused ultrasound	75
	6.9.9.1	Oncological outcomes	75
	6.9.9.2	Morbidity	76
	6.9.9.3	Summary of salvage high-intensity focused ultrasound	76
	6.9.10	Observation	76
	6.9.11	Salvage lymph node dissection	76
	6.9.11.1	Guidelines for salvage lymph node dissection	76
	6.9.12	Guidelines for second-line therapy after treatment with curative intent	76
6.10		Treatment: Castration-resistant PCa (CRPC)	77
	6.10.1	Non-metastatic castration-resistant PCa	77
	6.10.2	Metastatic castration-resistant PCa	77
	6.10.2.1	Conventional androgen deprivation in castration-resistant PCa	77
	6.10.3	First-line treatment of metastatic castration-resistant PCa	78
	6.10.3.1	Abiraterone	78
	6.10.3.2	Enzalutamide	78
	6.10.3.3	Docetaxel regimen	78
	6.10.3.4	Sipuleucel-T79	78
	6.10.4	Second-line treatment for mCRPC	80
	6.10.4.1	Cabazitaxel	80
	6.10.4.2	Abiraterone acetate after prior docetaxel	80
	6.10.4.3	Enzalutamide after docetaxel	80
	6.10.4.4	Radium-223	80

6.10.5	Treatment after docetaxel and one line of hormonal treatment for mCRPC	81
6.10.6	Monitoring of treatment	81
6.10.7	When to change treatments	81
6.10.8	Symptomatic management in metastatic castration-resistant PCa	81
6.10.8.1	Common complications due to bone metastases	81
6.10.9	Preventing skeletal-related events	82
6.10.9.1	Bisphosphonates	82
6.10.9.2	RANK ligand inhibitors	82
6.10.10	Summary of evidence and guidelines for life-prolonging treatments of castrate-resistant PCa	82
6.10.11	Guidelines for cytotoxic treatment in castrate-resistant PCa	83
6.10.12	Guidelines for supportive care of castrate-resistant PCa	83
7.	FOLLOW-UP	83
7.1	Follow-up: After local treatment	83
7.1.1	Definition	83
7.1.2	Why follow-up?	83
7.1.3	How to follow-up?	83
7.1.3.1	Prostate-specific antigen monitoring	83
7.1.3.2	Definition of prostate-specific antigen progression	84
7.1.3.3	Prostate-specific antigen monitoring after radical prostatectomy	84
7.1.3.4	PSA monitoring after radiotherapy	84
7.1.3.5	Digital rectal examination	84
7.1.3.6	Transrectal ultrasound, bone scintigraphy, computed tomography, magnetic resonance imaging, and ¹¹ C-choline positron emission tomography computed tomography	84
7.1.3.6.1	Transrectal ultrasonography/magnetic resonance imaging guided biopsy. Biopsy of the prostate bed and urethrovesical anastomosis or of the remaining prostate after radiotherapy, are only indicated if local recurrence affects treatment decisions.	84
7.1.4	When to follow-up?	84
7.1.5	Summary of evidence and guidelines for follow-up after treatment with curative intent	85
7.2	Follow-up: During hormonal treatment	85
7.2.1	Introduction	85
7.2.2	Purpose of follow-up	85
7.2.3	Methods of follow-up	85
7.2.3.1	Clinical follow-up	85
7.2.3.1.1	Prostate-specific antigen monitoring	85
7.2.3.1.2	Creatinine, haemoglobin and liver function monitoring	85
7.2.3.1.3	Bone scan, ultrasound and chest X-ray	86
7.2.3.1.4	Testosterone monitoring	86
7.2.3.1.5	Monitoring of metabolic complications	86
7.2.4	When to follow-up	86
7.2.4.1	Stage M0 - M1 patients	86
7.2.4.2	Castration-refractory PCa	86
7.2.5	Guidelines for follow-up during hormonal treatment	87
8.	QUALITY OF LIFE OUTCOMES IN PROSTATE CANCER	87
8.1	Introduction	87

1. INTRODUCTION

1.1 Aims and scope

The Prostate Cancer (PCa) Guidelines Panel have prepared this guidelines document to assist medical professionals in the evidence-based management of PCa.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account.

Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The PCa Guidelines Panel consists of an international multidisciplinary group of urologists, radiation oncologists, medical oncologists, radiologists, a pathologist and a patient representative.

All imaging sections in the text have been developed, jointly with the European Society of Urogenital Radiology (ESUR). Representatives of ESUR in the PCa Guidelines Panel are (in alphabetical order): Prof.Dr. O Rouvière and Dr. I.G. Schoots.

Section 6.3: Treatment - Definitive Radiotherapy, has been developed jointly with the European Society for Radiotherapy & Oncology (ESTRO). Representatives of ESTRO in the PCa Guidelines Panel are (in alphabetical order): Prof.Dr. M. Bolla, Prof.Dr. A.M. Henry, Prof.Dr. M.D. Mason and Prof.Dr. T. Wiegel.

All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website Uroweb: <http://uroweb.org/guideline/prostatecancer/?type=panel>.

1.2.1 Acknowledgement

The PCa Guidelines Panel are most grateful for the support and considerable expertise provided by Prof.Dr. J-P. Droz, Emeritus Professor of Medical Oncology (Lyon, France) on the topic of 'Management of PCa in senior adults'. As a leading expert in this field, and prominent member of the International Society of Geriatric Oncology, his contribution has been invaluable.

1.3 Available publications

A quick reference document (Pocket guidelines) is available, both in print and in a number of versions for mobile devices. These are abridged versions which may require consultation together with the full text version. Several scientific publications are available [1, 2] as are a number of translations of all versions of the PCa Guidelines. All documents can be accessed on the EAU website: <http://uroweb.org/guideline/prostate-cancer/>.

1.4 Publication history and summary of changes

1.4.1 Publication history

The EAU PCa Guidelines were first published in 2001. This 2017 document presents a full update of the 2016 full text document.

1.4.2 Summary of changes

New and relevant evidence has been identified, collated and appraised through a structured assessment of the literature and incorporated in all chapters of the 2017 EAU PCa Guidelines.

Key changes for the 2017 print:

- Chapter 3 - Epidemiology and aetiology. This section has been completely renewed.
- Chapter 4 - Classification and staging systems. This chapter has been expanded with a new section (4.3 Prognostic relevance of stratification). Additional information on the International Society of Urological Pathology Gleason grading has been included in Table 4.2.2 (EAU risk groups for biochemical recurrence of localised and locally advanced prostate cancer).
- Section 6.6.8 - Imaging as marker of response in metastatic prostate cancer. This is a new section.
- Chapter 6.7 - Management of PCa in older men. Two new figures have been included.
- Chapter 8 - Quality of life outcomes in prostate cancer. This chapter is partly based on the findings of a new systematic review (SR) (see below). A second review is ongoing, the findings of which will be incorporated in the 2018 print of these Guidelines.

Changes in the summaries of evidence and recommendations can be found in sections:

3.2.3 Summary of evidence and guidelines for epidemiology and aetiology

Summary of evidence
Prostate cancer is a major health issue in men, the incidence mainly dependent on age.
Genetic factors are associated with risk of (aggressive) PCa but ongoing trials will need to define the clinical applicability of screening for genetic susceptibility of PCa.
A variety of exogenous/environmental factors may have an impact on the risk of progression.
5-ARIs are not EMA-approved for PCa prevention.
Selenium or vitamin-E supplements have no beneficial effect in preventing PCa.
In hypogonadal men, testosterone supplementation does not increase the risk of PCa.

Recommendation
No definitive recommendation can be provided for specific preventive or dietary measures to reduce the risk of developing prostate cancer.

Table 4.2.2: EAU risk groups for biochemical recurrence of localised and locally advanced prostate cancer

Definition			
Low-risk	Intermediate-risk	High-risk	
PSA < 10 ng/mL and GS < 7 (ISUP Grade 1) and cT1-2a	PSA 10-20 ng/mL or GS 7 (ISUP Grade 2/3) or cT2b	PSA > 20 ng/mL or GS > 7 (ISUP Grade 4/5) or cT2c	any PSA any GS cT3-4 or cN+ Any ISUP Grade
Localised			Locally advanced

GS = Gleason score; ISUP = International Society for Urological Pathology; PSA = prostate-specific antigen.

6.1.5 Guidelines for active surveillance and watchful waiting

Recommendations - active surveillance	LE	GR
Perform multiparametric magnetic resonance imaging before a confirmatory biopsy.	2b	B
During confirmatory biopsy include systematic and targeted biopsies.	2a	B

6.2.7.5 Guidelines for eLND in prostate cancer and pN+ patients

Recommendation	LE	GR
Do not perform a frozen section of nodes during radical prostatectomy to decide whether to proceed with, or abandon, the procedure.	2a	A

6.2.10 Guidelines for radical prostatectomy

Recommendations	LE	GR
Offer both radical prostatectomy and radiotherapy in patients with low- and intermediate-risk disease and a life expectancy > 10 years.	1b	A
Offer active surveillance as an alternative to surgery in patients with low-risk disease and a life expectancy of > 10 years.	1b	A

6.3.8 Summary of evidence and guidelines for definitive radiotherapy

Summary of evidence	LE
The optimum duration of androgen deprivation therapy (ADT) with external beam radiation therapy (EBRT) is well established in the literature. There is no evidence that these durations should change when using brachytherapy boost with EBRT.	1b
Limited data, from experienced centres only, are available for the use of fractionated high-dose-rate brachytherapy as monotherapy in patients with low and intermediate-risk PCa.	2a

Recommendations	LE	GR
Moderate hypofractionation (HFX) with IMRT including image-guided radiation therapy (IGRT) to the prostate only can be offered to carefully selected patients with localised disease (as discussed in the text).	1a	A
Moderate HFX should adhere to radiotherapy-protocols from trials with equivalent outcome and toxicity, i.e. 60 Gy/20 fractions in four weeks or 70 Gy/28 fractions in six weeks.	1a	A

6.9.4.6 Guidelines for imaging in patients with biochemical recurrence

Prostate-specific antigen (PSA) recurrence after radical prostatectomy	LE	GR
PSA \geq 1 ng/mL: positron emission tomography (PET)/computed tomography (CT) imaging is recommended using choline or prostate-specific membrane antigen (PMSA).	2b	A

8.3.1.1 Guidelines for long term quality of life in men with localised disease

Recommendations	LE	GR
Advise eligible patients for active surveillance, that global quality of life is equivalent for up to five years compared to radical prostatectomy or radiotherapy.	1b	A
Discuss the negative impact of surgery on urinary and sexual function, as well as the negative impact of radiotherapy on bowel function with patients.	1b	A
Advise patients treated with brachytherapy of the negative impact on irritative urinary symptomatology at one year but not after five years.	1b	C

8.3.2.1 Guidelines on improving quality of life in men who have been diagnosed with prostate cancer

Recommendations	LE	GR
Offer men on androgen deprivation therapy, twelve weeks of supervised (by trained exercise specialists) combined aerobic and resistance exercise.	1a	A
Offer men with T1-T3 disease specialist nurse led, multi-disciplinary rehabilitation based on the patients' personal goals addressing incontinence, sexuality, depression and fear of recurrence, social support and positive lifestyle changes after any radical treatment.	1b	A

2. METHODS

2.1 Data identification

For the 2017 PCa Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature.

A broad and comprehensive literature search, covering all sections of the PCa Guidelines was performed. The search was limited to studies representing only high levels of evidence (i.e. SRs with meta-analysis, randomised controlled trials (RCTs), and prospective comparative studies) published in the English language. Databases searched included Medline, EMBASE and the Cochrane Libraries, covering a time

frame between June 1st 2015 to June 23rd, 2016. A total of 1,914 unique records were identified, retrieved and screened for relevance. A detailed search strategy is available online: <http://uroweb.org/guideline/prostatecancer/?type=appendices-publications>.

Specific sections of the text have been updated based on a SR questions prioritised by the Guidelines Panel. These reviews were performed using standard Cochrane systematic review methodology; <http://www.cochranelibrary.com/about/about-cochrane-systematic-reviews.html>:

- What is the negative predictive value of multiparametric MRI in excluding prostate cancer at biopsy? A systematic review and meta-analysis from the EAU Prostate Cancer Guidelines Panel [prior to print] [3].
- The Benefits and Harms of Different Extents of Lymph Node Dissection During Radical Prostatectomy for Prostate Cancer: A systematic review [4].
- Systematic review of quality of life outcomes as assessed by PROMS following primary treatment of clinically localised prostate cancer.

Recommendations in this text are assessed according to their level of evidence (LE) and Guidelines are given a grade of recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [5]. Additional methodology information can be found in the general Methodology section of this print, and online at the EAU website: <http://uroweb.org/guidelines/>.

A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address. In addition, the International Society of Geriatric Oncology (SIOG), the European Society for Radiotherapy & Oncology (ESTRO) and the European Society for Urogenital Radiology (ESUR) have endorsed the PCa Guidelines.

2.2 Review

Publications ensuing from the systematic reviews have all been peer-reviewed. The following sections were subjected to peer review prior to publication:

All Imaging sections:

- Section 5.2.3 - The role of imaging in PCa diagnosis;
- Section 5.3 - The role of imaging in clinical staging;
- Section 6.1.2.1 - The role of multiparametric magnetic resonance imaging in active surveillance
- Section 6.6.8 (new section) - Imaging as a marker of response in metastatic PCa,
- Sections 6.10.4 and 6.10.5 - The role of imaging in PSA-only recurrence after treatment with curative intent.
- Section 6.10 – Treatment - Management of PSA-only recurrence after treatment with curative intent.
- Section 6.10 – Treatment – Castration-resistant PCa

2.3 Future goals

The results of ongoing and new SRs will be included in the 2017 update of the PCa Guidelines.

Ongoing SRs:

- How does biochemical recurrence following curative treatment for prostate cancer impact on overall survival, cancer-specific survival and development of metastatic disease? [6].
- What evidence based supportive interventions improve disease-specific quality of life in men with prostate cancer?

3. EPIDEMIOLOGY AND AETIOLOGY

3.1 Epidemiology

Prostate cancer remains the second most commonly diagnosed cancer in men, with an estimated 1.1 million diagnoses worldwide in 2012, accounting for 15% of all cancers diagnosed [7]. The frequency of autopsy-detected PCa is roughly the same worldwide [8]. A SR of autopsy studies showed a prevalence of PCa at age < 30 years of 5% (95% CI: 3-8%), increasing by an odds ratio of 1.7 (1.6-1.8) per decade, to a prevalence of 59% (48-71%) by age > 79 years [9].

The incidence of PCa diagnosis, however, varies widely between different geographical areas, being highest in Australia/New Zealand and Northern America (age-standardised rates [ASR] of 111.6 and 97.2 per 100,000, respectively), and in Western and Northern Europe (ASR 94.9 and 85), largely due to the use of prostate specific antigen (PSA) testing and the aging population. The incidence is low in Eastern and South-

Central Asia (ASR 10.5 and 4.5), whilst rates in Eastern and Southern Europe, which were low, have showed a steady increase [7, 8].

There is relatively less variation in mortality rates worldwide, although rates are generally high in populations of African descent (Caribbean, 29 per 100,000 and Sub-Saharan Africa, ASRs 19-24 per 100,000), intermediate in the USA and very low in Asia (2.9 per 100,000 in South-Central Asia) [7].

3.2 Aetiology

3.2.1 Family history/genetics

Family history and racial/ethnic background are associated with an increased PCa incidence suggesting a genetic predisposition [10, 11]. However, only a small subpopulation of men with PCa (~9%) have true hereditary disease. This is defined as three or more affected relatives, or at least two relatives who have developed early-onset PCa (< 55 years) [11]. Patients with hereditary PCa usually have a disease onset six-seven years earlier than average, but their clinical course does not seem to differ in other ways, e.g. for disease aggressiveness [11, 12]. Men with African ethnicity origin show a higher incidence of PCa and generally have a more lethal course of disease [13].

Of the underlying determinants of genomic diversity and mechanisms between genetic and environmental factors, much remains unknown. Genome-wide association studies have identified 100 common susceptibility loci contributing to the risk for PCa, explaining ~38.9% of the familial risk for this disease [14, 15]. Furthermore, an incidence was found of 11.8% of germline mutations in genes mediating DNA-repair processes among men with metastatic PCa [16]. Germline mutations in genes such as HOXB13 and BRCA1/2 have been associated with an increased risk of PCa, targeted genomic analysis of these genes could offer options to identify families at high risk [17, 18]. Trials of screening for PCa-targeting BRCA mutation carriers are ongoing [19].

3.2.2 Risk factors

As Japanese men move from Japan to California, their risk of PCa increases, approaching that of American men [20]. A wide variety of exogenous/environmental factors have been discussed as being aetiologically important for the risk of progression from latent to clinical PCa [21]. However, currently there are no effective preventative dietary or pharmacological interventions.

3.2.2.1 Metabolic syndrome (MetS)

The single components hypertension ($p = 0.035$) and waist circumference > 102 cm ($p = 0.007$) of MetS have been associated with a significantly greater risk of PCa, but conversely, having ≥ 3 components of MetS is associated with a reduced risk (odds ratio [OR]: 0.70 95%; CI: 0.60-0.82) [22, 23].

3.2.2.1.1 Diabetes/metformin

On a population level, metformin users (but not other oral hypoglycaemics) were found to be at a decreased risk of PCa diagnosis, compared with never-users (adjusted OR: 0.84; 95% CI: 0.74-0.96) [24]. In 540 diabetic participants of the Reduction by Dutasteride of Prostate Cancer Events (REDUCE) study, metformin use was not significantly associated with PCa (OR: 1.19; $p = 0.50$) [25].

3.2.2.1.2 Cholesterol/statins

A meta-analysis of fourteen large prospective studies did not show an association between blood total cholesterol (TC), high-density lipoprotein cholesterol (HDL), low-density lipoprotein cholesterol (LDL) levels and the risk of either overall PCa or high-grade PCa [26]. Results of the REDUCE study also did not show a preventive effect of statins on PCa risk [25].

3.2.2.1.3 Obesity

Within the REDUCE study, obesity was associated with lower risk of low-grade PCa in multivariable analyses (OR: 0.79; $p = 0.01$), but increased risk of high-grade PCa (OR, 1.28; $p = 0.042$) [27]. This effect seems mainly explained by environmental determinants of height/BMI rather than genetically elevated height or BMI [28].

3.2.2.2 Dietary factors

The association between a wide variety of dietary factors and PCa have been studied (Table 3.1).

Table 3.1: Dietary factors that have been associated with prostate cancer

Alcohol	High alcohol intake, but also total abstinence from alcohol have been associated with a higher risk of PCa and PCa-specific mortality [29].
Dairy	A weak correlation between insulin-like growth factor-I (IGF-1) levels and high intake of protein from dairy products and the risk of PCa was found [30].
Fat	No association between intake of long-chain omega-3 poly-unsaturated fatty acids and PCa was found [31]. A relation between intake of fried foods and risk of PCa may exist [32].
Lycopene (carotenes)	A trend towards a favourable effect of lycopene on PCa incidence has been identified in meta-analyses [33], RCTs comparing lycopene with placebo did not identify a significant decrease in the incidence of PCa [34].
Meat	A meta-analysis did not show an association between red meat or processed meat consumption and PCa [35].
Vitamin D (25(OH)D)	An U-shaped association has been observed, with both low- and high vitamin-D concentrations being associated with an increased risk of PCa, and more strongly for high-grade disease [36, 37].
Selenium/Vitamin E	Selenium and Vitamin E were found not to affect PCa incidence [38].

3.2.2.3 *Hormonally active medication*

3.2.2.3.1 5-alpha-reductase inhibitors (5-ARIs)

Although it seems that 5-ARIs have the potential of preventing or delaying the development of PCa (~25%, for Gleason 6 cancer only), this must be weighed against treatment-related side effects as well as the potential small increased risk of high-grade PCa [39-41]. None of the available 5-ARIs have been approved by the European Medicines Agency (EMA) for this indication.

3.2.2.3.2 Testosterone

Hypogonadal men receiving testosterone supplementation did not have an increased risk of PCa [42].

3.2.2.4 *Other risk factors*

Balding was associated with a higher risk of PCa death [43]. Gonorrhoea was significantly associated with an increased incidence of PCa (OR:1.31; 95% CI: 1.14-1.52) [44]. Occupational exposure may also play a role, based on a meta-analysis, night-shift work is associated with an increased risk (2.8%; $p = 0.030$) of PCa [45]. Pilots also have been found to have an increased risk of PCa diagnosis (RR 2.0) [46]. Current cigarette smoking was associated with an increased risk of PCa death (RR: 1.24; 95% CI: 1.18-1.31) [47].

In contradiction, vasectomy was not associated with an increased risk of PCa [48]. No association between self-reported acne and risk of (aggressive) PCa was found [49]. There are conflicting data about the use of aspirin or non-steroidal anti-inflammatory drugs and the risk of PCa [50, 51].

Ultraviolet radiation exposure decreased the risk of PCa (hazard ratio [HR]: 0.91; 95% CI: 0.88-0.95) [52]. A protective effect for PCa of circumcision was found [53]. Higher ejaculation frequency (≥ 21 times a month versus 4-7 times) has been associated with a 20% lower risk of PCa [54].

3.2.3 **Summary of evidence and guidelines for epidemiology and aetiology**

Summary of evidence
Prostate cancer is a major health issue in men, the incidence mainly dependent on age.
Genetic factors are associated with risk of (aggressive) PCa but ongoing trials will need to define the clinical applicability of screening for genetic susceptibility of PCa.
A variety of exogenous/environmental factors may have an impact on the risk of progression.
5-ARIs are not EMA-approved for PCa prevention.
Selenium or vitamin-E supplements have no beneficial effect in preventing PCa.
In hypogonadal men, testosterone supplementation does not increase the risk of PCa.

Recommendation
No definitive recommendation can be provided for specific preventive or dietary measures to reduce the risk of developing prostate cancer.

4. CLASSIFICATION AND STAGING SYSTEMS

4.1 Classification

The objective of a tumour classification system is to combine patients with a similar clinical outcome. This allows for the design of clinical trials on relatively homogeneous patient populations, the comparison of clinical and pathological data obtained from different hospitals across the world, and the formulation of recommendations for the treatment of these patient populations. Throughout these Guidelines the 2017 Tumour, Node, Metastasis (TNM) classification for staging of PCa (Table 4.1.1) [55] and the EAU risk group classification, which is essentially based on D'Amico's classification system for PCa, are used (Table 4.2.2) [56]. The latter classification is based on the grouping of patients with a similar risk of biochemical recurrence (BCR) after surgery or external beam radiotherapy (EBRT).

Table 4.1.1: Tumour Node Metastasis (TNM) classification of PCa [55]

T - Primary Tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
T1	Clinically inapparent tumour that is not palpable
T1a	Tumour incidental histological finding in 5% or less of tissue resected
T1b	Tumour incidental histological finding in more than 5% of tissue resected
T1c	Tumour identified by needle biopsy (e.g. because of elevated prostate-specific antigen (PSA) level)
T2	Tumour that is palpable and confined within the prostate
T2a	Tumour involves one half of one lobe or less
T2b	Tumour involves more than half of one lobe, but not both lobes
T2c	Tumour involves both lobes
T3	Tumour extends through the prostatic capsule ¹
T3a	Extracapsular extension (unilateral or bilateral) including microscopic bladder neck involvement
T3b	Tumour invades seminal vesicle(s)
T4	Tumour is fixed or invades adjacent structures other than seminal vesicles: external sphincter, rectum, levator muscles, and/or pelvic wall
N - Regional Lymph Nodes²	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
M - Distant Metastasis³	
M0	No distant metastasis
M1	Distant metastasis
M1a	Non-regional lymph node(s)
M1b	Bone(s)
M1c	Other site(s)

¹Invasion into the prostate apex or into (but not beyond) the prostate capsule is not classified as T3, but as T2.

²Metastasis no larger than 0.2 cm can be designated pNmi.

²T2a to c only exist for clinical T2 (cT2). For pathological T2 they are no longer present in the 2017 TNM. Only pT2 exists.

³When more than one site of metastasis is present, the most advanced category is used. (p)M1c is the most advanced category.

4.2 Gleason score and International Society of Urological Pathology 2014 grade groups

The 2005 International Society of Urological Pathology (ISUP) modified Gleason score of biopsy-detected PCa comprises the Gleason grade or the most extensive (primary pattern) pattern, plus the second most common pattern (secondary pattern), if two are present. If one pattern is present, it needs to be doubled to yield the Gleason score. For three grades, the Gleason score comprises the most common grade plus the highest grade, irrespective of its extent. When a carcinoma is largely grade 4/5, identification of < 5% of Gleason grade 2 or 3 glands should not be incorporated in the Gleason score. A Gleason score ≤ 4 should not be given based on prostate biopsies [57]. In addition to reporting of the carcinoma features for each biopsy, an overall (or global) Gleason score based on the carcinoma-positive biopsies can be provided. The 2014 ISUP Gleason grading conference of prostatic carcinoma [58, 59] limits the number of PCa grades, ranging them from 1 to 5 (see table 4.2.1), in order to:

1. align the PCa grading with the grading of other carcinomas;

2. eliminate the anomaly that the most highly differentiated PCas have a Gleason score 6;
3. to further define the clinically highly significant distinction between Gleason score 7 (3 + 4) and 7 (4 + 3) PCa.

The ISUP 2014 Gleason grading represents a compression of Gleason scores ≤ 6 to ISUP grade 1, and Gleason scores 9-10 to ISUP grade 5, whereas Gleason score 7 is expanded to ISUP grade 2, i.e. 7 (3 + 4) and ISUP grade 3, i.e. 7 (4 + 3).

Table 4.2.1: International Society of Urological Pathology 2014 grades

Gleason score	ISUP grade
2-6	1
7 (3 + 4)	2
7 (4 + 3)	3
8 (4 + 4 or 3 + 5 or 5 + 3)	4
9-10	5

Table 4.2.2: EAU risk groups for biochemical recurrence of localised and locally advanced prostate cancer

Definition			
Low-risk	Intermediate-risk	High-risk	
PSA < 10 ng/mL and GS < 7 (ISUP grade 1) and cT1-2a	PSA 10-20 ng/mL or GS 7 (ISUP grade 2/3) or cT2b	PSA > 20 ng/mL or GS > 7 (ISUP grade 4/5) or cT2c	any PSA any GS cT3-4 or cN+ Any ISUP grade
Localised			Locally advanced

GS = Gleason score; ISUP = International Society for Urological Pathology; PSA = prostate-specific antigen.

4.3 Prognostic relevance of stratification

A more precise stratification of the clinically heterogeneous subset of intermediate-risk group patients could provide a better framework for their management. The adoption of the current ISUP grading system, defining the split-up of Gleason score 7 cancers into ISUP grade 2 (primary Gleason grade 3) and ISUP 3 (primary Gleason grade 4) because of their distinct prognostic impact [59] strengthens such a separation of the intermediate-risk group into a low-intermediate (ISUP grade 2) and high intermediate-risk (ISUP grade 3) group. Emerging clinical data support this distinction between favourable- and unfavourable-risk patient categories within the intermediate-risk group [60].

5. DIAGNOSTIC EVALUATION

5.1 Screening and early detection

Population or mass screening is defined as the 'systematic examination of asymptomatic men (at risk)' and is usually initiated by health authorities. In contrast, early detection or opportunistic (*ad-hoc*) testing consists of individual case findings, which are initiated by the man being tested (patient) and/or his physician. The co-primary objectives of both strategies are:

- reduction in mortality due to PCa;
- at least, a maintained quality of life (QoL) as expressed by QoL-adjusted gain in life years (QUALYs).

Prostate cancer mortality trends range widely from country to country in the industrialised world [61]. Mortality due to PCa has decreased in most Western countries but the magnitude of the reduction varies between countries. The reduced mortality rate seen recently in the USA is considered to be partly due to a widely adopted aggressive PCa screening policy [62]. However, there is still no level 1 evidence that PSA mass screening is cost-effective in reducing PCa mortality [63].

Currently, screening for PCa is one of the most controversial topics in the urological literature [64]. Three large

prospective RCTs published data on screening in 2009 [65-67]. Heated discussions and debates resulted in many conflicting positions and policy papers. Some authors argue that following the current American Urological Association (AUA) guidelines [68] or the US Preventive Services Task Force recommendations for screening [69] may lead to a substantial number of men with aggressive disease being missed [70, 71]. A comparison of systematic and opportunistic screening suggested over-diagnosis and mortality reduction in the systematic screening group compared to a higher over-diagnosis with a marginal survival benefit, at best, in the opportunistic screening regimen [72]. The potential impact of this topic would necessitate the highest level of evidence produced through a systematic literature search of all published trials or cohorts summarised in a meta-analysis. Subgroup analyses of cohorts that are part of large trials, or mathematical projections alone, cannot provide the quality of evidence needed to appropriately address this clinical question.

A Cochrane review published in 2013 [63], which has been updated since [73] presents the main overview of the date. The findings of the updated publication (based on a literature search until April 3, 2013) are almost identical to the 2013 review:

- Screening is associated with an increased diagnosis of PCa (RR: 1.3; 95% CI: 1.02-1.65).
- Screening is associated with detection of more localised disease (RR: 1.79; 95% CI: 1.19-2.70) and less advanced PCa (T3-4, N1, M1) (RR: 0.80; 95% CI: 0.73-0.87).
- From the results of five RCTs, randomising more than 341,000 men, no PCa-specific survival benefit was observed (RR: 1.00; 95% CI: 0.86-1.17). This was the main endpoint in all trials.
- From the results of four available RCTs, no overall survival (OS) benefit was observed (RR: 1.00; 95% CI: 0.96-1.03).

Moreover, screening was associated with minor and major harms such as over-diagnosis and over-treatment. Surprisingly, the diagnostic tool (i.e. biopsy) was not associated with any mortality in the selected papers, which is in contrast with other known data [40, 41].

The impact on the patient's overall QoL is still unclear [74-76], but screening has never been shown to be detrimental at population level. All these findings have led to strong advice against systematic population-based screening in all countries, including Europe.

Since 2013, the European Randomized Study of Screening for Prostate Cancer (ERSPC) data have been updated with 13 years of follow up (see Table 5.1.1) [77]. The key message is that with extended follow up, the mortality reduction remains unchanged (21%, and 29% after non-compliance adjustment). However the number needed to screen and to treat is decreasing, and is now below the number needed to screen observed in breast cancer trials [78].

Table 5.1.1: Follow-up data from the ERSPC study [77]

Years of follow-up	Number needed to screen	Number needed to treat
9	1,410	48
11	979	35
13	781	27

An individualised risk-adapted strategy for early detection might be offered to a well-informed man with at least ten-fifteen years of life expectancy. However, this approach may still be associated with a substantial risk of over-diagnosis. It is therefore important to carefully identify the patient cohorts likely to benefit most from individual early diagnosis, taking into account the potential balances and harms involved.

Men at elevated risk of having PCa are those > 50 years, or at age > 45 years with a family history of PCa (both paternal or maternal [79]), or African-Americans [80]. In addition, men with a PSA > 1 ng/mL at 40 years and > 2 ng/mL at 60 years [81, 82] are also at increased risk of PCa metastasis or death from PCa several decades later. The long-term survival and QoL benefits of such an approach remains to be proven at a population level. In 2014, as for breast cancer, a genetic abnormality associated with an increased risk has been shown prospectively i.e. BRCA2 [19, 83]. Several new biological markers such as TMPRSS2-Erg fusion, PCA3 [84, 85] or kallikreins as incorporated in the Phi or 4Kscore tests [86, 87] have been shown to add sensitivity and specificity on top of PSA, potentially avoiding unnecessary biopsies and lowering over-diagnosis. At this time there is too limited data to base a recommendation on.

Risk calculators may be useful in helping to determine (on an individual basis) what the potential risk of cancer may be, thereby reducing the number of unnecessary biopsies. Several tools developed from cohort studies are available:

- from the PCPT cohort: PCPTRC 2.0 <http://deb.uthscsa.edu/URORiskCalc/Pages/calcs.jsp>;
 - from the ERSPC cohort: <http://www.prostatecancer-riskcalculator.com/seven-prostate-cancer-riskcalculators>;
 - from a local Canadian cohort: <http://sunnybrook.ca/content/?page=occ-prostatecalc> (among others).
- Since none has clearly shown superiority it remains a personal decision which one to use [88].

Informed men requesting an early diagnosis should be given a PSA test and undergo a digital rectal examination (DRE) [89]. The optimal intervals for PSA testing and DRE follow-up are unknown, as they varied between several prospective trials. A risk-adapted strategy might be considered based on the initial PSA level. This could be every two years for those initially at risk, or postponed up to eight to ten years in those not at risk [90].

The age at which early diagnosis should be stopped remains controversial, but an individual's life expectancy must definitely be taken into account. Men who have less than a fifteen-year life expectancy are unlikely to benefit based on data from the Prostate Cancer Intervention Versus Observation Trial (PIVOT) and the ERSPC trials. Furthermore, although there is no simple tool to evaluate individual life expectancy, co-morbidity is at least as important as age. A detailed review can be found in Section 6.7 on senior adults and in the recently updated SIOG Guidelines [91].

Based on the tools currently available, an individualised strategy will diagnose many insignificant lesions (over 50% in some trials), most of which will not require any form of active treatment (see Section 6.1 - Deferred treatment). It is important to realise that breaking the link between diagnosis and active treatment is the only way to decrease over-treatment, while still maintaining the potential benefit of individual early diagnosis for men requesting it.

5.1.1 **Guidelines for screening and early detection**

Recommendations	LE	GR
Do not subject men to prostate-specific antigen (PSA) testing without counselling them on the potential risks and benefits.	3	B
Offer an individualised risk-adapted strategy for early detection to a well-informed man with a good performance status and a life-expectancy of at least ten to fifteen years.	3	B
Offer early PSA testing in well-informed men at elevated risk of having PCa: <ul style="list-style-type: none"> • men > 50 years of age; • men > 45 years of age and a family history of PCa; • African-Americans > 45 years of age; • men with a PSA level of > 1 ng/mL at 40 years of age; • men with a PSA level of > 2 ng/mL at 60 years of age. 	2b	A
Offer a risk-adapted strategy (based on initial PSA level), with follow-up intervals of two years for those initially at risk: <ul style="list-style-type: none"> • men with a PSA level of > 1 ng/mL at 40 years of age; • men with a PSA level of > 2 ng/mL at 60 years of age; Postpone follow-up to eight years in those not at risk.	3	C
Decide on the age at which early diagnosis of PCa should be stopped based on life expectancy and performance status; men who have a life-expectancy of < 15-years are unlikely to benefit.	3	A

5.2 **Clinical diagnosis**

Prostate cancer is usually suspected on the basis of DRE and/or PSA levels. Definitive diagnosis depends on histopathological verification of adenocarcinoma in prostate biopsy cores or specimens from transurethral resection of the prostate (TURP) or prostatectomy for benign prostatic enlargement (BPE).

5.2.1 **Digital rectal examination**

Most PCas are located in the peripheral zone and may be detected by DRE when the volume is ≥ 0.2 mL. In ~18% of cases, PCa is detected by suspect DRE alone, irrespective of PSA level [92]. Suspect DRE in patients with PSA level ≤ 2 ng/mL has a positive predictive value of 5-30% [93]. Abnormal DRE is associated with an increased risk of higher Gleason score and is an indication for biopsy [94, 95].

5.2.2 **Prostate-specific antigen**

The use of PSA as a serum marker has revolutionised PCa diagnosis [96]. Prostate-specific antigen is organ- but not cancer-specific, therefore, it may be elevated in benign prostatic hypertrophy (BPH), prostatitis and

other non-malignant conditions. As an independent variable, PSA is a better predictor of cancer than either DRE or transrectal ultrasound (TRUS) [97].

There are no agreed standards defined for measuring PSA [98]. PSA is a continuous parameter, with higher levels indicating greater likelihood of PCa. Many men may harbour PCa despite having low serum PSA [99]. Table 5.2.1 demonstrates the occurrence of Gleason ≥ 7 (or ISUP grade 2) PCa at low PSA levels, precluding an optimal PSA threshold for detecting non-palpable but clinically significant PCa. The use of nomograms may help in predicting indolent PCa [100].

Table 5.2.1: Risk of PCa in relation to low PSA values

PSA level (ng/mL)	Risk of PCa (%)	Risk of Gleason ≥ 7 PCa (%)
0.0-0.5	6.6	0.8
0.6-1.0	10.1	1.0
1.1-2.0	17.0	2.0
2.1-3.0	23.9	4.6
3.1-4.0	26.9	6.7

5.2.2.1 PSA density

Prostate specific antigen density is the level of serum PSA divided by the TRUS-determined prostate volume. The higher the PSA density, the more likely it is that the PCa is clinically significant (see Section 6.1.3).

5.2.2.2 PSA velocity and doubling time

There are two methods of measuring PSA kinetics:

- PSA velocity (PSAV): absolute annual increase in serum PSA (ng/mL/year) [101];
- PSA doubling time (PSA-DT): which measures the exponential increase in serum PSA over time [102].

Prostate specific antigen velocity and PSA-DT may have a prognostic role in treating PCa [103], but limited diagnostic use because of background noise (total prostate volume, and BPH), different intervals between PSA determinations, and acceleration/deceleration of PSAV and PSA-DT over time. These measurements do not provide additional information compared with PSA alone [104-107].

5.2.2.3 Free/total PSA ratio

Free/total (f/t) PSA ratio can be used to differentiate BPH from PCa. It stratifies the risk of PCa in men with 4-10 ng/mL total PSA and negative DRE. Prostate cancer was detected by biopsy in 56% of men with f/t PSA < 0.10 , but in only 8% with f/t PSA > 0.25 ng/mL [108]. Free/total PSA is of no clinical use if total serum PSA is > 10 ng/mL or during follow up of known PCa.

Free/total PSA must be used cautiously because it may be adversely affected by several pre-analytical and clinical factors (e.g., instability of free PSA at 4°C and room temperature, variable assay characteristics, and concomitant BPH in large prostates) [109].

5.2.2.4 Additional serum testing

A few assays measuring a panel of kallikreins in serum or plasma are now commercially available, including the FDA-approved Prostate Health Index (PHI) test, combining free and total PSA and the (-2)pro-PSA isoform (p2PSA), and the four kallikrein (4K) score test (measuring free, intact and total PSA and kallikrein-like peptidase 2 [hK2]). Both tests are intended to reduce the number of unnecessary prostate biopsies in PSA-tested men. A few prospective multicentre studies demonstrated that both the PHI and 4K test out-performed f/t PSA PCa detection, with an improved prediction of clinically significant PCa in men with a PSA between 2-10 ng/mL [87, 110] [111]. In a head to head comparison both tests performed equally [112].

5.2.2.5 PCA3 marker

Prostate cancer gene 3 (PCA3) is a prostate-specific, non-coding mRNA biomarker that is detectable in urine sediments obtained after three strokes of prostatic massage during DRE. The commercially available ProgenSA urine test for PCA3 is superior to total and percent-free PSA for detection of PCa in men with elevated PSA as it shows significant increases in the area under the receiver-operator characteristic curve for positive biopsies [113-116].

PCA3 score increases with PCa volume, but there are conflicting data about whether it independently predicts Gleason score, and its use for monitoring in active surveillance (AS) is, as yet, not confirmed [117]. Currently, the main indication for the ProgenSA test is to determine whether repeat biopsy is needed after an initially negative biopsy, but its clinical effectiveness for this purpose is uncertain [118].

5.2.2.6 Guidelines for risk-assessment of asymptomatic men

Recommendations	LE	GR
In order to avoid unnecessary biopsies, offer further risk-assessment to asymptomatic men with a prostate specific antigen level between 2-10 ng/mL prior to performing a prostate biopsy. Use one of the following tools: <ul style="list-style-type: none"> risk-calculator; an additional serum or urine-based test (e.g. Prostate Health Index test [PHI], four kallikrein [4K]score or Prostate cancer gene 3 [PCA3]) or imaging. 	3	C

5.2.3 Prostate biopsy

5.2.3.1 Baseline biopsy

The need for prostate biopsy is based on PSA level and/or suspicious DRE. Age, potential comorbidity, and therapeutic consequences should also be considered and discussed beforehand [119]. Risk stratification is a potential tool for reducing unnecessary biopsies [119].

Limited PSA elevation alone should not prompt immediate biopsy. Prostate specific antigen level should be verified after a few weeks using the same assay under standardised conditions (i.e., no ejaculation, manipulations, and urinary tract infections [UTIs]) in the same laboratory [120, 121]. Empiric use of antibiotics in an asymptomatic patient in order to lower the PSA should not be undertaken [122].

Ultrasound (US)-guided biopsy is now the standard of care. A transrectal approach is used for most prostate biopsies, although some urologists prefer a perineal approach. Cancer detection rates are comparable with both approaches [123, 124].

5.2.3.2 Repeat biopsy after previously negative biopsy

The indications for repeat biopsy are:

- rising and/or persistently elevated PSA (see Table 5.2.1 for risk estimates);
- suspicious DRE, 5-30% cancer risk [92, 93];
- atypical small acinar proliferation (i.e., atypical glands suspicious for cancer), 40% risk [125];
- extensive (multiple biopsy sites, i.e., ≥ 3) high-grade prostatic intraepithelial neoplasia (HGPIN), ~30% risk [125, 126];
- a few atypical glands immediately adjacent to high-grade prostatic intraepithelial neoplasia (i.e., PINATYP), ~50% risk [127];
- intraductal carcinoma as a solitary finding, > 90% risk of associated high-grade prostate carcinoma [128];
- positive multiparametric magnetic resonance imaging (mpMRI) findings (see Section 5.2.4).

Additional information may be gained by the ProgenSA DRE urine test for PCA3, the serum 4Kscore and PHI tests or a tissue-based epigenetic test (ConfirmMDx). The role of PHI and ProgenSA PCA3 in deciding whether to take a repeat biopsy in men who had a previous negative biopsy is uncertain and probably not cost-effective [118]. The ConfirmMDx test is based on the concept that benign prostatic tissue in the vicinity of a PCa focus shows distinct epigenetic alterations. If, due to sampling bias, the PCa is missed at biopsy, demonstration of epigenetic changes in the adjacent benign tissue would indicate the presence of carcinoma. The ConfirmMDX test quantifies the methylation level of promoter regions of three genes (RASSF1, GSTP1 and APC) in benign prostatic tissue. A multicentre study found a negative predictive value of 88% when methylation was absent in all three markers, implying that a repeat biopsy could be avoided in these men [129]. Given the limited available data, no recommendation can be made regarding its routine application.

Table 5.2.2: Description of additional investigational tests after a negative prostate biopsy*

Name of test	Test substrate	Molecular	FDA approved
ProgenSA	DRE urine	lncRNA PCA3	yes
PHI	Serum	Total, free and p2PSA	yes
4Kscore Test	Serum/plasma	Total, free, intact PSA, hK2	no
ConfirmMDX	Benign prostate biopsy	Methylated APC, RASSF1 and GSTP1	no

*Isolated high-grade PIN in one or two biopsy sites is no longer an indication for repeat biopsy [130].

5.2.3.3 Saturation biopsy

The incidence of PCa detected by saturation repeat biopsy (> 20 cores) is 30-43% and depends on the number of cores sampled during earlier biopsies [131]. Saturation biopsy may be performed with the transperineal technique, which detects an additional 38% of PCa. The high rate of urinary retention (10%) is a drawback [132].

5.2.3.4 Sampling sites and number of cores

On baseline biopsies, the sample sites should be bilateral from apex to base, as far posterior and lateral as possible in the peripheral gland. Additional cores should be obtained from suspect areas by DRE/TRUS. Sextant biopsy is no longer considered adequate. For a prostate volume of 30-40 mL, ≥ 8 cores should be sampled. Ten to twelve core biopsies are recommended [133], with > 12 cores not being significantly more conclusive [134, 135].

5.2.3.5 Diagnostic transurethral resection of the prostate

Transurethral resection of the prostate should not be used as a tool for cancer detection [136].

5.2.3.6 Seminal vesicle biopsy

Indications for seminal vesicle (staging) biopsies are poorly defined. At a PSA of > 15 ng/mL, the odds of tumour involvement are 20-25% [137]. A seminal vesicle staging biopsy is only useful if it has a decisive impact on treatment, such as ruling out radical tumour resection or for potential subsequent radiotherapy. Its added value compared with mpMRI is questionable.

5.2.3.7 Transition zone biopsy

Transition zone sampling during baseline biopsies has a low detection rate and should be limited to repeat biopsies [138].

5.2.3.8 Antibiotics prior to biopsy

Oral or intravenous antibiotics are recommended. Quinolones are the drugs of choice, with ciprofloxacin being superior to ofloxacin [139]. Increased quinolone resistance [140] is associated with a rise in severe post-biopsy infection [141].

5.2.3.9 Local anaesthesia prior to biopsy

Ultrasound-guided periprostatic block is recommended [142]. It is not important whether the depot is apical or basal. Intrarectal instillation of local anaesthesia is inferior to periprostatic infiltration [143].

5.2.3.10 Fine-needle aspiration biopsy

Fine-needle aspiration biopsy is no longer recommended.

5.2.3.11 Complications

Biopsy complications are listed in Table 5.2.3 [144]. Severe post-procedural infections were initially reported in < 1% of cases, but have increased as a consequence of antibiotic resistance [145]. Low-dose aspirin is no longer an absolute contraindication [146]. A SR found favourable infections rates for transperineal compared to transrectal biopsies with similar rates of haematuria, haematospermia and urinary retention [147].

Table 5.2.3: Percentage of complications per biopsy session, irrespective of the number of cores

Complications	Percentage of patients affected
Haematospermia	37.4
Haematuria > 1 day	14.5
Rectal bleeding < 2 days	2.2
Prostatitis	1.0
Fever > 38.5°C	0.8
Epididymitis	0.7
Rectal bleeding > 2 days +/- surgical intervention	0.7
Urinary retention	0.2
Other complications requiring hospitalisation	0.3

5.2.4 The role of imaging

5.2.4.1 Transrectal ultrasound (TRUS) and ultrasound-based techniques

Grey-scale TRUS is not reliable at detecting PCa [148]. Thus, there is no evidence that US-targeted biopsies can replace systematic biopsies. New sonographic modalities such as sonoelastography and contrast-enhanced US are still under investigation. Currently there is not enough evidence for their routine use.

5.2.4.2 Multiparametric magnetic resonance imaging

Correlation with radical prostatectomy (RP) shows that mpMRI, associating T2-weighted imaging with diffusion-weighted imaging, dynamic contrast-enhanced imaging, and/or H1-spectroscopy, has good sensitivity for the detection and localisation of Gleason score ≥ 7 cancers (see Table 5.2.4) [149-152].

Table 5.2.4: PCa detection rates (%) by mpMRI for tumour volume and Gleason score in radical prostatectomy specimen [151]

Gleason score	Tumour volume (mL)		
	< 0.5	0.5-2	> 2
GS6	21-29%	43-54%	67-75%
GS7	63%	82-88%	97%
GS >7	80%	93%	100%

Multiparametric magnetic resonance imaging can reliably detect aggressive tumours in candidates for prostate biopsy with a negative (NPV) and positive predictive value (PPV) ranging from 63 to 98% and from 34 to 68%, respectively [153]. As a result, mpMRI is increasingly performed before prostate biopsy.

Theoretically, pre-biopsy mpMRI could be used in two different ways. The first strategy uses mpMRI to improve the detection of clinically significant prostate cancer (csPCa). In this diagnostic pathway, MRI-targeted biopsy (TBx) would be added to systematic biopsies in case of positive mpMRI, and systematic biopsies would be performed in all patients with negative mpMRI. The second strategy uses mpMRI as a triage test before biopsy. In this diagnostic pathway, only MRI-TBx would be performed in case of a positive mpMRI. Patients with negative mpMRI results would not undergo a prostate biopsy at all.

A large body of evidence suggests that MRI-TBx has a higher detection rate of detecting csPCa as compared to systematic biopsy [154-158]. However, sub-groups analysis showed that the impact of mpMRI was most marked in the repeat-biopsy setting, but not in biopsy-naïve men [154, 155]. Single centre RCTs performed in biopsy-naïve men provided contradictory findings as to whether or not the combination of systematic biopsies and MRI-TBx had a higher detection rate for PCa and csPCa than systematic biopsies alone [159-161]. Two large multicentre studies (MRI-FIRST and PRECISION) are currently ongoing to define the added value of pre-biopsy MRI in biopsy-naïve patients. It is therefore too early to make recommendations on the routine use of pre-biopsy mpMRI in biopsy-naïve patients.

Magnetic resonance imaging-targeted biopsies can be obtained through cognitive guidance, Ultrasound/mpMRI fusion software or direct in-bore guidance. Controlled studies and a SR did not show a clear superiority of one technique over the others [158, 162-164].

Whether systematic biopsies can be omitted in patients (or prostate lobes) with negative mpMRI depends on the NPV of mpMRI. A SR performed under the auspices of the EAU-ESTRO-ESUR-SIOG PCa Guidelines Panel showed a highly variable prevalence of overall PCa (13.0-74.7%) and csPCa (13.7-50.9%) in patients undergoing pre-biopsy mpMRI (unpublished results). Due to the fact that the NPV decreases when prevalence increases, it is necessary to risk-stratify patients before defining the patients that could safely omit biopsy in case of a negative mpMRI. Prostate-specific antigen density [165] or risk calculators [88] can be used to identify groups of patients with low risk of PCa in whom mpMRI would have a high NPV. The impact of these risk-stratification tools on the NPV of pre-biopsy mpMRI needs to be carefully evaluated, both in the biopsy-naïve and in the repeat-biopsy setting.

Despite the use of the new PIRADS v2 scoring system [166], mpMRI has a low specificity, with high rates of false positives, especially among lesions scored 3/5 and 4/5 [167]. Multiparametric magnetic resonance imaging inter-reader reproducibility is also moderate [168-171], which currently limits its broad use outside expert centres. At this moment it is too soon to define if quantitative approaches and computer-aided diagnosis systems will improve the characterisation of lesions seen at mpMRI in the future [172-174].

5.2.4.3 Guidelines for imaging

Recommendations	LE	GR
Before repeat biopsy, perform multiparametric magnetic resonance imaging (mpMRI) when clinical suspicion of PCa persists in spite of negative biopsies.	1a	A
During repeat biopsy, include systematic biopsies and targeting of any mpMRI lesions seen.	2a	B

5.2.5 Pathology of prostate needle biopsies

5.2.5.1 Processing

Prostate core biopsies from different sites are processed separately. Before processing, the number and length of the cores are recorded. The length of biopsy tissue significantly correlates with the PCa detection rate [175]. To achieve optimal flattening and alignment, a maximum of three cores should be embedded per tissue cassette, and sponges or paper used to keep the cores stretched and flat [176, 177]. To optimise detection of small lesions, paraffin blocks should be cut at three levels [138] and intervening unstained sections are kept for immunohistochemistry.

5.2.5.2 Microscopy and reporting

Diagnosis of PCa is based on histology. The diagnostic criteria include features pathognomonic of cancer, major and minor features favouring cancer and features against cancer. Ancillary staining and additional (deeper) sections should be considered if a suspect lesion is identified [178-180]. Diagnostic uncertainty is resolved by intradepartmental or external consultation [178]. Table 5.2.5 lists the recommended terminology for reporting prostate biopsies [176].

Table 5.2.5: Recommended terminology for reporting prostate biopsies [176]

Benign/negative for malignancy; if appropriate, include a description
Active inflammation
Granulomatous inflammation
High-grade prostatic intraepithelial neoplasia (PIN)
High-grade PIN with atypical glands, suspicious for adenocarcinoma (PINATYP)
Focus of atypical glands/lesion suspicious for adenocarcinoma/atypical small acinar proliferation, suspicious for cancer
Adenocarcinoma
Intraductal carcinoma

Each biopsy site should be reported individually, including its location (in accordance with the sampling site) and histopathological findings, which include the histological type and the ISUP 2014 Gleason grading system [181]. A global Gleason score comprising all biopsies is also reported according to the ISUP 2014 grade (see Section 4.2). Intraductal carcinoma, lymphovascular invasion (LVI) and extra-prostatic extension (EPE) must each be reported, if identified. More recently, expansile cribriform pattern of PCa as well as intraductal carcinoma in biopsies were identified as independent prognosticators of metastatic disease [182].

The proportion of carcinoma-positive cores as well as the extent of tumour involvement per biopsy core correlate with the Gleason score, tumour volume, surgical margins and pathologic stage in RP specimens and predicts BCR, post-prostatectomy progression and RT failure. These parameters are included in nomograms created to predict pathologic stage and seminal vesicle invasion after RP and RT failure [183-185]. A pathology report should therefore provide both the proportion of carcinoma-positive cores and the extent of cancer involvement for each core. The length in mm and percentage of carcinoma in the biopsy have equal prognostic impact [186]. An extent of > 50% of adenocarcinoma in a single core is used in some AS protocols as a cut off [187] triggering immediate treatment vs. AS in patients with Gleason score 6.

A prostate biopsy that does not contain glandular tissue should be reported as diagnostically inadequate. Mandatory elements to be reported for a carcinoma-positive prostate biopsy are:

- type of carcinoma;
- primary and secondary/worst Gleason grade (per biopsy site and global);
- percentage high-grade carcinoma (global);
- extent of carcinoma (in mm or percentage) (at least per biopsy site);
- if present: EPE, seminal vesicle invasion, LVI, intraductal carcinoma/cribriform pattern, peri-neural invasion;
- ISUP 2014 grade (global).

5.2.5.3 Tissue-based prognostic biomarker testing

The Prolaris test (Myriad Genetics) measures the expression of 31 cell-cycle associated genes in biopsy-derived PCa tissue and may be of clinical use to determine whether a patient needs curative treatment or may have his treatment deferred [188]. Similarly, Oncotype Dx is a RNA-based test based on 12 carcinoma-associated genes and 5 reference genes which can be applied to carcinoma tissue in prostate biopsies to determine the aggressiveness of the carcinoma. Both tests were shown in prospective studies to provide prognostic information in men with clinically localised PCa, additional to conventional clinico-pathological parameters, including Gleason score and PSA level. The results of prospective multicentre studies are awaited before a recommendation can be made regarding their routine application.

5.2.6 Histopathology of radical prostatectomy specimens

5.2.6.1 Processing of radical prostatectomy specimens

Histopathological examination of RP specimens describes the pathological stage, histopathological type, grade and surgical margins of PCa. It is recommended that RP specimens are totally embedded, to enable assessment of cancer location, multifocality and heterogeneity. For cost-effectiveness, partial embedding may also be considered, particularly for prostates > 60 g. The most widely accepted method includes complete embedding of the posterior prostate, and a single mid-anterior left and right section. Compared with total embedding, partial embedding detected 98% of PCa with a Gleason score ≥ 7 and accurate staging in 96% of cases [189].

Ink the entire RP specimen upon receipt in the laboratory, to demonstrate the surgical margins. Specimens are fixed by immersion in buffered formalin for at least 24 hours, preferably before slicing. Fixation can be enhanced by injecting formalin, which provides more homogeneous fixation and sectioning after 24 hours [190]. After fixation, the apex and the base (bladder neck) are removed and cut into (para)sagittal or radial sections; the shave method is not recommended [57]. The remainder of the specimen is cut in transverse, 3-4 mm sections, perpendicular to the long axis of the urethra. The resultant tissue slices can be embedded and processed as whole-mounts or after quadrant sectioning. Whole-mounts provide better topographic visualisation, faster histopathological examination and better correlation with pre-operative imaging, although they are more time-consuming and require specialist handling. For routine sectioning, the advantages of whole mounts do not outweigh their disadvantages.

5.2.6.1.1 Guidelines for processing prostatectomy specimens

Recommendations	LE	GR
Ensure total embedding, by conventional (quadrant) or whole-mount sectioning.	3	C
Ink the entire surface before cutting, to evaluate the surgical margin.	3	A
Examine the apex and base separately, using the cone method with sagittal or radial sectioning.	3	A

5.2.6.2 Radical prostatectomy specimen report

The pathology report provides essential information on the prognostic characteristics relevant for clinical decision-making (Table 5.2.6). As a result of the complex information to be provided for each RP specimen, the use of synoptic(-like) or checklist reporting is recommended (Table 5.2.7). Synoptic reporting results in more transparent and complete pathology reporting [191].

Table 5.2.6: Mandatory elements provided by the pathology report

Histopathological type: > 95% of PCa represents conventional (acinar) adenocarcinoma.
Grading according to Gleason score (or therapy-related changes) and ISUP 2014 grade group.
Tumour (sub)staging and surgical margin status: location and extent of extraprostatic extension (EPE), presence of bladder neck invasion, laterality of EPE or seminal vesicle invasion, location and extent of positive surgical margins.
Additional information may be provided on multifocality, and diameter/volume and zonal location of the dominant tumour.

Table 5.2.7: Example checklist: reporting of prostatectomy specimens

Histopathological type
Type of carcinoma, e.g. conventional acinar, or ductal
Histological grade
Primary (predominant) Gleason grade
Secondary Gleason grade
Tertiary Gleason grade (if applicable)
Global Gleason score/ISUP 2014 grade
Approximate percentage of Gleason grade 4 or 5
Tumour quantitation (optional)
Percentage of prostate involved
Size/volume of dominant tumour nodule
Pathological staging (pTNM)
<i>If extraprostatic extension is present:</i> indicate whether it is focal or extensive; specify sites; indicate whether there is seminal vesicle invasion.
<i>If applicable, regional lymph nodes:</i> location; number of nodes retrieved; number of nodes involved.
Surgical margins
<i>If carcinoma is present at the margin:</i> specify sites.
Other
Presence of lymphovascular/angio-invasion
Location of dominant tumour
Presence of intraductal carcinoma/cribriform architecture

5.2.6.2.1 Gleason score in prostatectomy specimens

Grading of conventional prostatic adenocarcinoma using the (ISUP 2014 modified) Gleason system [181] is the strongest prognostic factor for clinical behaviour and treatment response. The Gleason score is incorporated in nomograms that predict disease-specific survival (DSS) after prostatectomy [192].

The Gleason score is the sum of the most and second-most dominant (in terms of volume) Gleason grade. If only one grade is present, the primary grade is doubled. If a grade comprises $\leq 5\%$ of the cancer volume, it is not incorporated in the Gleason score (5% rule). The primary and secondary grades are reported in addition to the Gleason score. A global Gleason score is given for multiple tumours, but a separate tumour focus with a higher Gleason score should also be mentioned. Tertiary Gleason grade 4 or 5, particularly if $> 5\%$ of the PCa volume, is an unfavourable prognostic indicator for BCR. The tertiary grade and its approximate proportion of the cancer volume should also be reported [193] in addition to the global Gleason score as well as the ISUP 2014 grade group (see Section 4.2).

5.2.6.2.2 Definition of extraprostatic extension

Extraprostatic extension is defined as carcinoma mixed with periprostatic adipose tissue, or tissue that extends beyond the prostate gland boundaries (e.g., neurovascular bundle, anterior prostate). Microscopic bladder neck invasion is considered EPE. It is useful to report the location and extent of EPE because the latter is related to recurrence risk [194].

There are no internationally accepted definitions of focal or microscopic, vs. non-focal or extensive EPE. Some describe focal as a few glands [195] or extension as < 1 high-power field (HPF) [196], whereas others measure the depth of extent in millimetres [197].

At the apex of the prostate, tumour mixed with skeletal muscle does not constitute EPE. In the bladder neck, microscopic invasion of smooth muscle fibres is not equated to bladder wall invasion, i.e., not as pT4, because it does not carry independent prognostic significance for PCa recurrence [198, 199] and should be recorded as EPE (pT3a). A positive margin at the bladder neck should be reported as EPE (pT3a) with positive margin, and not as pT4.

Stage pT4 is only assigned when the tumour invades the bladder muscle wall as determined macroscopically [200].

5.2.6.3 PCa volume

The independent prognostic value of PCa volume in RP specimens has not been established [196, 201-204]. Nevertheless, a cut-off of 0.5 mL is commonly used to distinguish insignificant from clinically relevant cancer [201]. Improvement in prostatic radio-imaging allows more accurate pre-operative measurement of cancer volume. It is recommended that at least the diameter/volume of the dominant tumour nodule should be assessed, or a rough estimate of the percentage of cancer tissue provided [205].

5.2.6.4 Surgical margin status

Surgical margin is an independent risk factor for BCR. Margin status is positive if tumour cells are in contact with the ink on the specimen surface. Margin status is negative if tumour cells are close to the inked surface [202] or at the surface of the tissue lacking ink. In tissues that have severe crush artefacts, it may not be possible to determine margin status [206].

Surgical margin is separate from pathological stage, and a positive margin is not evidence of EPE [207]. There is insufficient evidence to prove a relationship between margin extent and recurrence risk [196]. However, some indication must be given of the multifocality extent of margin positivity, such as the linear extent in mm of involvement: focal, ≤ 1 mm vs. extensive, > 1 mm [208], or number of blocks with positive margin involvement.

5.2.7 Guidelines for the clinical diagnosis of prostate cancer

Recommendations	LE	GR
Do not use transurethral resection of the prostate as a tool for cancer detection.	2a	A
Use the International Society of Urological Pathology (ISUP) 2014 Gleason grading system for grading of PCa.	2a	A
In symptomatic men, base the initial decision to perform a biopsy on prostate-specific antigen (PSA) testing and digital rectal examination (DRE).	2b	A
Use the additional diagnostic options in asymptomatic men with a normal DRE and a PSA between 2.0 and 10 ng/mL (risk calculator, or an additional serum or urine-based test [e.g. Prostate Health Index, 4Kscore or prostate cancer gene 3] or imaging).	3	C
Do not initially offer transition zone biopsies due to low detection rates.	2b	B
For initial diagnosis, perform a core biopsy of ten to twelve systematic transrectal or transperineal peripheral zone biopsies under ultrasound guidance.	2a	B
Perform transrectal prostate needle biopsies under antibiotic protection.	1b	A
Use a local anaesthetic by periprostatic infiltration for transrectal prostate needle biopsies.	1a	A
Ensure that prostate core biopsies from different sites are submitted separately for processing and pathology reporting.	3	A
Adhere to the 2010 ISUP consensus meeting Guidelines for processing and reporting of prostatectomy specimens.	3	A
Perform one set of repeat biopsies for persistent indications for PCa (abnormal DRE, elevated PSA or histopathological findings suggestive of malignancy at initial biopsy).	2a	B

5.3 Diagnosis: Clinical staging

The extent of PCa is evaluated by DRE and PSA, and may be supplemented with bone scanning and computed tomography (CT) or mpMRI.

5.3.1 T-staging

5.3.1.1 Definitions

Extraprostatic extension is defined as carcinoma mixed with periprostatic adipose tissue, or tissue that extends beyond the prostate gland (e.g., neurovascular bundle, anterior prostate, or bladder neck) and corresponds to stage T3a. It is to be distinguished from seminal vesicle invasion (SVI) which corresponds to stage T3b (see Section 5.2 for details).

5.3.1.2 DRE, PSA level and biopsy findings

The first level of assessment is local tumour stage because the distinction between organ-confined (T1/T2) and extraprostatic (T3/T4) disease affects treatment decisions. Digital rectal examination is positively correlated with tumour stage in $< 50\%$ of cases [209], although it often underestimates tumour extension. More extensive T-staging is only recommended if it directly affects treatment decisions.

Serum PSA levels increase with tumour stage, although they are limited for accurate prediction of final

pathological stage [210]. In prostate needle biopsy, the percentage of cancerous tissue is a strong predictor of positive surgical margins, SVI, and non-organ-confined disease [211]. An increase in tumour-positive biopsies is an independent predictor of EPE, margin involvement, and lymph node (LN) invasion [212]. Serum PSA, Gleason score, and T-stage are more useful together than alone in predicting final pathological stage [192, 213]. Models may help to select candidates for nerve-sparing surgery and lymphadenectomy LND) (see Section 6.2.5).

Seminal vesicle invasion is predictive of local relapse and distant metastatic failure. Seminal vesicle biopsies can improve pre-operative staging accuracy [214]. This is not recommended for first-line examination, but should be reserved for patients with high risk of SVI in whom a positive biopsy would modify treatment. Patients with T-stage > 2a and serum PSA > 10 ng/mL are candidates for SV biopsy [215, 216]. Patients with positive biopsies from the base of the prostate are more likely to have positive SV biopsies [217].

Transperineal 3D prostate mapping biopsy (PMB) is an alternative to transrectal biopsies because it provides more accurate tumour localisation, extent and Gleason grading [218], and has acceptable morbidity [147].

5.3.1.3 *Transrectal ultrasound*

Transrectal ultrasound is no more accurate at predicting organ-confined disease than DRE [219]. Transrectal ultrasound-derived techniques (e.g. 3D-TRUS, colour Doppler) [220, 221] cannot differentiate between T2 and T3 tumours with sufficient accuracy to be recommended for routine staging.

5.3.1.4 *Multiparametric magnetic resonance imaging*

T2-weighted imaging remains the most useful method for local staging on mpMRI. At 1.5T (Tesla), mpMRI has good specificity but low sensitivity for detecting T3 stages. Pooled data from a meta-analysis for EPE, SVI, and overall stage T3 showed a sensitivity and specificity of 0.57 (95% CI: 0.49-0.64) and 0.91 (95% CI: 0.88-0.93), 0.58 (95% CI: 0.47-0.68) and 0.96 (95% CI: 0.95-0.97), and 0.61 (95% CI: 0.54-0.67) and 0.88 (95% CI: 0.85-0.91), respectively [222]. Multiparametric magnetic resonance imaging cannot detect microscopic EPE. Its sensitivity increases with the radius of extension within peri-prostatic fat. In one study, the EPE detection rate increased from 14 to 100% when the radius of extension increased from < 1 mm to > 3 mm [223]. In another study, mpMRI sensitivity, specificity and accuracy for detecting pT3 stage was, 40%, 95% and 76%, respectively, for focal (i.e. microscopic) EPE, and 62%, 95% and 88% for extensive EPE [224].

The use of high field (3T) or functional imaging in addition to T2-weighted imaging improves sensitivity for EPE or SVI detection [222], but the experience of the reader remains of paramount importance [225] and the inter-reader agreement remains moderate with kappa values ranging from 0.41 to 0.68 [226]. Multiparametric magnetic resonance imaging, although not perfect for local staging, may improve prediction of the pathological stage when combined with clinical data [227, 228]. Other MRI-derived parameters such as the tumour volume or the contact length of the tumour with the capsule [229-231], or the Gleason score obtained through MRI-TBx [232] could further improve the local staging.

Given its low sensitivity for focal (microscopic) EPE, mpMRI is not recommended for local staging in low-risk patients [227, 233, 234]. However, mpMRI can still be useful for treatment planning in selected low-risk patients (e.g. candidates for brachytherapy) [235].

5.3.2 *N-staging*

N-staging should be performed only when it might directly influence treatment decisions. High PSA values, T2b-T3 stage, poor tumour differentiation and perineural invasion are associated with high risk of nodal metastases [236, 237]. Measurement of PSA alone is unhelpful in predicting LN metastases. Nomograms can define patients at low risk (< 10%) of nodal metastasis, although nomograms may be more accurate in establishing the extent of nodal involvement [213, 238]. The simple Roach formula can also be used [239]. Patients with low- and intermediate-risk PCa may be spared N-staging before potentially curative treatment.

Gleason 4 pattern in sextant biopsies can define the risk of N1 disease. Risk of nodal metastases was 20-45% if any core had a predominant Gleason 4 pattern, or > 3 cores had any Gleason 4 pattern. For the remaining patients, the risk was 2.5%, suggesting that nodal staging is unnecessary in selected patients [240].

5.3.2.1 *Computed tomography and magnetic resonance imaging*

Abdominal CT and T1-T2-weighted MRI indirectly assess nodal invasion by using LN diameter and morphology. However, the size of non-metastatic LNs varies widely and may overlap with the size of LN metastases, since microscopic invasion does not enlarge LNs. The normal range for non-metastatic LNs also varies with different anatomical regions. As a result, the ideal size threshold remains unclear [241, 242]. Computed tomography and MRI sensitivity is less than 40% [243, 244]. Among 4,264 patients 654 (15.3%) of

whom had positive LNs at LND, CT was positive in only 105 (2.5%) patients [241]. Detection of microscopic LN invasion by CT is < 1% in patients with a Gleason score < 8, PSA < 20 ng/mL, or localised disease [245-247].

Diffusion-weighted MRI may detect metastases in normal-sized nodes, but a negative diffusion-weighted MRI cannot rule out the presence of LN metastases [242, 248]. Moreover, this scan is technically challenging to perform in the pelvis where artifacts due to bowel gas can interfere with the quality of the imaging.

Because of their low sensitivity, CT or MRI should not be used for nodal staging in low-risk patients and be reserved for high-risk cancer patients.

5.3.2.2 Choline PET/CT

^{11}C - or ^{18}F -choline positron emission tomography (PET)/CT have good specificity for LN metastases, but a sensitivity of 10-73% [249, 250].

In a meta-analysis of 609 patients, pooled sensitivity and specificity of choline PET/CT for pelvic LN metastases were 62% (95% CI: 51-66%) and 92% (95% CI: 89-94%), respectively [251]. In a prospective trial of 75 patients at intermediate risk of nodal involvement (10-35%), the sensitivity was only 8.2% in a region based and 18.9% at a patient-based analysis, which is too low to be of clinical interest [252].

In intermediate/high-risk patients, comparisons between choline PET/CT and diffusion-weighted MRI gave contradictory results, with PET/CT sensitivity found to be superior [253], similar [254, 255] or inferior [252] than that of diffusion-weighted MRI.

Because of its insufficient sensitivity, choline PET/CT does not reach clinically acceptable diagnostic accuracy for detection of LN metastases.

5.3.2.3 New methods

^{68}Ga -labelled prostate-specific membrane antigen-PET CT (^{68}Ga -PSMA PET/CT) seems to exhibit promising sensitivity for LN involvement. A recent meta-analysis of five retrospective studies, performed in an initial staging and/or recurrence setting, reported combined sensitivities and specificities of 86% (95% CI: 37-98%) and 86% (95% CI: 3-100%) at patient level, and 80% (95% CI: 66-89%) and 97% (95% CI: 92-99%) at lesion level [256]. Similarly, ^{18}F -labelled PSMA targeting compounds are being developed commercially. However, these results must be interpreted with care, as careful validation studies have not been performed.

5.3.3 M-staging

5.3.3.1 Bone scan

$^{99\text{m}}\text{Tc}$ -Bone scan (BS) has been the most widely used method for evaluating bone metastases of PCa. A 2014 meta-analysis showed a combined sensitivity and specificity of 79% (95% CI: 73-83%) and 82% (95% CI: 78-85%) at patient level and 59% (95% CI: 55-63%) and 75% (95% CI: 71-79%) at lesion level [257]. Adding single-photon emission computed tomography (SPECT) to plain BS has been shown to reduce the number of equivocal lesions [258]. Bone scan diagnostic yield is significantly influenced by the PSA level, the clinical stage and the tumour Gleason score and these three factors were the only independent predictors of BS positivity in a study of 853 patients [259]. The mean BS positivity rate in 23 different series was 2.3% in patients with PSA levels < 10 ng/mL, 5.3% in patients with PSA level between 10.1 and 19.9 ng/mL, and 16.2% in patients with PSA levels of 20.0-49.9 ng/mL. It was 6.4% in men with organ-confined cancer and 49.5% in men with locally advanced cancers. Detection rates were 5.6% and 29.9% for Gleason scores of 7 and ≥ 8 respectively [241]. In two studies, a major Gleason pattern of 4 was found to be a significant predictor of positive BS [260, 261].

Bone scanning should be performed in symptomatic patients, independent of PSA level, Gleason score or clinical stage [241].

5.3.3.2 Other modalities

^{18}F -sodium fluoride (^{18}F -NaF) PET or PET/CT shows similar specificity and superior sensitivity to BS. It may even have the highest sensitivity for bone metastases, as compared to all other imaging techniques [262, 263]. However, unlike choline PET/CT, it does not detect LN metastases, and it is less cost-effective compared to BS [262].

It remains unclear whether choline PET/CT is more sensitive than conventional BS, but it has higher specificity, with fewer indeterminate bone lesions [249, 251, 264].

Diffusion-weighted whole-body and axial MRI are more sensitive than BS and targeted conventional radiography in detecting bone metastases in high-risk PCa [265, 266]. Whole-body MRI is also more sensitive and specific than combined BS, targeted radiography and abdominopelvic CT [267]. A meta-analysis found that MRI is more sensitive than choline PET/CT and BS for detecting bone metastases on a per-patient basis, although choline PET/CT had the highest specificity (Table 5.3.1) [257].

Only limited evidence is available on the performance of ^{68}Ga -PSMA PET/CT in initial staging. A meta-analysis reported a combined positivity rate of 40% (95% CI: 19-64%) in patients undergoing primary staging. However, the positivity rate fell to 27% (95% CI: 15-42%) when studies with a sample size < 10 were excluded [256].

Table 5.3.1: Sensitivity and specificity for detecting bone metastases on a per-patient basis [257]

Imaging modality	Sensitivity %	Specificity %	CI
Bone scan	78	85	95% (0.73-0.83)
Choline PET/CT	91	99	95% (0.83-0.96)
MRI	97	95	95% (0.91-0.99)

CI = confidence interval; mpMRI = multiparametric magnetic resonance imaging; PET = positron emission tomography.

Although evidence shows that choline PET/CT and mpMRI are more accurate than BS, the clinical benefit of detecting bone metastases at an earlier time-point using more sensitive techniques remains unclear in the initial staging setting [268]. Bone scan is therefore usually preferred in most centres.

5.4 Guidelines for staging of prostate cancer

Any risk group staging	LE	GR
Do not use computed tomography and transrectal ultrasound for local staging.	2a	A

Low-risk localised PCa	LE	GR
Do not use additional imaging for staging purposes.	2a	A

Intermediate-risk PCa	LE	GR
In predominantly Gleason pattern 4 (ISUP grade 3), include at least cross-sectional abdominopelvic imaging and a bone-scan for metastatic screening.	2a	A*
In predominantly Gleason pattern 4 (ISUP grade 3), use prostate multiparametric magnetic resonance imaging (mpMRI) for local staging.	2b	A

*Upgraded following panel consensus.

High-risk localised PCa/High-risk locally advanced PCa	LE	GR
Use prostate mpMRI for local staging.	2b	A
Perform metastatic screening including at least cross-sectional abdominopelvic imaging and a bone-scan.	2a	A

6. DISEASE MANAGEMENT

6.1 Treatment: Deferred treatment (active surveillance/watchful waiting)

6.1.1 Introduction

Many men with screening-detected localised PCa will not benefit from definitive treatment [269] and 45% of them are candidates for deferred management. There are two distinct strategies for conservative management that aim to reduce over-treatment: active surveillance (AS) and watchful waiting (WW) (Table 6.1.1).

6.1.1.1 Definition

6.1.1.1.1 Active surveillance

Active surveillance aims to achieve correct timing for curative treatment in patients with clinically localised PCa, rather than delay palliative treatment [270]. Patients remain under close surveillance, and treatment is prompted by predefined thresholds indicative of potentially life-threatening disease, still potentially curable, while considering individual life expectancy.

6.1.1.1.2 Watchful waiting

Watchful waiting (WW) is also known as deferred or symptom-guided treatment. It refers to conservative management, until the development of local or systemic progression with (imminent) disease-related complaints. Patients are then treated according to their symptoms, in order to maintain QoL.

Table 6.1.1: Definitions of active surveillance and watchful waiting [269]

	Active surveillance	Watchful waiting
Treatment intent	Curative	Palliative
Follow-up	Predefined schedule	Patient-specific
Assessment/markers used	DRE, PSA, re-biopsy, mpMRI	Not predefined
Life expectancy	> 10 years	< 10 years
Aim	Minimise treatment-related toxicity without compromising survival	Minimise treatment-related toxicity
Comments	Low-risk patients	Can apply to patients with all stages

DRE = digital rectal examination; PSA = prostate-specific antigen; mpMRI = multiparametric magnetic resonance imaging.

6.1.2 Deferred treatment of localised PCa (stage T1/T2, Nx/N0, M0)

Mortality from untreated screen-detected PCa in patients with Gleason scores 5-7 might be as low as 7% at fifteen years follow-up [269].

6.1.2.1 Active surveillance

Active surveillance is currently reserved for selected low-risk patients. Current data are from ongoing prospective or retrospective cohorts; no formal RCT is available comparing this modality to standard treatment. The ProtecT trial [271] is discussed later as it is not a formal AS strategy.

One of the largest published cohorts with the longest follow-up in a mainly low-risk population includes 993 patients (mean age: 67.8 years) [272]. These men presented with stage T1c or T2a and PSA ≤ 10 ng/mL, age ≤ 70 years and a Gleason score ≤ 6 or age > 70 years with a Gleason score of ≤ 7 . After a median follow-up of 6.4 years the ten- and fifteen-year OS were 80% and 62%, respectively, and DSS rates were 98.1% and 94.3%, respectively. Twenty-seven percent of this cohort eventually underwent radical treatment, prompted by a PSA-DT < 3 years (43.5%), a Gleason score progression on repeat biopsies (35%) and patient preference (6%). Thirty men (3%) developed metastases during follow-up: 2% of those initially classified as Gleason 6 compared to 9.7% if initially Gleason 7, and fifteen men died [273].

Several cohorts have investigated AS in organ-confined disease, the findings of which were summarised in a SR including $> 3,900$ patients [274]. There is considerable variation between studies regarding patient selection, follow-up policies and when active treatment should be instigated.

Selection criteria for AS are limited by a lack of prospective RCTs, or findings from a formal consensus meeting. The criteria most often published include: Gleason 6, when specified $< 2-3$ positive cores with $< 50\%$ cancer involvement in every positive core, a clinical T1c or T2a, a PSA < 10 ng/mL and a PSA density < 0.15 ng/mL/cc [274, 275]. The latter threshold remains controversial [275, 276]. A pathology consensus group suggested excluding men from AS when any of the following features were present: predominant ductal carcinoma (including pure intraductal carcinoma), sarcomatoid carcinoma, small cell carcinoma, EPE or LVI in needle biopsy [277] and perineal invasion [278]. A Canadian consensus group pose that AS is the treatment of choice for low-risk disease, without stratifying for biopsy results, although they clearly recommend that men < 55 years should be closely scrutinised for high-volume Gleason 6 cancer. The same authors pose that low volume Gleason 7 (3 + 4) ($< 10\%$ pattern 4) may also be considered for AS. However, recent findings suggest that any grade 4 pattern is associated with a three-fold increased risk of metastases compared to Gleason 6, while a PSA up to 20 ng/mL might be an acceptable threshold [279-281].

In this setting, re-biopsy within six to twelve months to exclude sampling error is mandatory [275, 281] even if this could be modified in the future [282].

Biological markers, including urine PCA3, transmembrane protease, serine 2-TMPRSS2-ERG fusion, or PSA isoforms appear promising, as does genomics on the tissue sample itself [283-285]. However, further data will be needed before such markers can be used in standard clinical practice.

Imaging with mpMRI is of particular interest due to its high NPV value for lesion upgrading and for staging anterior prostate lesions [286, 287]. A formal SR is available [287]. The added value of mpMRI and targeted biopsies could be promising in:

1. reducing misclassifications at initial diagnosis and follow-up;
2. reducing unnecessary (targeted or systematic) biopsies at follow-up, and;
3. aiding in monitoring patients on surveillance.

The added value may differ at different time points in an AS setting. At confirmatory biopsy in men who did not have an mpMRI before, the reclassification rate due to targeted biopsies can be estimated to be 2-22% (absolute numbers) [287-291]. The added value of mpMRI for surveillance/repeat biopsies (hence more than one year following the confirmatory biopsy assessment) has not been evaluated yet. However, combined data of confirmatory and surveillance repeat biopsies show a reclassification rate due to targeted biopsies of 2-14% (absolute numbers) [292-294]. These numbers are directly related to the eligibility criteria for AS, and the reclassification criteria used within these populations.

The concordance of systematic and targeted biopsies at confirmatory biopsies is approximately 80%. However omitting systematic biopsies may induce a misclassification rate of 3-13% [287-290, 292-294], therefore systematic biopsy should be systematically performed, even facing a normal mpMRI.

Targeted biopsies of suspicious lesions on mpMRI are mainly performed for Likert/PIRADS (Prostate Image Reporting and Data System) ≥ 3 lesions. Although increased rates of reclassification occur in PIRADS 4 and 5 lesions, a substantial proportion of PIRADS 3 lesions show reclassification following targeted biopsies [288, 289], thereby confirming the significance to biopsy Likert/PIRADS ≥ 3 lesions within AS management.

The follow up strategy is based on serial DRE (at least once/year), PSA (at least once, every six months) and repeated biopsy (at a minimum interval of three to five years). Based on two small single centre studies [295, 296], not all patients with progression/reclassification at biopsy had radiological progression and vice versa. Therefore, mpMRI cannot be used as a stand-alone tool to trigger follow-up biopsies, but efforts are being made to define and standardise radiological progression during AS [297].

Risk prediction in men on AS is under investigation to further reduce unnecessary biopsies and misclassification [298]. In an AS cohort of 259 men with Gleason 6 and Gleason 7 (3 + 4) cancers detected by MRI-targeted and systematic biopsies, independent predictors of upgrading at 3 years were Gleason 7 (3 + 4), PSA density ≥ 0.15 ng/mL/cm³ and a score 5 lesion on MRI [299]. Thus, the role of mpMRI in risk prediction should be further investigated.

Switching to active treatment

The decision to start active treatment should be based on a change in the biopsy results (Gleason score, number of positive cores, length in the core involvement), or T-stage progression. These criteria are recognised in all published cohorts. A PSA change (especially a PSA-DT < 3 years) is a less powerful indicator to change management based on its weak link with grade progression [300, 301]. Active treatment may also be instigated upon a patient's request. This occurs in around 10% of patients on AS [302]. Overall, no major perturbation of health-related QoL (HRQoL) and psychological well-being was apparent in the first years [303].

Table 6.1.2: Active surveillance in screening-detected prostate cancer

Studies	n	Median follow-up (mo)	pT3 in RP patients*	OS	CSS
Van As <i>et al.</i> , 2008 [304]	326	22	8/18 (44%)	98	100
Carter <i>et al.</i> , 2007 [305]	407	41	10/49 (20%)	98	100
Adamy <i>et al.</i> , 2011 [306]	533-1,000	48	4/24 (17%)	90	99
Soloway <i>et al.</i> , 2010 [307]	99	45	0/2	100	100
Roemeling <i>et al.</i> , 2007 [308]	278	41		89	100
Khatami <i>et al.</i> , 2007 [309]	270	63		n.r.	100
Klotz <i>et al.</i> , 2015 [272]	993	77	n.r.	85	98.1
Total	2,130-3,000	43		90	99.7

* Patients receiving active therapy following initial active surveillance.

CSS = cancer-specific survival; n = number of patients; n.r. = not reported; OS = overall survival; RP = radical prostatectomy.

6.1.2.2 Watchful waiting

The rationale behind WW is that PCa often progresses slowly, and is predominantly diagnosed in older men with a high incidence of comorbidity and other causes of mortality [310]. Watchful waiting is possible in patients with localised PCa and a limited life expectancy.

6.1.2.2.1 Patient selection for watchful waiting

Studies on WW have included patients with up to 25 years of follow-up, with endpoints of OS and CSS. Several series have shown a consistent CSS rate of 82-87% at ten years [311-316], and 80-95% for T1/T2 and Gleason score ≤ 7 [317]. In three studies with data beyond fifteen years, the DSS was 80%, 79% and 58% [313, 315, 316], and two reported twenty-year CSS rates of 57% and 32%, respectively [313, 315]. Many patients classified as Gleason 6 would now be classified as Gleason 7 based on the revised Gleason classification, suggesting that the above-mentioned results should be considered as minimal. Patients with well-, moderately- and poorly-differentiated tumours had ten-year CSS rates of 91%, 90% and 74%, respectively, correlating with data from the pooled analysis [317]. Observation was most effective in men aged 65-75 years with low-risk PCa [318].

Gleason 6-10 tumours carry a continuously increasing mortality risk up to fifteen years follow-up after WW [319]. Others have shown that the mortality risk of PCa was high in Gleason 7-10 tumours, intermediate in Gleason 6 tumours, but low in Gleason 2-5 tumours (Table 6.1.3) [320, 321].

In an analysis at ten years follow up in 19,639 patients aged > 65 years who were not given curative treatment, most men with a Charlson comorbidity index (CCI) score ≥ 2 died from competing causes at ten years whatever their initial age. Tumour aggressiveness had little impact on OS suggesting that patients could have been spared biopsy and diagnosis of cancer. Men with a CCI score ≤ 1 had a low risk of death at ten years, especially for well- or moderately-differentiated lesions [322]. This highlights the importance of checking the CCI before considering a biopsy.

Table 6.1.3: Fifteen-year mortality risk for localised PCa in relation to Gleason score in patients aged 55-74 years [320, 321, 323]

Gleason score	Cancer mortality risk* (%)	Cancer-specific mortality† (%)
2-4	4-7	8
5	6-11	14
6	18-30	44
7	42-70	76
8-10	60-87	93

* Figures differ among age groups and represent the true risk in the study population (considering actual competing mortality from other causes).

† Figures compensate for differences in competing mortality and indicate outcome if the patient lives for fifteen years.

6.1.2.2.2 Outcome of watchful waiting compared to active treatment

The SPCG-4 randomised study compared WW to RP (Table 6.1.4) [323] before the PSA era and found RP to provide superior CSS, OS and progression-free survival (PFS) compared to WW at a median follow-up of 12.8 years. The PIVOT trial made a similar comparison in 731 randomised men (50% with non-palpable disease) [324] and found no benefit of treatment within ten years. Only patients with serum PSA > 10 ng/mL or high-risk PCa had a significant OS benefit from RP, with a relative-risk reduction in mortality of 33% and 31%, respectively. Patients who underwent RP also had a significant reduction in bone metastases (4.7% vs. 10.6%). Overall, no major perturbation of HRQoL and psychological well-being was apparent in the first years [325].

Table 6.1.4: Outcome of SPCG-4 at fifteen years follow-up [323]

	RP (n = 348) (%)	Watchful waiting (n = 348) (%)	Relative risk (95% CI)	p-value
Disease-specific mortality	14.6	20.7	0.62	0.010
Overall mortality	46.1	57.2	0.75 (0.61-0.92)	0.007
Metastatic progression	21.7	33.4	0.59 (0.45-0.79)	< 0.001
Local progression	21.5	49.3	0.34 (0.26-0.45)	n.r.

CI = confidence interval; n.r. = not reported; RP = radical prostatectomy.

The data on deferred and conservative management of low-risk disease contrasts with the recent increase in the incidence of local treatment from 25 to 34% in the USA in men with a life expectancy < 10 years [326]. Swedish data show a higher prevalence of deferred treatment in low-risk disease of 46% [327].

6.1.2.3 The ProtecT study

The ProtecT trial randomised 1,643 patients between active treatment (RP or EBRT) and active monitoring (AM) [271]. In this AM schedule, patients with a PSA rise of more than 50% in twelve months underwent a repeat biopsy, but none had systematic repeat biopsies (which presents an intermediary approach, between AS and WW). Most patients had low-risk disease with 90% PSA < 10 ng/mL, 77% Gleason 6 (20% Gleason 7), 76% T1c. After ten years of follow up, the CSS was the same between those actively treated and those on AM (99% and 98.8% respectively), as was the OS. Only metastatic progression differed (6% in the AM group as compared to 2.6% in the treated group). The key finding is that AM is as effective as active treatment at ten years, at a cost of increased progression and a double metastatic risk. Metastases remain quite rare (6%), but more frequent compared to results from AS protocols based on patient selection. This confirms that for low-risk patients, some form of initial AM is safe. Beyond ten years, no data is available yet and AS is possibly safer, especially in younger men, based on initial patient selection. Individual life expectancy must be evaluated before considering any active treatment in low-risk situations, and for those with up to ten years individual life expectancy, AM or WW are probably very good options.

6.1.3 Deferred treatment for locally advanced PCa (stage T3-T4, Nx-N0, M0)

The final analysis of the largest RCT focusing on this specific question was published in 2013 [328]. Nine hundred and eighty-five patients with T0-4 N0-2 M0 PCa were treated with androgen-deprivation therapy (ADT), either immediately or after symptomatic progression or occurrence of serious complications. After a median follow-up of 12.8 years, the OS HR was 1.21 (95% CI: 1.05-1.39), favouring immediate treatment but showing no significant difference in PCa mortality or symptom-free survival which raises the question of its clinical value. Patients with a baseline PSA > 50 ng/mL had a > 3.5-fold higher mortality risk than those with a PSA baseline of ≤ 8 ng/mL. If baseline PSA was 8-50 ng/mL, the mortality risk was ~7.5-fold higher in patients with a PSA-DT of < 12 months compared with > 12 months. The median time to start deferred treatment was seven years. In the deferred arm, 25.6% died without needing treatment (44%).

6.1.4 Deferred treatment for metastatic PCa (stage M1)

The only candidates with metastasised disease who may possibly be considered for deferred treatment are asymptomatic patients with a strong wish to avoid treatment-related side-effects. Median survival is 42 months, therefore, the time without treatment (before symptoms) is short in most cases. The risk of developing symptoms, and even death from PCa, without receiving any benefit from hormone treatment has been highlighted [329, 330]. Patients with deferred treatment for advanced PCa must be amenable to close follow-up.

6.1.5 Guidelines for active surveillance and watchful waiting

Recommendations - active surveillance	LE	GR
Discuss surgery and radiotherapy as treatment options with patients suitable for such treatments.	1a	A
Offer active surveillance to patients with the lowest risk of cancer progression: > ten years life expectancy, cT1/2, PSA ≤ 10 ng/mL, biopsy Gleason score ≤ 6, ≤ 2 positive biopsies, minimal biopsy core involvement (≤ 50% cancer per biopsy).	2a	A
Counsel patients about the possibility of needing further treatment in the future.	2a	A
Perform multiparametric magnetic resonance imaging before a confirmatory biopsy.	2b	B
During confirmatory biopsy include systematic and targeted biopsies.	2a	B
Base follow up on digital rectal examination, prostate-specific antigen (PSA) and repeated biopsies.	2a	A

Recommendations - watchful waiting for localised prostate cancer	LE	GR
Offer watchful waiting to patients not eligible for local curative treatment and those with a short life expectancy.	1b	A
While on watchful waiting, base the decision to start non-curative treatment on symptoms and disease progression (see Section 6.1.2.2).		B

Recommendations - watchful waiting for locally advanced prostate cancer	LE	GR
In locally advanced M0 patients unwilling or unable to receive any form of local treatment, offer a deferred treatment policy using androgen-deprivation therapy as monotherapy to asymptomatic patients with a PSA doubling time > 12 months and a PSA < 50 ng/mL and non-poorly differentiated tumour.	1b	A

6.2 Treatment: Radical prostatectomy

6.2.1 Introduction

The goal of RP by any approach must be eradication of disease, while preserving continence and, whenever possible, potency [331]. Increasing comorbidity greatly increases the risk of dying from non-PCa-related causes [322]. An estimation of life expectancy is paramount in counselling a patient about surgery [332] (see also Section 6.7). Currently, three large prospective RCTs have reported the benefit of RP over WW [324, 333] and over AM [271] in men with low- and intermediate-risk PCa.

Radical prostatectomy can be performed by open, laparoscopic or robot-assisted (RARP) approach. In a randomised phase III trial, RARP was shown to have reduced admission times and blood loss but not early (twelve weeks) functional or oncological outcomes [334, 335]. Lower rates of positive surgical margins for high-volume surgeons suggest that experience and careful attention to surgical details, adjusted for the characteristics of the cancer being treated, can improve cancer control with RP [336-338].

Management decisions should be made after all treatments have been discussed in a multidisciplinary team (including urologists, radiation oncologists, medical oncologists and radiologists), and after balancing benefits and side effects of each therapy modality, together with the patient.

6.2.2 Low-risk PCa

At ten years' follow-up, a benefit for metastases-free and PFS but not CSS or OS for RP compared to AM was seen in the ProtecT study where the majority of men had early, localised disease (i.e. > 75% had either clinical T1 or Gleason sum score 6 disease) [271]. In the SPCG-4 study [333], death from any cause and distant metastases was significantly reduced in low-risk PCa at eighteen years of follow up for RP compared with WW, although this finding was based on a sub-group analysis as the majority of men in the trial (i.e. 62%) did not have low-risk disease. However, death from PCa was not reduced. In the PIVOT trial, a pre-planned subgroup analysis of men with low-risk PCa showed that RP did not significantly reduce all-cause mortality or death from PCa at ten years compared with WW.

The decision to offer RP in cases of low-risk cancer should be based on the probability of clinical progression, side-effects and potential benefit to survival [339]. The results of the ProtecT trial suggest that AM and surgery are alternatives to EBRT in patients whose tumours are most likely to be clinically insignificant (this is covered in more detail in Sections 6.1 and 6.3). Apart from disease characteristics, age and comorbidities also impact

on decision-making regarding treatment choices. Individual patient preferences should always be considered in shared decision-making.

If RP is performed in low-risk PCa, pelvic LND is not necessary as the risk for pN+ does not exceed 5% [340].

6.2.3 Intermediate-risk, localised PCa

Patients with intermediate-risk PCa should be informed about the results of two RCTs [324, 333] comparing RP vs. WW in localised PCa. In the SPCG-4 study, death from any cause (RR: 0.71; 95% CI: 0.53-0.95), death from PCa (RR: 0.38; 95% CI: 0.23-0.62) and distant metastases (RR: 0.49; 95% CI: 0.32-0.74) were significantly reduced in intermediate-risk PCa at eighteen years. In the PIVOT trial, according to a pre-planned subgroup analysis among men with intermediate-risk tumours, RP significantly reduced all-cause mortality (HR: 0.69; 95% CI: 0.49-0.98), but not death from PCa (0.50; 95% CI: 0.21-1.21) at ten years.

When managed with non-curative intent, intermediate-risk PCa is associated with ten- and fifteen-year PCa-specific mortality (PCSM) rates of 13% and 19.6%, respectively [341].

The risk of having positive LNs in intermediate-risk PCa is between 3.7% and 20.1% [340]. An eLND should be performed in intermediate-risk PCa if the estimated risk for pN+ exceeds 5% [340]. In all other cases, eLND can be omitted, which means accepting a low risk of missing positive nodes. Table 6.2.1 presents data from three RCTs.

Table 6.2.1: Oncological results of radical prostatectomy in organ-confined disease

Study	Trial	Population	Year of treatment	Median follow-up (mo)	Risk category	12-year CSS (%)	18-year CSS (%)
Bill-Axelsson, <i>et al.</i> 2014 [333]	SPCG-4	Pre-PSA era	1989-1999	160	Low-risk Intermediate-risk		89.8** 84.9**
Wilt, <i>et al.</i> 2012 [324]	PIVOT	Early years of PSA testing	1994-2002	120	Low-risk Intermediate-risk	100** 94.2**	n.a
Hamdy, <i>et al.</i> 2016 [271]	ProtecT	Case-finding	1999-2009	120	Low and intermediate-risk	99.0*	n.a

*10-year CSS

** Based on sub-group analysis of risk groups

CSS = cancer-specific survival; n = number of patients; n.r. = not reported; PSA = prostate-specific antigen; RP = radical prostatectomy.

6.2.4 High-risk and locally advanced PCa

Patients with high-risk PCa are at an increased risk of PSA failure, need for secondary therapy, metastatic progression and death from PCa. Nevertheless, not all high-risk PCa patients have a uniformly poor prognosis after RP [342]. When managed with non-curative intent, high-risk PCa is associated with ten- and fifteen-year PCSM rates of 28.8% and 35.5%, respectively [341].

There is no consensus regarding the optimal treatment of men with high-risk PCa. Provided that the tumour is not fixed to the pelvic wall, or that there is no invasion of the urethral sphincter, RP is a reasonable first step in selected patients with a low tumour volume. Extended LND should be performed in all high-risk PCa cases, as the estimated risk for positive LNs is 15-40% [340].

6.2.4.1 High-risk PCa

6.2.4.1.1 Gleason score 8-10

The incidence of organ-confined disease is 26-31% in men with a Gleason 8-10 on biopsy. A high rate of downgrading exists between the biopsy Gleason score and the Gleason score of the resected specimen [343]. Several retrospective case series have demonstrated CSS rates over 60% at fifteen years after RP in the context of a multimodal approach (adjuvant or salvage ADT and/or RT) for patients with a biopsy GS > 8 [343-346] [347].

6.2.4.1.2 Prostate-specific antigen > 20 ng/mL

Reports in patients with a PSA > 20 ng/mL who underwent surgery as initial therapy within a multimodal approach demonstrated a CSS at fifteen years of over 70% [345, 346, 348-351].

6.2.4.2 *Locally advanced PCa*

Surgery for locally advanced disease as part of a multimodal therapy has been reported [352-354]. Retrospective case series demonstrated over 60% CSS at fifteen years and over 75% OS at ten years [352-359].

For cT3b-T4 disease, PCa cohort studies showed a ten-year CSS of over 87% and an OS of 65% [360-362].

The indication for RP in all previously described stages assumes the absence of clinically detectable nodal involvement. Only limited evidence exists supporting RP of cN+ patients. In a recent study, the outcomes of 50 patients with cN+ were compared with those of 252 patients with pN1, but cN0 at pre-operative staging, and cN+ was not a significant predictor of CSS [363].

6.2.5 **Indication and extent of pelvic lymph node dissection**

A recent SR did not show any benefit of performing any PLND during RP for any oncological outcome, including survival [4]. However, it is generally accepted that eLND provides important information for staging and prognosis which cannot be matched by any other currently available procedure [255]. The individual risk of identifying positive LNs can be estimated using pre-operative nomograms. Only a few of these nomograms are based on eLND templates. A risk of nodal metastases over 5% (Briganti nomogram, MSKCC, or Roach formula) is an indication to perform nodal sampling by an eLND [340, 364, 365].

6.2.5.1 *Technique of lymph node dissection*

Extended LND includes removal of the nodes overlying the external iliac artery and vein, the nodes within the obturator fossa located cranially and caudally to the obturator nerve, and the nodes medial and lateral to the internal iliac artery. With this template, 94% of patients are correctly staged [366].

6.2.5.1.1 Sentinel node biopsy analysis

Sentinel node biopsy (SNB) was shown to have a sensitivity of 95.2% for detecting metastases at eLND in a SR [367]. Due to lack of any reliable evidence regarding oncological effectiveness, SNB is still an experimental nodal staging procedure (see Section 5.3.2.3). In addition, controversy regarding definitions and thresholds has limited its application in clinical practice, although efforts to standardise definitions based on consensus have recently been attempted [368].

6.2.6 **Radical prostatectomy in cN0 patients who are found to have pathologically confirmed lymph node invasion (pN1)**

At fifteen years of follow up, cN0 patients who were treated with RP but were found to have pN1 at the time of surgery, were reported to have a CSS and OS of 45% and 42%, respectively [369-375].

In terms of performing frozen section of nodes during RP, two retrospective observational studies have shown a better CSS and OS in favour of a completed RP vs. an abandoned RP in patients who were found to be pN+ at the time of surgery [372, 373, 376]. This highlights the fact that frozen section should no longer be performed and supports the role of RP as an important component of multimodal strategies of pN+ PCa.

6.2.6.1 *Outcome of pN1 disease*

6.2.6.1.1 Prognostic indicators

The number of positive LNs [377], the number of removed LNs [369, 374, 377-382], tumour volume within the LN, and capsular perforation of the nodal metastases are predictors of early recurrence after RP for pN1 disease [383]. A LN density (defined as the percentage of positive LNs in relation to the total number of analysed/removed LNs) over 20% was found to be associated with poor prognosis [384].

6.2.7 **Adjuvant treatment**

6.2.7.1 *Adjuvant treatment after RP*

For patients classified as pT3 pN0 with a high risk of local failure after RP due to positive margins (highest impact), capsule rupture, and/or invasion of the seminal vesicles, who present with a PSA level of < 0.1 ng/mL, both adjuvant or salvage radiotherapy to the prostatic fossa can be offered. (see Section 6.3.6). Adjuvant androgen ablation with bicalutamide did not improve PFS in localised disease after RP [385]. A SR showed a possible benefit for PFS but not OS for adjuvant androgen ablation therapy [386].

6.2.7.2 *Adjuvant androgen ablation in men with pN1 disease*

The combination of RP and early adjuvant HT in pN+ PCa has been shown to achieve a ten-year CSS rate of 80% [370, 371]. In patients who prove to be pN+ after RP, early adjuvant HT has been shown to significantly improve CSS and OS in a prospective RCT [371]. However, this trial included mostly patients with high-volume

nodal disease and multiple adverse tumour characteristics and the findings may not apply to men with less extensive nodal metastases.

6.2.7.3 Adjuvant radiotherapy in men with pN1 disease

In a retrospective multicentre cohort study, maximal local control with RT of the prostatic fossa appeared to be beneficial in PCa patients with pN1 after RP, treated adjuvantly with continuous ADT [375]. However, the beneficial impact of adjuvant RT on survival in patients with pN1 PCa was highly influenced by tumour characteristics. Men with low-volume nodal disease (< 3 LNs) and GS 7-10 and pT3-4 or R1, as well as men with three to four positive nodes were more likely to benefit from RT after surgery, while the other subgroups did not [375]. In a Surveillance, Epidemiology and End Results (SEER) retrospective population-based analysis, adding RT to RP showed a non-significant trend for improved OS but not PCa-specific survival, but data on the extent of additional RT is lacking in this study [376]. No recommendation can be made for the extent of adjuvant RT in pN1 disease although whole pelvis RT was given in more than 70% of men in a large retrospective series which identified a benefit for adding RT to androgen ablation in pN1 patients [375]. However the optimal field (prostatic fossa only or whole pelvis) remains unclear.

6.2.7.4 Adjuvant chemotherapy

The TAX3501 trial, compared the role of leuprolide (eighteen months) with, and without, docetaxel (six cycles) closed prematurely due to poor accrual [387]. Adjuvant chemotherapy after RP should only be considered within a clinical trial.

6.2.7.5 Guidelines for extended lymph node dissection in prostate cancer and pN+ patients

Recommendations	LE	GR
Do not perform a lymph node dissection (LND) in low-risk PCa.	2b	A
Perform an extended(e)LND in intermediate-risk PCa if the estimated risk for positive lymph nodes exceeds 5%.	2b	B
Perform an eLND in high-risk PCa.	2a	A
Do not perform a frozen section of nodes during radical prostatectomy (RP) to decide whether to proceed with, or abandon, the procedure.	2a	A
Do not perform a limited LND.	2a	A
Upon detection of nodal involvement during RP:		
• offer adjuvant androgen deprivation therapy (ADT);	1b	A
• discuss adjuvant ADT with additional radiotherapy (see Section 6.2.6.3);	2b	A
• offer observation (expectant management) to a patient after eLND with < 2 nodes with microscopic involvement, and a PSA < 0.1 ng/mL and absence of extranodal extension.	2b	B

6.2.8 Comparing RP surgical approaches

A previous SR and meta-analysis of non-RCTs demonstrated that RARP had lower peri-operative morbidity and a reduced risk of positive surgical margins compared with laparoscopic prostatectomy (LRP), although there was considerable methodological uncertainty [388]. There was no evidence of differences in urinary incontinence (UI) rates at twelve months and there was insufficient evidence to draw conclusions on differences in cancer-related, patient-driven or erectile dysfunction (ED) outcomes. There is a lack of studies comparing the different surgical modalities for these longer-term outcomes [388-394]. Another SR and meta-analysis [335] included two small RCTs comparing RARP vs. LRP. The results suggested higher rates of erectile function recovery (RR 1.51; 95% CI: 1.19-1.92) and restoring early continence (RR 1.14; 95% CI: 1.04-1.24) in the RARP group. Increased surgical experience has lowered the complication rates of RP and improved cancer cure [395-398]. Consequently, there is emerging data to suggest some benefits of the robotic approach over the laparoscopic and open approaches, in terms of perioperative, recovery and short-term functional outcomes; however, there is uncertainty over oncological outcomes, longer-term functional and QoL outcomes [334].

6.2.9 Indications for nerve-sparing surgery

Nerve-sparing RP can be performed safely in most men with localised PCa [399, 400]. Clear contraindications are patients in whom there is a high risk of extracapsular disease, such as any cT2c or cT3 PCa, and any GS > 7 on biopsy. An externally validated nomogram predicting side-specific extracapsular extension can help guide decision making [401, 402]. Multiparametric MRI might be helpful in selecting a nerve-sparing approach (see Section 5.3.1.4).

If any doubt remains regarding residual tumour, the surgeon should remove the neurovascular bundle (NVB). Alternatively, the use of intra-operative frozen-section analysis can help guide these decisions [403].

There is conflicting data on the early use of phosphodiesterase-5 (PDE5) inhibitors in penile rehabilitation post-surgery [404, 405]. However, a large multicentre RCT including men < 68 years old with normal pre-operative erectile function, showed benefit from daily dosing of 5 mg tadalafil, after nerve-sparing RP for organ-confined non-metastatic PCa [406].

6.2.10 Guidelines for radical prostatectomy

Recommendations	LE	GR
Offer both radical prostatectomy (RP) and RT in patients with low- and intermediate-risk disease and a life expectancy > 10 years.	1b	A
Offer AS as an alternative to surgery or RT in patients with low-risk disease and a life expectancy of > 10 years.	1b	A
Offer nerve-sparing surgery in patients with a low risk of extracapsular disease (refer to Partin tables/nomograms).	2b	B
Offer RP in patients with high-risk localised PCa and a life expectancy of > 10 years only as part of multi-modal therapy.	2a	A
Offer RP in selected patients with locally advanced (cT3a) disease and a life expectancy > 10 years only as part of multi-modal therapy.	2b	B
Offer RP in highly selected patients with locally advanced disease (cT3b-T4 N0 or any T N1) only as part of multi-modal therapy.	3	C
Do not offer neoadjuvant hormonal therapy before RP.	1a	A
Do not offer adjuvant hormonal therapy after RP for pN0 disease.	1a	A

6.3 Treatment: definitive radiotherapy

6.3.1 Introduction

Intensity-modulated radiotherapy (IMRT), with or without image-guided radiotherapy (IGRT), is the accepted best standard for EBRT. Regardless of the technique used, the choice of treatment is multidisciplinary. After the extent of the tumour has been properly assessed, the following are taken into account [407]:

- 2017 TNM classification;
- gleason score, defined using an adequate number of core biopsies (at least 10);
- baseline PSA;
- age of the patient;
- patient's comorbidity, life expectancy, and QoL;
- International Prostate Symptom Score (IPSS) and uroflowmetry recordings (max urinary peak flow > 15 mL/s when considering brachytherapy [408]);
- and the EAU prognostic factors classification.

6.3.2 Technical aspects: three-dimensional conformal radiotherapy and intensity-modulated external-beam radiotherapy

Anatomical data are acquired by scanning the patient in the treatment position. The data are transferred to the three-dimensional (3D) treatment planning system, which visualises the clinical target volume and then adds a surrounding safety margin. Real-time verification of the irradiation field using portal imaging allows comparison of the treated and simulated fields, and correction of deviations where displacement is more than 5 mm.

It is possible to use IMRT with linear accelerators, equipped with the latest multileaf collimators and specific software. At the time of irradiation, a multileaf collimator automatically (and in the case of IMRT continuously) adapts to the contours of the target volume seen by each beam. This allows for a more complex distribution of the dose to be delivered within the treatment field and provides concave isodose curves, which are particularly useful as a means of sparing the rectum. To date, no RCT have been published comparing dose escalation using IMRT and 3D-CRT.

With dose escalation using IMRT, organ movement becomes a critical issue, in terms of both tumour control and treatment toxicity. Evolving techniques will therefore combine IMRT with some form of IGRT, in which organ movement can be visualised and corrected for in real time, although the optimum means of achieving this is still unclear [409]. Tomotherapy is another evolving technique for the delivery of IMRT, which uses a linear accelerator mounted on a ring gantry that rotates as the patient is delivered through the centre of the ring, analogous to spiral CT scanning.

Whatever the techniques and their degree of sophistication, quality assurance plays a major role in the management of RT, requiring the involvement of physicians, physicists, dosimetrists, radiographers, radiologists and computer scientists.

6.3.3 Radiotherapy for localised PCa

6.3.3.1 Dose escalation

Several RCTs have shown that dose escalation (range 74-80 Gy) has a significant impact on five-year survival without biochemical relapse [410-419]. These trials have generally included patients from several risk groups, and the use of neoadjuvant/adjuvant HT has varied. The best evidence of an OS benefit for patients with intermediate- or high-risk PCa, but not with low-risk PCa, comes from a non-randomised but well conducted propensity-matched retrospective analysis of the U.S. National Cancer Database (NCDB) covering a total of 42,481 patients [420].

In everyday practice, a minimum dose of ≥ 74 Gy is recommended for EBRT + HT.

Currently, it is not possible to make different recommendations according to the patient's risk group.

If IMRT and IGRT are used for dose escalation, severe late side effects \geq Grade 3 for the rectum is about 2-3% and for the genito-urinary tract is 2-5% [412, 419, 421-434] (see also Chapter 8).

Table 6.3.1: Randomised trials on dose escalation in localised PCa

Trial	n	PCa condition	Radiotherapy Dose	Follow-up	Outcome	Results
MD Anderson 2011 [410]	301	T1-T3, N0, M0, PSA 10 ng/mL vs. PSA > 10 ng/mL	70 vs. 78 Gy	Median 9 yr	Disease specific mortality (DSM) vs. other cause of death	High risk/PSA > 10 16 % DSM @ 70 Gy 4% DSM @ 78 Gy ($p = 0.05$) Higher risk 15% DSM @ 70 Gy 2% DSM @ 78 Gy ($p = 0.03$)
PROG 95-09 2010 [411]	393	T1b-T2b PSA 15 ng/mL 75% GS < 6	70.2 vs. 79.2 Gy including proton boost 19.8 vs. 28.8 Gy	Median 8.9 yr. for survivors	10-year ASTRO BCF	All patients: 32% BF @ 70.2 Gy 17% BF @ 79.2 Gy ($p < 0.0001$) Low-risk patients: 28% BF @ 70.2 Gy 7% BF @ 79.2 Gy ($p < 0.0001$)
MRC RT01 2014 [407]	843	T1b-T3a, N0, M0 PSA < 50 ng/mL neoadjuvant HT	64 vs. 74 Gy	Median 10 yr.	BFS; OS	43% BFS @ 64 Gy 55% BFS @ 74 Gy ($p = 0.0003$) 71% OS both groups ($p = 0.96$)
Dutch RCT 2014 [419]	664	T1b-T4 143 pts. with (neo)adjuvant HT	68 vs. 78 Gy	Median 110 mo.	Freedom biochemical (Phoenix) and/or clinical failure (FFF) @ 10 yr.	43% FFF @ 68 Gy 49% FFF @ 78 Gy ($p = 0.045$)
French GETUG 06 2011 [414]	306	T1b-T3a, N0, M0 PSA < 50 ng/mL	70 vs. 80 Gy	Median 61 mo.	BCF (ASTRO)	39% BF @ 70 Gy 28% BF @ 80 Gy
Retrospective NCDB study 2015 [420]	16,714	intermediate risk 73% T \leq 2a 76% GS \leq 7a	< 75.6 Gy vs. \geq 75.6 Gy 49% HT	Median 85-86 mo.	OS	Propensity adjusted HR: 0.84 favouring dose escalation ($p < 0.001$)
	13,538	high risk 40% T \geq 2b 67% GS \geq 7b	< 75.6 Gy vs. \geq 75.6 Gy 77% HT			Propensity adjusted HR: 0.82 favouring dose escalation ($p < 0.001$)

BCF = biochemical failure; BFS = biochemical progression-free survival; GS = Gleason score; HR = hazard ratio; HT = hormone therapy; OS = overall survival; PSA = prostate-specific antigen.

6.3.3.2 Hypofractionation

In radiobiology, the linear quadratic model uses two coefficients, alpha (α) and beta (β) to describe the dose-response relationship. In clinical practice, these coefficients are used to calculate the effect of different fractionation schemes. Fractionated RT utilises differences in the DNA repair capacity of normal and tumour tissue. In fast growing tissue including many tumours, cells have little time to repair photon-induced DNA damage. The α/β ratio is then typically around 10 Gy. In contrast, tissue with a low cell renewal has a good opportunity for repair between fractions of irradiation. In such tissue, the α/β ratio is 3 Gy or lower. Slowly proliferating cells with low α/β ratios are very sensitive to an increased dose per fraction [417].

While the correct α/β ratio is still controversial, a meta-analysis of 25 studies with > 14,000 patients concludes that PCa, due to its slow growth, has an α/β ratio of approximately 1.5 Gy. Assuming this value, hypofractionated RT could be more effective than conventional fractions of 1.8-2 Gy [418]. Beyond the radiobiological aspects, hypofractionation (HFX) can increase the convenience for the patient and lower costs for the health care system.

Several studies report on HFX applied in various techniques and in part also including HT [435-444]. A SR concludes that studies on moderate HFX (2.5-4 Gy/fx) delivered with conventional 3D-CRT/IMRT have sufficient follow-up to support the safety of this therapy, but long-term efficacy data are still lacking [445]. Extreme HFX (5-10 Gy/fx) typically requires IGRT and stereotactic body radiotherapy (SBRT). Short-term biochemical control is comparable to conventional fractionation. However, there are concerns about high-grade genitourinary and rectal toxicity, and long-term side effects may not all be known yet [445-447].

On behalf of the German Society of Radiation Oncology, an international expert panel has released a comprehensive overview on HFX for clinical routine [448]. Taking into account the published results and the uncertainties of the correct α/β ratio, moderate HFX (Table 6.3.2) plus dose escalation should be done by experienced teams, accompanied by meticulous RT quality assessment and close attention to organ-at-risk dose-constraints until long-term data are available. It should be restricted to high-quality EBRT using IGRT and IMRT in carefully selected patients and adhere to published phase 3 protocols with documented safety and efficacy. The Conventional or Hypofractionated High-dose Intensity Modulated Radiotherapy in Prostate Cancer (CHHiP)-regimen with 60 Gy in 20 fractions over four weeks or the RTOG regimen with 70 Gy in 28 fractions over six weeks at present seem to be the first choices. Meticulous follow-up and documentation of outcome and late toxicity are mandatory. Hypofractionation to the pelvic LNs and post-operative HFX in the adjuvant or salvage setting are experimental and should be reserved for clinical trials.

Radiotherapy with > 3.4 Gy has been suggested to define extreme HFX [448]. Respective studies largely include low- to intermediate-risk patients and obtain very favourable results. Table 6.3.3 gives an overview on selected studies. It seems prudent to restrict extreme HFX to prospective clinical trials and to inform patients on the uncertainties of the long-term outcome.

6.3.3.3 Neoadjuvant or adjuvant hormone therapy plus radiotherapy

The combination of RT with luteinising-hormone-releasing hormone (LHRH) ADT has definitively proven its superiority compared with RT alone followed by deferred ADT on relapse, as shown by phase III RCTs [451-455] (Table 6.3.3). These trials included high-risk PCa patients, mostly by virtue of locally advanced (T3-T4 N0-X) disease, though with a wide range of clinical risk factors, such as PSA level or Gleason grade (high-risk localised, T1-2, N0-X PCa). The most powerful conclusion from these studies comes from the EORTC 22863 trial, which is the basis for the combination of RT and ADT in patients with locally advanced PCa as standard practice today.

In daily practice, ADT starts either at the onset of RT (for adjuvant ADT) or two or three months before (for neoadjuvant), but the concomitant component is crucial to potentiate RT. Long-term ADT, ranging from two to three years is recommended for locally advanced disease [416, 456] rather than short term (six months) [455]. Dose escalation phase III RCTs are on-going to assess its impact on DFS. Cardiovascular mortality may be related to ADT, not RT, as addressed in Section 8.2

Whether these results should be applied to patients with intermediate- or high-risk localised PCa is unclear. The Boston trial has shown an improved eight-year OS rate for patients without moderate or severe comorbidity assigned to six months of complete ADT ($p = 0.01$) [454], and the RTOG 94-08 study showed an increased ten-year OS rate for intermediate risk only with four months of complete ADT ($p = 0.003$) [415].

The EORTC trial 22961, an equivalence trial with 970 patients (78% T3-4, 92% N0) combined RT (70 Gy) with either six months or with three years of LHRH analogue treatment. With a median follow-up of 6.4 years, both CSS and overall mortality were significantly lower with long-term androgen suppression [416].

In the RTOG 9910 trial, 1,579 intermediate-risk PCa patients were randomised to LHRH antagonist therapy for eight weeks before RT (70.2 Gy in 2-D or 3-D techniques) followed by either another eight or 28 weeks of anti-hormonal treatment. Extended androgen suppression did not significantly improve ten-year rates of distant (both arms 6%), loco-regional (6% vs. 4%) or biochemical progression (both arms 27%), or DSS (96% vs. 95%) or OS (66% vs. 67%). The 8 + 8 week scheme was confirmed as a standard procedure [457].

Table 6.3.3: Studies of use and duration of androgen deprivation therapy in combination with radiotherapy for prostate cancer

Trial	TNM stage	n	Trial	ADT	RT	Effect on OS
EORTC 22863, 2010 [451]	T1-2 poorly differentiated and M0, or T3-4 N0-1 M0	415	EBRT ± ADT	LHRH agonist for 3 yr. (adjuvant)	70 Gy RT	Significant benefit at ten yr. for combined treatment (HR: 0.60, 95% CI: 0.45-0.80, $p = 0.0004$).
RTOG 85-31, 2005 [452]	T3 or N1 M0	977	EBRT ± ADT	Orchiectomy or LHRH agonist 15% RP	65-70 Gy RT	Significant benefit for combined treatment ($p = 0.002$) seems to be mostly caused by patients with GS 7-10
Granfors, <i>et al.</i> 2006 [458]	T3 N0-1 M0	91	EBRT ± ADT	Orchiectomy	65 Gy RT	Significant benefit ($p = 0.02$ $p = 0.03$), mainly caused by LN-positive tumours
D'Amico, <i>et al.</i> 2008 [454]	T2 N0 M0 (localised unfavourable risk)	206	EBRT ± ADT	LHRH agonist plus flutamide for 6 mo.	70 Gy 3D-CRT	Significant benefit (HR: 0.55, 95% CI: 0.34-0.90, $p = 0.01$) that may pertain only to men with no, or minimal, comorbidity TROG 96-01

Denham, <i>et al.</i> 2011 [455]	T2b-4 N0 M0	802	Neoadjuvant ADT duration	Goserelin plus flutamide 3 or 6 mo. before, plus concomitant suppression	66 Gy 3D-CRT	No significant difference in OS reported; benefit in PCa-specific survival (HR: 0.56; 95% CI: 0.32-0.98, p = 0.04) (10 yr.: HR: 0.84, 0.65-1.08; p = 0.18)
RTOG 94-13, 2007 [459]	T1c-4 N0-1 M0	1292	ADT timing comparison	2 mo. neoadjuvant plus concomitant vs. 4 mo. adjuvant suppression	Whole pelvic RT vs. prostate only; 70.2 Gy	No significant difference between neoadjuvant plus concomitant vs. adjuvant androgen suppression therapy groups (interaction suspected)
RTOG 86-10, 2008 [453]	T2-4 N0-1	456	EBRT ± ADT	Goserelin plus flutamide 2 mo. before, plus concomitant therapy	65-70 Gy RT	No significant difference at 10 yr.
RTOG 92-02, 2008 [456]	T2c-4 N0-1 M0	1554	Short vs. prolonged ADT	LHRH agonist given for 2 years as adjuvant after 4 mo. as neoadjuvant	65-70 Gy RT	p = 0.73 p = 0.36 overall; significant benefit (p = 0.044) (p = 0.0061) in subset with GS 8-10
EORTC 22961, 2009 [416]	T1c-2ab N1 M0, T2c-4 N0-1 M0	970	Short vs. prolonged ADT	LHRH agonist for 6 mo. vs. 3 yr.	70 Gy 3D-CRT	Better result with 3-year treatment than with 6 mo. (3.8% improvement in survival at 5 yr.)
Pisansky, <i>et al.</i> 2014 [457]	intermediate risk (94% T1-T2, 6% T3-4)	1579	Short vs. prolonged ADT	LHRH antagonist 8 + 8 vs. 8 + 28 wk	70.2 Gy 2D/3D	67 vs. 68% p = 0.62, confirms 8 + 8 weeks LHRH as a standard
SPCG-7/SFUO-3, 2014 [460]	T1b-2 Grade 2-3, T3 N0 M0	875	ADT ± EBRT	LHRH agonist for 3 mo plus continuous flutamide	70 Gy 3D-CRT vs. no RT	18.9% (30.7%) vs. 8.3% (12.4%) cancer specific mortality at 10 (15) yr. favouring combined treatment (HR: 0.35; p < 0.0001 for 15 yr. results) NCIC CTG PR.3/MRC
PRO7/SWOG, 2014, 2015 [461, 462]	T3-4 (88%), PSA > 20 ng/mL (64%), GLS 8-10 (36%) N0 M0	1205	ADT ± EBRT	Continuous LHRH agonist	65-70 Gy 3D-CRT vs. no RT	10 yr. OS = 49% vs. 55% favouring combined treatment (HR: 0.7, p < 0.001)
Mottet, <i>et al.</i> 2012 [463]	T3-4 N0 M0	273 264	ADT ± EBRT	LHRH agonist for 3 yr.	70 Gy 3D-CRT vs. no RT	Significant reduction of clinical progression; 5 yr. OS 71.4% vs. 71.5%

ADT = androgen deprivation therapy; EBRT = external beam radiation therapy; GS = Gleason score; LHRH = luteinising-hormone-releasing hormone; OS = overall survival; RT = radiotherapy; HR = hazard ratio; 3D-CRT = three-dimensional conformal radiotherapy.

6.3.3.4 *Neoadjuvant chemotherapy plus radiotherapy*

The GETUG 12 trial investigated the impact of neoadjuvant chemotherapy with docetaxel on the PFS in a cohort of 413 high-risk patients. Patients were randomly assigned to either goserelin 10.8 mg every three months for three years, plus four cycles of docetaxel and estramustine or to goserelin alone (arm 2). Local therapy was administered at three months and consisted of RT in 358 patients (87%). Toxicity included Grade 3-4 neutropenia (27%) with neutropenic fever in 2%, but no toxicity-related death. A PSA response (PSA < 0.2 ng/mL after three months of treatment) was obtained in 34% in the ADT + docetaxel arm and 15% in the ADT arm. With a median follow-up period of 4.6 years, the four-year PFS was 85% in arm 1 vs. 81% in arm 2 ($p = 0.26$), but the data need to mature [464].

6.3.3.5 *Combined dose-escalated radiotherapy and androgen-deprivation therapy*

Zelevsky *et al.* [465] reported a retrospective analysis comprising 571 patients with low-risk PCa (22.4%), 1,074 with intermediate-risk PCa (42.1%), and 906 with high-risk PCa (35.5%). Three-dimensional-conformal RT or IMRT were administered. The prostate dose ranged from 64.8 to 86.4 Gy; doses beyond 81 Gy were delivered during the last ten years of the study using image-guided IMRT. Complete androgen blockade was administered at the discretion of the treating physician to 623 high-risk PCa (69%), 456 intermediate-risk PCa (42%) and 170 low-risk PCa (30%) patients. The duration of ADT was three months for low-risk patients and six months for intermediate-risk and high-risk patients, starting three months before RT. The ten-year biochemical disease-free rate (BDFR) was significantly improved by dose escalation: 84% (> 75.6 Gy) vs. 70% for low-risk PCa ($p = 0.04$), 76% (> 81 Gy) vs. 57% for intermediate-risk PCa ($p = 0.0001$), and 55% (> 81 Gy) vs. 41% for high-risk patients ($p = 0.0001$). The six-month ADT also influenced the BDFR in intermediate- and high-risk patients, with 55% for intermediate-risk vs. 36% for high-risk patients ($p < 0.0001$). In the multivariate analysis, a dose > 81 Gy ($p = 0.027$) and ADT ($p = 0.052$) were found to be predictive factors for distant metastasis-free survival, but none of these parameters influenced OS.

6.3.3.6 *Recommended external beam radiation therapy treatment policy for localised PCa*

6.3.3.6.1 Low-risk PCa

Intensity-modulated RT with escalated dose without ADT is an alternative to brachytherapy (see below).

6.3.3.6.2 Intermediate-risk PCa

Patients suitable for ADT can be given combined IMRT with short-term ADT (four to six months) [415, 466, 467]. For patients unsuitable for ADT (e.g. due to comorbidities) or unwilling to accept ADT (e.g. to preserve their sexual health), the recommended treatment is IMRT at an escalated dose (76-80 Gy) or a combination of IMRT and brachytherapy.

6.3.3.6.3 Localised high-risk PCa

The high risk of relapse outside the irradiated volume makes it mandatory to use a combined modality approach, consisting of dose-escalated IMRT, possibly including the pelvic lymphatics + long-term ADT. The duration of ADT has to take into account WHO PS, comorbidities, and the number of poor prognostic factors. It is important to recognise that EBRT + short-term ADT did not improve OS in high-risk localised PCa, in the Boston and RTOG 94-13 and 86-10 trials [453, 454, 459], and long-term ADT is currently recommended for these patients.

6.3.3.6.4 Locally advanced PCa: T3-4 N0, M0

In locally advanced disease, RCTs have clearly established that the additional use of long-term ADT combined with RT produces better OS. Whilst RT is effective in this patient group, combined RT + ADT is clearly superior to ADT alone.

6.3.3.6.5 MRC PR3/PR07 study - The National Cancer Institute of Canada (NCIC)/UK Medical Research Council (MRC)/Southwest Oncology Group (SWOG) intergroup PR3/PR07 study

This study comprised 1,205 patients, consisting of T3-4 ($n = 1,057$), or T2, PSA > 40 ng/mL ($n = 119$), or T2, PSA > 20 ng/mL and Gleason score > 8 ($n = 25$), who were randomly assigned to lifelong ADT (bilateral orchidectomy or LHRH agonist), with or without RT (65-70 Gy to the prostate, with or without 45 Gy to the pelvic LNs). With a median follow-up of eight years, OS was significantly improved in the patients allocated to ADT + RT (HR: 0.70; 95% CI: 0.57-0.85; $p < 0.001$). Deaths from PCa were significantly reduced by the addition of RT to ADT (HR: 0.46; 95% CI: 0.34-0.61; $p < 0.001$). Patients on ADT + RT reported a higher frequency of adverse events related to bowel toxicity, but only two of 589 patients had Grade 3 or greater diarrhoea at 24 months after RT [462].

A total of 273 patients with locally advanced PCa T3-4 or pT3 N0 M0 were randomly assigned to three years

of ADT using an LHRH agonist (leuprorelin), with or without RT (70 Gy to the prostate plus 48 ± 2 Gy to the pelvic LNs). After a median follow-up period of 67 months, there was a significant improvement in the five-year DFS ($p < 0.001$), metastatic DSS ($p < 0.018$), and loco-regional PFS ($p < 0.0002$), but the effect on OS was not reported [463].

Another study compared hormonal treatment alone (i.e. three months of continuous androgen blockade followed by continuous flutamide treatment ($n = 439$) with the same treatment combined with RT ($n = 436$) [460]. The ten (fifteen) year cumulative PCSM was 18.9% (30.7%) and 8.3% (12.4%) (HR: 0.35; [$p < 4.1E-10$ for fifteen year results]), and overall mortality was 35.3% (56.7%) and 26.4% (43.4%) (HR: 0.70; $p = 0.0006$ for fifteen-year results), respectively.

6.3.3.7 *Lymph node irradiation*

6.3.3.7.1 Prophylactic LN irradiation in clinically N0 prostate cancer (estimated cN0)

There is no level 1 evidence for prophylactic whole-pelvic irradiation, since RCTs have failed to show that patients benefit from prophylactic irradiation (46-50 Gy) of the pelvic LNs in high-risk cases. Such studies include the RTOG 77-06 study ($n = 484$ with T1b-T2) [468], the Stanford study ($n = 91$) [469], and the GETUG 01 trial ($n = 444$ with T1b-T3 N0 pNx M0) [470]. In the RTOG 94-13 study [459], there were no differences in the PFS in patients treated with whole-pelvic or prostate-only RT, but interactions between whole-pelvic RT and the duration of ADT were reported following the subgroup analysis. Pelvic LND may be needed to improve the selection of patients who may be able to benefit from pelvic LN irradiation and to supplement the use of the Briganti tables [340] and/or the Roach formula [471]. The results of pelvic LND, especially in young patients, allows radiation oncologists to tailor both the planning target volume and the duration of ADT, particularly ensuring that there is no pelvic irradiation for pN0 patients, while it is possible to irradiate, in combination with long-term ADT. The real impact of such an approach remains, so far, hypothetical, since no randomised trials are available. The benefits of pelvic nodal irradiation at a high dosage using IMRT merit further investigation in a phase II trial. One such trial is currently recruiting through the RTOG, and PIVOTAL, a UK randomised phase II trial, has completed accrual.

6.3.3.7.2 Clinical, or pathological node positive, M0 disease

Outcomes in this group after RT as a sole modality are poor [416], and these patients should receive RT plus long-term ADT. The RTOG 85-31 randomised phase III trial, with a median follow-up period of 6.5 years, showed that 95 of the 173 pN1 patients who received pelvic RT with immediate HT had better five-year (54%) and nine-year (10%) PFS rates (PSA < 1.5 ng/mL) vs. 33% and 4%, respectively, for radiation alone ($p < 0.0001$). Multivariate analysis showed that this combination had a statistically significant impact on the OS [472]. Patients with pelvic LN involvement lower than the iliac regional nodes, < 80 years old, with a WHO PS 0-1 and no severe comorbidity, may be candidates for EBRT + immediate long-term HT. Recent data from the UK Systemic Therapy in Advancing or Metastatic Prostate cancer: Evaluation of Drug Efficacy (STAMPEDE) trial suggests that pelvic RT could be beneficial for N1 disease, but this is not based on a randomised comparison [473] (see also Section 6.3.7).

6.3.4 **Proton beam therapy**

In theory, proton beams are an attractive alternative to photon-beam RT for PCa, as they deposit almost all their radiation dose at the end of the particle's path in tissue (the Bragg peak), in contrast to photons, which deposit radiation along their path. There is also a very sharp fall-off for proton beams beyond their deposition depth, meaning that critical normal tissues beyond this depth could be effectively spared. In contrast, photon beams continue to deposit energy until they leave the body, including an exit dose.

Two recent planning studies comparing conformal proton therapy with IMRT have yielded conflicting results; one study suggested that the two are equivalent in terms of rectal dose sparing, but that IMRT is actually superior in terms of bladder sparing [474]; the other study suggested a clearer advantage for protons [475].

One RCT on dose escalation (70.2 vs. 79.2 Gy) has incorporated protons for the boost doses of either 19.8 or 28.8 Gy. This trial shows improved outcome with the higher dose, but it cannot be used as evidence for the superiority of proton therapy per se [411]. Thus, unequivocal information that shows an advantage of protons over IMRT photon therapy is still not available.

Studies from the SEER database, and from Harvard [476, 477], describing toxicity and patient reported outcomes do not point to an inherent superiority for protons. In terms of longer term gastrointestinal (GI) toxicity, proton therapy might even be inferior to IMRT [477].

A retrospective 2:1 matched-control analysis of 27,647 U.S. Medicare patients compared 314 men receiving proton therapy with 628 men who had IMRT. Despite the considerably higher costs for proton

therapy, there was some improvement in GU-tract toxicity after 6 months, but not after 12 months, and not at the GI tract [478].

A randomised trial comparing equivalent doses of proton-beam therapy with IMRT is needed to compare the efficacy of protons vs. photons; a study of this type is under consideration by the RTOG. Meanwhile, proton therapy must be regarded as a promising, but experimental, alternative to photon-beam therapy.

6.3.5 **Low-dose rate and high-dose rate brachytherapy**

6.3.5.1 *Low-dose rate (LDR) brachytherapy*

There is a consensus on the following eligibility criteria for LDR monotherapy [479]:

- stage cT1b-T2a N0, M0;
- Gleason score 6 with \leq 50% of biopsy cores involved with cancer or;
- Gleason score 3 + 4 with \leq 33% of biopsy cores involved with cancer;
- an initial PSA level of \leq 10 ng/mL;
- a prostate volume of $<$ 50 cm³;
- an International Prostatic Symptom Score (IPSS) \leq 12 and maximal flow rate $>$ 15 mL/min on urinary flow tests [408].

Low-dose rate brachytherapy uses radioactive seeds permanently implanted into the prostate. Patients with low- and favourable intermediate-risk PCa are the most suitable candidates for LDR brachytherapy as monotherapy. The use of guidelines is strongly recommended [479-481]. There have been no RCTs comparing brachytherapy as monotherapy with other curative treatment modalities. Outcome data are available from a number of large population cohorts with mature follow-up [482-489]. The BDFS for Gleason 6 patients after five and ten years has been reported to range from 71% to 93% and 65% to 85%, respectively [482-489].

A significant correlation has been shown between the implanted dose and recurrence rates [490]. Patients receiving a D90 (dose covering 90% of the prostate volume) of $>$ 140 Gy had a significantly higher biochemical control rate (PSA $<$ 1.0 ng/mL) after four years than patients who received less than 140 Gy (92 vs. 68%).

In men with intermediate- or high-risk PCa, LDR brachytherapy boost with supplemental EBRT and hormonal treatment [491] may be considered. Dose-escalated EBRT has been compared with EBRT and LDR brachytherapy boost in intermediate-risk and high-risk patients in a RCT [492]. The ASCENDE-RT (Androgen Suppression Combined with Elective Nodal and Dose Escalated Radiation Therapy) multi-centre Canadian trial compared EBRT (total dose of 78 Gy) to EBRT (total dose 46 Gy) followed by LDR brachytherapy boost (prescribed dose 115 Gy). The use of LDR boost resulted in five- and seven-year PSA PFS rates of 89% and 86%, respectively compared to 84% and 75% in those treated with EBRT alone. This improvement in PSA control came with an increase in late urinary toxicity with 18% experiencing G3+ toxicity in the LDR boost arm as compared to 8% in the EBRT alone arm. Toxicity was mainly due to urethral strictures and incontinence and great care should be taken during treatment planning.

6.3.5.2 *High-Dose Rate (HDR) brachytherapy*

High-dose rate brachytherapy uses a radioactive source temporarily introduced into the prostate to deliver radiation. The technical differences are outlined in the table below. The use of published guidelines is strongly recommended [493]. High-dose rate brachytherapy can be delivered in single or multiple fractions and is often combined with EBRT of at least 45 Gy [494]. A single RCT of EBRT vs. EBRT and HDR brachytherapy boost has been reported [495]. A total of 218 patients with organ-confined PCa were randomised to EBRT alone with a dose of 55 Gy in twenty fractions, or EBRT with a dose of 35.75 Gy in thirteen fractions, followed by HDR brachytherapy with a dose of 17 Gy in two fractions over 24 hours. In comparison with EBRT alone, the combination of EBRT and HDR brachytherapy showed a significant improvement in the BDFR ($p = 0.04$) with five-, seven- and ten-year estimates of biochemical control of 75%, 66% and 46% for combination treatment compared to 61%, 48% and 39% for external beam alone. There were no differences in the rates of late bowel, urinary or sexual patient QoL over a ten-year follow-up period. However, a very high, uncommon rate of early recurrences was observed in the EBRT arm alone, even after two years, possibly due to a dose lower than the current standard used [495]. A SR of non-randomised trials has suggested the possibility that outcomes with EBRT plus HDR brachytherapy are superior to brachytherapy alone, but this needs confirmation in a prospective RCT [496].

Fractionated HDR brachytherapy as monotherapy can be offered to patients with low and intermediate-risk PCa, who should be informed that results are only available from limited series in very experienced centres [497, 498]. Five year PSA control rates over 90% are reported, with late G3+ genito-urinary toxicity rates $<$ 5% and no, or very minimal, G3+ gastro-intestinal toxicity rates [497, 498].

	Differences in prostate brachytherapy techniques
Low Dose Rate (LDR)	<ul style="list-style-type: none"> • Permanent seeds implanted • Uses I-125 (most common), Pd-103 or Cs-131 isotopes • Radiation dose delivered over weeks and months • Acute side effects resolve over months • Radiation protection issues for patient and carers
High Dose Rate (HDR)	<ul style="list-style-type: none"> • Temporary implantation • Ir-192 isotope introduced through implanted needles or catheters • Radiation dose delivered in minutes • Acute side effects resolve over weeks • No radiation protection issues for patient or carers

A SR and meta-analysis of observational studies comparing patients exposed or unexposed to RT in the course of treatment for PCa demonstrate an increased risk of developing second cancers for bladder (OR 1.39), colorectal (OR 1.68) and rectum (OR 1.62) with similar risks over lag times of five and ten years. Absolute risks over ten years are small (1-4%) but should be discussed with younger men in particular [499].

6.3.6 **Immediate (adjuvant) post-operative external irradiation after RP (cN0 or pN0) (Table 6.3.5)**

Extracapsular invasion (pT3), Gleason score ≥ 7 and positive surgical margins (R1) are associated with a risk of local recurrence, which can be as high as 50% after five years [500]. Three prospective RCTs have assessed the role of immediate post-operative RT (adjuvant RT [ART]), as follows:

6.3.6.1 *EORTC 22911*

EORTC 22911 [501], with a target sample size of 1,005 patients, compared immediate post-operative RT (60 Gy) with RT delayed until local recurrence (70 Gy) in patients classified as pT3 pN0 with risk factors R1 and pT2R1 after radical retropubic prostatectomy (RRP). Grade 4 toxicity was not observed (for criteria: see Tables 8.2.2 and 8.2.3). The rate of Grade 3 GU toxicity was 5.3% vs. 2.5% in the observation group after ten years. For patients younger than 70 years, the study concluded that immediate post-operative RT after surgery significantly improved the ten-year biological PFS to 60.6% vs. 41.1% in the observation group. Local-regional control was better in the long-term follow-up at ten years after immediate irradiation (HR: 0.45; $p < 0.0001$). However, ART patients with pT2-3 R1 also showed an improved clinical PFS after ten years (HR: 0.69; $p = 0.008$). Overall survival did not differ significantly between the treatment arms. After re-evaluation using a central pathological review, the highest impact of ART was on biochemical progression (HR reduced to 0.3) seen in patients with positive margins, but there was also a positive effect of 10% after five years for pT3 with negative margins and other risk factors [501].

6.3.6.2 *ARO trial*

The conclusions of ARO trial 96-02 ($n = 385$) appear to support those of the EORTC study. After a median follow-up period of 112 months, the RT group (60 Gy) demonstrated a significant improvement in BDFR of 56% vs. 35%, respectively ($p = 0.0001$). However, unlike other studies, and of major interest, the randomisation of patients was carried out after they had achieved an undetectable PSA level following RP (< 0.1 ng/mL) and only pT3 tumours were included. This result indicates that ART is effective, even in the setting of an undetectable PSA after RP and additional risk factors [502].

6.3.6.3 *SWOG 8794 trial*

Conversely, the updated results, with a median follow-up of more than twelve years, of the SWOG 8794 trial, which randomly assigned 425 pT3 patients, showed that adjuvant radiation significantly improved the metastasis-free survival, with a ten-year metastasis-free survival of 71% vs. 61% (median prolongation of 1.8 years, $p = 0.016$) and a ten-year OS of 74% vs. 66% (median: 1.9 years prolongation; $p = 0.023$) [503, 504].

6.3.6.4 *Conclusion*

Thus, for patients classified as pT3 pN0 with a high risk of local failure after RP due to positive margins (highest impact), capsule rupture, and/or invasion of the seminal vesicles, who present with a PSA level of < 0.1 ng/mL, two options can be offered in the framework of informed consent. These are:

- immediate ART to the surgical bed [501, 502, 504] after recovery of urinary function.
- or
- clinical and biological monitoring followed by salvage radiotherapy (SRT) before the PSA exceeds 0.5 ng/mL [505, 506] (see Section 6.10.5.1).

Table 6.3.4: Overview of all three randomised trials for adjuvant radiation therapy after radical prostatectomy*

Reference	n	Inclusion criteria	Randomisation	Definition of BCR PSA (ng/mL)	Median FU (mo)	Biochemical PFS survival	OS
SWOG 8794, 2009 [504]	431	pT3 cN0 ± involved SM	60-64 Gy vs. observation	> 0.4	152	10 yr: 53% vs. 30% (p < 0.05)	10 yr.: 74% vs. 66% Median time: 15.2 vs. 13.3 yr. p = 0.023
EORTC 22911, 2012 [501]	1,005	pT3 ± involved SM pN0 pT2 involved SM pN0	60 Gy vs. observation	> 0.2	127	10 yr: 60.6% vs. 41% (p < 0.001)	81% vs. 77% n.s.
ARO 96-02, 2014 [502]	388	pT3 (± involved SM) pN0 PSA post-RP undetectable	60 Gy vs. observation	> 0.05 + confirmation	112	10 yr: 56% vs. 35% (p = 0.0001)	10 yr.: 82% vs. 86% n.s.

*See Section 6.10.5.1 for delayed (salvage) post-radical prostatectomy external irradiation.

BCR = biochemical recurrence; n = number of patients; OS = overall survival; PFS = progression-free survival; PSA = prostate-specific antigen; RP = radical prostatectomy; SM = surgical margin.

6.3.7 Summary of evidence and guidelines for definitive radiotherapy

Summary of evidence	LE
The highest effect of adjuvant radiotherapy is seen in patients with pT3R1 PCa.	1a
The optimum duration of androgen deprivation therapy (ADT) with external beam radiation therapy (EBRT) is well established in the literature. There is no evidence that these durations should change when using brachytherapy boost with EBRT.	1b
Limited data, from experienced centres only, are available for the use of fractionated high-dose-rate brachytherapy as monotherapy in patients with low and intermediate-risk PCa.	2a

Recommendations	LE	GR
Offer external beam radiation therapy (EBRT) to all risk groups of non-metastatic PCa	1b	A
In low-risk PCa, use a total dose of 74 to 78 Gy.	1a	A
In patients with low-risk PCa, and selected intermediate-risk PCa, without a previous transurethral resection of the prostate (TURP) and with a good International Prostate Symptom Score and a prostate volume < 50 mL, offer low-dose rate (LDR) brachytherapy.	2a	A
In patients with intermediate-risk PCa use a total dose of 76-78 Gy, in combination with short-term ADT (four to six months).	1b	A
In patients with high-risk localised PCa and locally advanced cN0 PCa, use EBRT to a dose of 76-78 Gy, or combined EBRT with brachytherapy boost (either high-dose rate [HDR] or LDR). Radiotherapy should be given in combination with long-term androgen deprivation therapy (two to three years).	1a EBRT	A
	1b brachytherapy	
Offer intensity-modulated radiotherapy (IMRT) for definitive treatment of PCa by EBRT.	2a	A
Moderate hypofractionation (HFX) with IMRT including image-guided radiation therapy (IGRT) to the prostate only can be offered to carefully selected patients with localised disease (as discussed in the text).	1a	A
Moderate HFX should adhere to radiotherapy-protocols from trials with equivalent outcome and toxicity, i.e. 60 Gy/20 fractions in four weeks or 70 Gy/28 fractions in six weeks.	1a	A

In patients with cN+ or pN+ PCa offer pelvic external irradiation in combination with immediate long-term ADT.	2b	B
In patients with pT3, N0M0 PCa and an undetectable prostate-specific antigen (PSA) following radical prostatectomy, discuss adjuvant EBRT because it improves at least biochemical-free survival.	1a	A
Inform patients with an undetectable PSA following RP about salvage irradiation as an alternative to adjuvant irradiation when PSA increases (see Section 6.9.5.1).	1b	A

6.4 Treatment: Options other than surgery and radiotherapy for the primary treatment of localised prostate cancer

6.4.1 Background

Besides RP, EBRT and brachytherapy, other modalities have emerged as therapeutic options in patients with clinically localised PCa [507-510]. In this section, both whole gland and focal treatment will be considered, looking particularly at high-intensity focused US (HIFU) and cryosurgical ablation of the prostate (CSAP) as sufficient data are available to form the basis of some initial judgements on these latest additions to the management of PCa. Other options - such as photodynamic therapy, radiofrequency ablation and electroporation, among others - are considered to be in the early phases of evaluation and will therefore not be discussed in this edition of the Guidelines. Both HIFU and CSAP have been developed as minimally invasive procedures with the aim of providing equivalent oncological safety, reduced toxicity and improved functional outcomes. In addition, a relatively newer development is focal ablative therapy, whereby lesion-targeted ablation is undertaken in a precise, organ-sparing manner.

6.4.2 Cryosurgery

Cryosurgery uses freezing techniques to induce cell death by:

- dehydration resulting in protein denaturation;
- direct rupture of cellular membranes by ice crystals;
- vascular stasis and microthrombi, resulting in stagnation of the microcirculation with consecutive ischaemic apoptosis [507-510].

Freezing of the prostate is ensured by the placement of 12-15 x 17 gauge cryoneedles under TRUS guidance, placement of thermosensors at the level of the external sphincter and bladder neck, and insertion of a urethral warmer. Two freeze-thaw cycles are used under TRUS guidance, resulting in a temperature of -40°C in the mid-gland and at the neurovascular bundle. Currently, third and fourth generation cryosurgery devices are mainly used.

Potential candidates for CSAP are those who have organ-confined PCa and those identified as having minimal tumour extension beyond the prostate [507-509], The PSA should be < 20 ng/mL, and the Gleason score should be < 7:

- patients with low-risk PCa, or intermediate-risk PCa whose condition prohibits RT or surgery;
- at the time of therapy, the size of the prostate should be < 40 mL; volume reduction may be achieved by androgen ablation to avoid any technical difficulty in placing cryoprobes under the pubic arch.

It is important that patients with a life expectancy > 10 years should be fully informed that there are limited data on the long-term outcome for cancer control > 10 years and that this treatment modality is still considered as experimental.

6.4.2.1 Results of cryosurgery for PCa

A comparative assessment of primary ablative therapies for localised PCa, including CSAP, was recently undertaken by Ramsay *et al.* [511]. The SR and network meta-analysis compared CSAP vs. RP and EBRT. Data from 3,995 patients across nineteen studies (including one RCT, four non-randomised comparative studies, and fourteen case series) were included. In the short-term, there was conflicting evidence relating to cancer-specific outcomes when CSAP was compared with either EBRT or RP. The only finding that reached statistical significance was one-year DFS, which was worse for cryotherapy than for either EBRT or RP. However, none of the other cancer-specific outcomes, such as BCF or OS, showed any significant differences. Overall, because of the high risk of bias across the studies, the findings for cancer-specific outcomes were considered inconclusive. The review noted significant inconsistencies in outcome definitions, measurement and reporting in the evidence base, in particular BCR.

6.4.3 High-intensity focused ultrasound of the prostate

High-intensity focused ultrasound consists of focused US waves, emitted from a transducer, that cause tissue

damage by mechanical and thermal effects as well as by cavitation [512]. The goal of HIFU is to heat malignant tissues above 65°C so that it is destroyed by coagulative necrosis. High-intensity focused ultrasound is performed under general or spinal anaesthesia, with the patient lying in the lateral position. Potential candidates are patients with low-to-moderate risk as part of clinical trials. The patient should be informed about the lack of long-term outcome data at > 10 years (see Section 7.4.4.2).

6.4.3.1 Results of high-intensity focused ultrasound in PCa

As with CSAP, various PSA thresholds are defined for biochemical cure, and no international consensus exists on objective response criteria. The Stuttgart criteria (> PSA nadir + 1.2 ng/mL) have been proposed to define BCR after HIFU treatment [513].

A recent SR and comparative assessment by network meta-analysis [511] compared HIFU vs. RP and EBRT as primary treatment for localised PCa. Data from 4,000 patients across 21 studies (including one non-randomised comparative study and 20 case series) were included. There was some evidence that BCF rates were significantly higher at one year with HIFU than with EBRT. However, the difference was no longer statistically significant at five years. Similar statistically significant findings were observed with regard to DFS at one year, with worse outcomes for HIFU than for EBRT. The differences were no longer significant at three years. At four years, in contrast to OS, the biochemical result was higher when using HIFU.

In an earlier SR and meta-analysis [514], 150 papers related to HIFU were identified and evaluated with regard to various oncological and functional outcome parameters [514]. No RCT was available for analysis, and no survival data were presented. No validated biochemical surrogate end-point was available for HIFU therapy. The review found HIFU to be associated with a PFS (based on PSA ± biopsy data) of 63-87% (projected three- to five-year data), but median follow up in the studies ranged from 12-24 months only.

6.4.4 Focal therapy of PCa

During the past two decades, there has been a trend towards earlier diagnosis of PCa as a result of greater public and professional awareness, leading to the adoption of both formal and informal screening strategies. The effect of this has been to identify men at an earlier stage with smaller tumours that occupy only 5-10% of the prostate volume, with a greater propensity for unifocal or unilateral disease [515-517]. Most focal therapies to date have been achieved with ablative technologies: cryotherapy, HIFU, photodynamic therapy, electroporation, and focal RT by brachytherapy or CyberKnife Robotic Radiosurgery System technology (Accuray Inc., Sunnyvale, CA, USA). The main purpose of focal therapy is to ablate tumours selectively whilst limiting toxicity by sparing the neurovascular bundles, sphincter and urethra [518-520].

Ramsay *et al.*'s [502] SR and network meta-analysis of ablative therapy in men with localised PCa performed a sub-group analysis of focal therapy vs. RP and EBRT. Nine case series reporting on focal therapy were identified (five studies reporting on focal CSAP, three studies on focal HIFU, and one study reporting on both). For focal CSAP vs. RP or EBRT, no statistically significant differences were found for BCR at three years. For focal HIFU vs. RP or EBRT, there were no comparable data on oncological, continence nor potency outcomes at one year or more. More recently, Valerio *et al.* [521] performed a SR to summarise the evidence regarding the effectiveness of focal therapy in localised PCa. Data from 3,230 patients across 37 studies were included, covering different energy sources including HIFU, CSAP, photodynamic therapy, laser interstitial thermotherapy, focal brachytherapy, irreversible electroporation and radiofrequency ablation. The overall quality of the evidence was low, due to the majority of studies being single-centre, non-comparative and retrospective in design, heterogeneity of definitions, approaches, follow-up strategies, outcomes, and duration of follow-up. Although the review suggests that focal therapy has a favourable toxicity profile in the short to medium-term, its oncological effectiveness remains unproven due to lack of reliable comparative data against standard interventions such as RP and EBRT. Robust prospective trials reporting standardised outcomes [522] are needed before recommendations in support of focal therapy for routine clinical practice can be made.

6.4.5 **Summary of evidence and guidelines for experimental therapeutic options to treat clinically localised prostate cancer**

Summary of evidence	LE
The available short-term data regarding cryosurgery and high-intensity focused ultrasound (HIFU) does not prove equivalence to standard interventions.	2b
There is no reliable long-term comparative data to indicate that cryosurgery or HIFU leads to equivalent oncological outcomes compared with radical prostatectomy or external beam radiation therapy.	3
Prostate specific antigen nadir values after ablative therapies may have prognostic value.	3
Focal therapy of any sort appears promising but remains investigational, with uncertainties surrounding outcome definitions, follow-up and re-treatment criteria.	3

Recommendations	LE	GR
Only offer cryotherapy and high-intensity focused ultrasound within a clinical trial setting.	3	A
Only offer focal therapy within a clinical trial setting.	3	A

6.5 **Treatment: Hormonal therapy - rationale and available drugs**

6.5.1 **Introduction**

6.5.1.1 *Different types of hormonal therapy*

Androgen deprivation can be achieved by either suppressing the secretion of testicular androgens or inhibiting the action of circulating androgens at the level of their receptor. These two methods can be combined to achieve what is known as complete (or maximal or total) androgen blockade (CAB) [523].

6.5.2 **Testosterone-lowering therapy (castration)**

6.5.2.1 *Castration level*

Surgical castration is still considered the primary treatment modality for ADT. It leads to a considerable decline in testosterone levels: the 'castration level'.

The castrate level is < 50 ng/dL (1.7 nmol/L), which was defined more than 40 years ago, when testosterone testing was limited. Current methods have shown that the mean value after surgical castration is 15 ng/dL [524]. Therefore, a more appropriate level is defined as < 20 ng/dL (1 nmol/L). This new definition is important as better results are repeatedly observed with lower testosterone levels compared to 50 ng/dL [525-527]. However, the castrate level considered by the regulatory authorities and in clinical trials addressing castration in PCa is still < 50 ng/dL (1.7 mmol/L).

6.5.2.2 *Bilateral orchiectomy*

Bilateral orchiectomy, or subcapsular pulpectomy, is a simple, cheap and virtually complication-free surgical procedure. It is easily performed under local anaesthesia [528] and it is the quickest way to achieve a castration level, which is usually reached within less than twelve hours. It is irreversible and does not allow for intermittent treatment.

6.5.3 **Oestrogens**

Treatment with oestrogens results in testosterone suppression and is not associated with bone loss [529]. Early studies tested oral diethylstilboestrol (DES) at several doses. Due to severe side effects, especially thromboembolic complications, even at lower doses [530, 531] these drugs are not considered as standard first-line treatment.

6.5.4 **Luteinising-hormone-releasing hormone agonists**

Long-acting LHRH agonists are currently the main forms of ADT. These synthetic analogues of LHRH, are delivered as depot injections on a 1-, 2-, 3-, 6-monthly, or yearly basis. After the first injection, they induce a transient rise in luteinising hormone (LH) and follicle-stimulating hormone (FSH) leading to the 'testosterone surge' or 'flare-up' phenomenon, which starts two to three days after administration and lasts for about one week. The different products have practical differences that need to be considered in everyday practice, including the storage temperature, whether a drug is ready for immediate use or requires reconstitution, and whether a drug is given by subcutaneous or intramuscular injection.

6.5.4.1 *Achievement of castration levels*

Chronic exposure to LHRH agonists results in the down-regulation of LHRH-receptors, suppressing LH and

FSH secretion and therefore testosterone production. A castration level is usually obtained within two to four weeks [532]. Although there is no formal direct comparison between the various compounds, they are considered to be equally effective [533] and comparable to orchiectomy [533, 534].

6.5.4.2 'Flare-up' phenomenon

The 'flare-up' phenomenon might lead to detrimental clinical effects (the clinical flare) such as increased bone pain, acute bladder outlet obstruction, obstructive renal failure, spinal cord compression, and cardiovascular death due to hypercoagulation status [535].

Patients at risk are usually those with high-volume, symptomatic, bony disease. Concomitant therapy with an anti-androgen decreases the incidence of clinical flare, but does not completely remove the risk.

6.5.5 Luteinising-hormone-releasing hormone antagonists

Luteinising-hormone releasing hormone antagonists immediately bind to LHRH receptors, leading to a rapid decrease in LH, FSH and testosterone levels without any flare. The practical shortcoming of these compounds is the lack of a long-acting depot formulation with only monthly formulations being available.

Degarelix

Degarelix is an LHRH antagonist. The standard dosage is 240 mg in the first month, followed by monthly injections of 80 mg. Most patients achieve a castrate level at day three [536]. An extended follow-up has been published, suggesting a better PFS compared to monthly leuporelin [536]. Its definitive superiority over the LHRH analogues remains to be proven.

6.5.6 Anti-androgens

These oral compounds are classified according to their chemical structure as:

- steroidal, e.g. cyproterone acetate (CPA), megestrol acetate and medroxyprogesterone acetate;
- non-steroidal or pure, e.g. nilutamide, flutamide and bicalutamide.

Both classes compete with androgens at the receptor level. This is the sole action of non-steroidal anti-androgens and leads to an unchanged or slightly elevated testosterone level. Conversely, steroidal anti-androgens have progestational properties leading to central inhibition by crossing the blood-brain barrier.

6.5.6.1 Steroidal anti-androgens

These compounds are synthetic derivatives of hydroxyprogesterone. Their main pharmacological side-effects are secondary to castration (gynaecomastia is quite rare) whilst the non-pharmacological side effects are cardiovascular toxicity (4-40% for cyproterone acetate [CPA]) and hepatotoxicity.

6.5.6.1.1 Cyproterone acetate

Cyproterone acetate was the first licensed anti-androgen, but the least studied. Its most effective dose as monotherapy is still unknown. Although CPA has a relatively long half-life (31-41 hours), it is usually administered in two or three fractionated doses of 100 mg each. In one RCT [537] CPA showed a poorer OS when compared with LHRH analogues. An underpowered RCT comparing CPA monotherapy with flutamide in M1b PCa did not show any difference in disease-specific and OS at a median follow-up of 8.6 years [538]. Other CPA monotherapy studies suffer from methodological limitations preventing firm conclusions.

6.5.6.2 Non-steroidal anti-androgens

Non-steroidal anti-androgen monotherapy does not suppress testosterone secretion and it is claimed that libido, overall physical performance and bone mineral density (BMD) are frequently preserved [539]. Non-androgen pharmacological side effects differ between agents, with bicalutamide showing a more favourable safety and tolerability profile than flutamide and nilutamide [540]. All three agents share a common potential liver toxicity (occasionally fatal), requiring regular monitoring of patients' liver enzymes.

6.5.6.2.1 Nilutamide

Nilutamide monotherapy has not been compared to castration and is not licensed for monotherapy. Non-androgen pharmacological side effects are visual disturbances (i.e. delayed adaptation to darkness), alcohol intolerance, nausea, and specifically severe interstitial pneumonitis (potentially life-threatening).

6.5.6.2.2 Flutamide

Flutamide has been studied as monotherapy. Flutamide is a pro-drug, and the half-life of the active metabolite is five-six hours, allowing for a three times daily dose. The recommended total daily dosage is 750 mg. The

non-androgen pharmacological side-effect of flutamide is diarrhoea.

6.5.6.2.3 Bicalutamide

The dosage licensed for use in CAB is 50 mg/day, and 150 mg for monotherapy. The androgen pharmacological side-effects are mainly gynaecomastia (70%) and breast pain (68%). However, bicalutamide monotherapy offers clear bone protection compared with LHRH analogues and probably LHRH antagonists [539, 541].

6.5.7 **New compounds (for castrate-resistant patients only)**

During castration, the occurrence of castration-resistance (CRPC) is systemic. It is considered to be mediated through two main overlapping mechanisms, which are androgen-receptor (AR)-independent and AR-dependent (see Section 6.10 - Castrate-resistant PCa). In CRPC, the intracellular androgen level is increased compared to androgen sensitive cells, and an over-expression of the AR has been observed, suggesting an adaptive mechanism [542]. This has led to the development of two new compounds targeting the androgen axis: abiraterone acetate and enzalutamide. Both are currently approved for mCRPC only.

6.5.7.1 *Abiraterone acetate*

Abiraterone acetate (AA) is a CYP17 inhibitor (a combination of 17 α -hydroxylase and 17,20-lyase inhibition). By blocking CYP17, AA significantly decreases the intracellular testosterone level by suppressing its synthesis at the adrenal level and inside the cancer cells (intracrine mechanism). This compound must be used together with prednisone/prednisolone (2 x 5 mg) to prevent drug-induced hyperaldosteronism.

6.5.7.2 *Enzalutamide*

Enzalutamide is a novel anti-androgen with a higher affinity than bicalutamide for the AR receptor. While non-steroidal anti-androgens still allow transfer of ARs to the nucleus, enzalutamide also blocks AR transfer and therefore suppresses any possible agonist-like activity.

6.5.8 **Cost-effectiveness of hormonal therapy options**

A formal meta-analysis evaluated the cost-effectiveness of various long-term androgen suppression options in advanced PCa. For men who can accept it, bilateral orchiectomy is the most cost-effective form of ADT, providing a higher quality-adjusted survival, while CAB is the least economically attractive option, yielding small health benefits at relatively high costs. Furthermore, the greatest QoL gains and least costs may be obtained by starting ADT when symptoms from distant metastases have occurred [543]. Finally, once ADT is started and if a major response is obtained, intermittent androgen deprivation (IAD) may be an effective option to lower treatment costs.

6.6 **Treatment: Metastatic prostate cancer**

6.6.1 **Introduction**

A SR of ADT in PCa has recently been published [523].

6.6.2 **Prognostic factors**

Median survival of patients with newly diagnosed metastases is at least 42 months [544] but the M1 population is very heterogeneous. Several prognostic factors for survival have been suggested including the number and location of bone metastases, visceral metastases, Gleason score, PS status and initial PSA [545], alkaline phosphatase [546], but none of these have been validated in a direct comparison. In clinical trials, the number and location of bone metastases and the presence of visceral lesion are the prognostic factors most often used [547].

Based on a large SWOG 9346 cohort, the PSA level after seven months of ADT was used to create three prognostic groups, group 1 with a PSA < 0.2 ng/mL and a median survival of 75 months, group 2 with a PSA < 4 ng/mL with a median survival of 44 months and group 3 with a PSA > 4 ng/mL and only thirteen months median survival [548]. This grouping, however, requires independent confirmation.

6.6.3 **First-line hormonal treatment**

Primary ADT has been the standard of care for over 50 years [523]. There is no level 1 evidence for, or against, a specific type of ADT, whether orchiectomy, an LHRH analogue or antagonist, except in patients with impending spinal cord compression for whom either a bilateral orchidectomy, or an LHRH antagonist are the preferred options.

6.6.3.1 Prevention of 'flare-up'

The initial testosterone flare associated with LHRH agonists can be prevented by co-administration of an anti-androgen [549]. Prevention of 'flare-up' is important in symptomatic patients or when a clinical flare might lead to severe complications. Anti-androgen therapy is usually continued for four weeks but neither the timing nor the duration of anti-androgen therapy are based on strong evidence. In addition, the long-term impact of preventing 'flare-up' is unknown [550].

6.6.4 Combination therapies

6.6.4.1 Complete androgen blockade

The largest RCT in 1,286 M1b patients found no difference between surgical castration with or without flutamide [551]. However, results with other anti-androgens or castration modalities have differed and SRs have shown that CAB using a non-steroidal anti-androgen (NSAA) appears to provide a small survival advantage (< 5%) vs. monotherapy (surgical castration or LHRH agonists) [552, 553] beyond five years of survival [554] but this minimal advantage in a small subset of patients must be balanced against the increased side effects associated with long-term use of NSAAs.

6.6.4.2 Non-steroidal anti-androgen monotherapy

Based on a Cochrane SR [555] comparing NSAA monotherapy to castration (either medical or surgical), NSAA was considered to be less effective in terms of OS, clinical progression, treatment failure and treatment discontinuation due to adverse events. The evidence quality of the studies included in this review was rated as moderate.

6.6.4.3 Intermittent versus continuous androgen deprivation therapy

Three independent reviews [556-558] and two meta-analyses [559, 560], looked at the clinical efficacy of IAD therapy. All of these reviews included eight RCTs of which only three were conducted in patients with exclusively M1 disease. The five remaining trials included different patient groups, mainly locally advanced and metastatic patients relapsing.

So far, the SWOG 9346 [561] is the largest trial conducted in M1b patients. Out of 3,040 selected patients, only 1,535 were randomised based on the inclusion criteria set. This highlights that, at best, only 50% of M1b patients might be candidates for IAD, i.e. the best PSA responders. This was a non-inferiority trial leading to inconclusive results: (HR: 1.1; CI: 0.99-1.23), with the upper limit being above the pre-specified 90% upper limit of 1.2. The pre-specified non-inferiority limit was not achieved, and the results did not show a significant inferiority for any treatment arm. However, inferior survival with IAD cannot be completely ruled out based on this study.

Other trials did not show any survival difference with a HR for OS of 1.04 (0.91-1.19). These reviews and the meta-analyses came to the conclusion that there was no difference in OS or CSS between IAD and continuous androgen deprivation. A recent review of the available phase III trials highlighted the limitations of most trials and suggests a cautious interpretation of the non-inferiority results [562]. None of the trials addressing M1 patients only showed a survival benefit, but there was a trend favouring continuous treatment for OS and PFS. Most of these trials, however, were non-inferiority trials. There is a trend favouring IAD in terms of QoL, especially regarding treatment-related side effects, such as hot flushes. In some cohorts the negative impact on sexual function was less pronounced with IAD. Two prospective trials came to the same conclusions [563, 564].

Other possible long-term benefits of IAD include bone protection [565] and a protective effect against metabolic syndrome. This possible protective effect has been challenged recently [566] with an increased risk for thrombotic and ischaemic events, while no benefit was observed for the endocrine, psychiatric, sexual and neurological side effects based on a detailed analysis from the SWOG 9346 trial. Testosterone recovery was observed in most studies [567] leading to intermittent castration. This, as well as the lack of any survival benefit in M1 patients, suggests that this modality must only be considered as an option in a well-informed patient bothered by significant side effects and willing to avoid them.

The PSA threshold at which ADT must be stopped or resumed still needs to be defined in prospective studies [557, 567]. Nevertheless, there is consensus amongst authors on some statements:

- Intermittent androgen deprivation is based on intermittent castration; therefore, only drugs leading to castration are suitable.
- Luteinising-hormone releasing hormone antagonist might be a valid alternative to an agonist.
- The induction cycle cannot be longer than nine months, otherwise testosterone recovery is unlikely.
- Androgen deprivation therapy should be stopped only if patients have fulfilled all of the following criteria:

- well-informed and compliant patient;
- no clinical progression;
- a clear PSA response, empirically defined as a PSA < 4 ng/mL in metastatic disease.
- Strict follow-up is mandatory, with clinical examination every three to six months. The more advanced the disease, the closer the follow-up should be. The same laboratory should be used to assess the PSA level.
- Treatment is resumed when the patient progresses clinically, or has a PSA rising above a pre-determined (empirically set) threshold: usually 10-20 ng/mL in metastatic patients.
- The same treatment is used for at least three to six months.
- Subsequent cycles of treatment are based on the same principles until the first sign of castration resistance becomes apparent.
- The group of patients who will benefit most from IAD still has to be defined but the most important factor seems to be the patient's response to the first cycle of IAD, e.g. the PSA level response [557].

6.6.4.4 Immediate versus deferred androgen deprivation therapy

In symptomatic patients, immediate treatment is mandatory. However, controversy still exists for asymptomatic metastatic patients due to the lack of quality studies. A Cochrane review extracted four good-quality RCTs: the VACURG I and II trials, the MRC trial, and the ECOG 7887 study [555]. All of these studies were conducted in the pre-PSA era and included patients with advanced PCa, who had received early vs. deferred ADT, either as primary therapy or as adjuvant therapy after RP [568]. No improvement in OS was observed in the M1a/b population, although early ADT significantly reduced disease progression and associated complications.

6.6.5 Hormonal treatment combined with chemotherapy

Three large RCT were conducted [473, 547, 569]. All trials compared ADT alone as the standard of care with ADT combined with immediate docetaxel (75 mg/sqm, every three weeks) (within three months of ADT initiation). The primary objective in all three studies was OS. The key findings are summarised in Table 6.6.1.

Table 6.6.1: Key findings - Hormonal treatment combined with chemotherapy

Study	Population	n	Med FU (mo)	Median OS (mo)		HR	p-value
				ADT + D	ADT		
Gravis, <i>et al.</i> [569]	M1	385	50	58.9	54.2	1.01 (0.75-1.36)	0.955
ASCO GU 2015 [570]	HV : 47%		82.9	60.9	46.5	0.9 (0.7-1.2)	0.44
Sweeney, <i>et al.</i> [547]	M1 HV: 65%	790	28.9	57.6	44	0.61 (0.47-0.8)	< 0.001
STAMPEDE [473]	M1 [61%]/N+ [15%]/relapse	1,184 /593 (D) 593 (D + ZA)		81	71	0.78 (0.66-0.93)	0.006
	M1 only	725 + 362 (D)		76	NR	0.82 (0.69-0.97)	0.022
				60	45	0.76 (0.62-0.92)	0.005

D = docetaxel; FU = follow-up; HR = hazard ratio; HV = high volume: either visceral metastases or more than four bone metastases, with at least one outside the spine and pelvis; n = number of patients; ZA = zoledronic acid.

In the GETUG 15 trial [569], all patients had newly diagnosed M1 PCa, either primary or after a primary treatment. They were stratified based on previous treatment, and Glass risk factors [545]. In the Chemohormonal Therapy versus Androgen Ablation Randomized Trial for Extensive Disease in Prostate Cancer (CHAARTED) trial, the same inclusion criteria applied and patients were stratified according to disease volume; high volume being defined as either presence of visceral metastases or four, or more, bone metastases, with at least one outside the spine and pelvis [547].

STAMPEDE is a multi-arm multi-stage trial in which the reference arm (ADT monotherapy) included 1,184 patients. One of the experimental arms was docetaxel combined with ADT (n = 593 patients), another was docetaxel combined with zoledronic acid (n = 593). Patients were included with either M1, or N1 or having two criteria out of three: T3/4, PSA ≥ 40 ng/mL, Gleason 8-10. Also relapsed patients after local treatment were included if they met one of the following criteria: PSA ≥ 4 ng/mL with a PSA-DT < 6 months, a PSA ≥ 20 ng/mL, N1 or M1. No stratification was used regarding metastatic disease volume (high/low volume) [473].

In the three trials toxicity was mainly haematological with around 12-15% Grade 3-4 neutropenia, and 6-12% Grade 3-4 febrile neutropenia. Determination of granulocyte colony-stimulating factor receptor (GCSF) was shown to be helpful and its use should be based on available guidelines [571, 572].

Based on these data, upfront docetaxel combined with ADT should be considered as a new standard in men presenting with metastases at first presentation, provided they are fit enough to receive the drug [571]. Docetaxel is used at the standard regimen of 75 mg/sqm combined with steroids premedication, but without prolonged corticotherapy.

6.6.6 **Prostate targeted therapy in newly diagnosed metastatic disease**

Data from the retrospective SEER data-base [573] and the Munich cancer registry [574] suggest an OS and CSS benefit when RP or brachytherapy are added to ADT in newly diagnosed M1 patients. A small prospective experimental cohort of well selected patients responding to six months ADT and with ≤ 3 bone spots confirmed the feasibility and after a median 34 months follow up suggested a better CSS [575]. However, these results must be considered as experimental and deserve prospective trials (already underway) before being adopted in daily practice.

6.6.7 **Metastasis-directed therapy**

In patients relapsing after a local treatment, a metastases-targeting therapy has been proposed, with the aim to delay systemic treatment. A recent SR clearly highlighted that at this time this approach must, as yet, be considered as experimental [576].

6.6.8 **Imaging as marker of response in metastatic prostate cancer**

Treatment response in soft-tissue metastases can be assessed by morphological imaging methods (CT or MRI) using the Response Evaluation Criteria in Solid Tumours (RECIST) criteria. However, these criteria cannot be used in bone where response assessment is difficult [577, 578].

Quantitative estimation of tracer uptake at BS can be obtained through automated methods such as the Bone Scan Index [579]. Nonetheless, BS is limited by the so-called 'flare' phenomenon which is defined by the development of new images induced by treatment on a first follow-up scan that actually represent a favourable response on longer observation. Flare is observed within eight-twelve weeks of treatment initiation and can lead to false-positive diagnosis of disease progression. As a result, the Prostate Cancer Clinical Trials Working Group (PCWG) suggested that all patients with at least two new lesions on the first follow-up BS require a confirmatory BS at least six weeks later while the treatment is continued [580]. This means that a management change for primary therapy resistance cannot occur until after at least fourteen weeks of treatment. Computed tomography cannot be used to monitor sclerotic bone lesions because bone sclerosis can occur under effective treatment and reflects bone healing. The ability of choline PET/CT to assess response has been assessed in a few studies that showed changes in disease extent and specific uptake values. It is noteworthy that the flare phenomenon can also be observed with choline PET/CT. Magnetic resonance imaging can directly assess the bone marrow and could assess progression based on morphologic criteria or changes in apparent diffusion coefficient. However, a large-scale validation of these criteria has not been performed [577, 578].

In practice, imaging to assess progression leading to treatment change must be limited to a clear progression: RECIST criteria for non-bone lesions; for bone lesions, only BS progression (occurrence of two new hot spots, later confirmed) should be considered. The practical impact of mpMRI in assessing bone progression remains unclear.

6.6.9 **Guidelines for the first-line treatment of metastatic prostate cancer**

Recommendations	LE	GR
Offer castration combined with chemotherapy (docetaxel) to all patients whose first presentation is M1 disease and who are fit enough for chemotherapy.	1a	A
Offer castration alone, with or without an anti-androgen, to patients unfit for, or unwilling to consider, castration combined with chemotherapy.	1b	A
Do not prescribe abiraterone acetate or enzalutamide outside of a clinical trial.	3	A
Use castration combined with any local treatment (radiotherapy/surgery) in an investigational setting only.	3	A

6.6.10 **Guidelines for hormonal treatment of metastatic prostate cancer**

Recommendations	LE	GR
In M1 symptomatic patients, offer immediate castration to palliate symptoms and reduce the risk for potentially catastrophic sequelae of advanced disease (spinal cord compression, pathological fractures, ureteral obstruction, extra-skeletal metastasis).	1b	A
In M1 asymptomatic patients, offer immediate castration to defer progression to a symptomatic stage and prevent serious disease progression-related complications.	1b	A
In newly diagnosed M1 patients, offer castration combined with docetaxel, provided patients are fit enough to receive chemotherapy.	1a	A
In M1 asymptomatic patients, discuss deferred castration with a well-informed patient since it lowers the treatment side effects, provided the patient is closely monitored.	2b	B
Anti-androgens		
In M1 patients treated with a luteinising-hormone releasing hormone (LHRH) agonist, offer short-term administration of anti-androgens to reduce the risk of the 'flare-up' phenomenon.	2a	A
Start anti-androgens used for 'flare-up' prevention on the same day as an LHRH analogue is started or for up to seven days before the first LHRH analogue injection if the patient has symptoms. Treat for four weeks.	3	A
Do not offer anti-androgen monotherapy.	1a	A
Intermittent treatment		
In asymptomatic M1 patients, offer intermittent treatment to highly motivated men, with a major prostate-specific antigen (PSA) response after the induction period.	1b	B
<ul style="list-style-type: none"> In M1 patients, follow the schedules used in published clinical trials on timing of intermittent treatment. Stop treatment when the PSA level is < 4 ng/mL after six to seven months of treatment. Resume treatment when the PSA level is > 10-20 ng/mL (or returned to the initial level of < 20 ng/mL). 	4	C
In M1 patients, offer combined treatment with LHRH agonists and a non-steroidal anti-androgen.	1b	A
Offer LHRH antagonists, especially in patients with an impending spinal cord compression or bladder outlet obstruction.	2	B

6.7 Management of prostate cancer in older men**6.7.1 Evaluating health status in senior adults****6.7.1.1 Introduction**

With a median age at diagnosis of 68 years, PCa is common in men aged > 70 years. However, in the USA, the increase in men aged > 65 years being diagnosed will result in an estimated 70% increase in annual diagnosis of PCa by 2030 [581]. A similar increase is expected in Europe [582].

The SEER database shows that 71% of PCa-related deaths occur in men aged ≥ 75 years [583], probably due to the higher incidence of advanced/metastatic disease [584-586].

Despite the high incidence and mortality rates in senior adults, they may be under-treated [587, 588]. In the USA, only 41% of patients aged > 75 years with intermediate- and high-risk disease receive curative treatment compared to 88% aged 65-74 [589].

6.7.1.2 Evaluation of life expectancy, comorbidity and health status

In localised disease, > 10 years life expectancy is considered mandatory for any benefit from local treatment. However, comorbidity is more important than age in predicting overall mortality in localised PCa [322]. Besides comorbidities, dependence in daily activities, malnutrition and cognitive impairment are associated with worse survival.

6.7.1.2.1 Comorbidity

Comorbidity is a major predictor of non-cancer-specific death in localised PCa treated with RP [590]. This can be explained by the observations from a study in which patients did not receive active local treatment for their PCa [322]. At ten years, most men with a CCI score > 2 had died from competing causes, irrespective of age or tumour aggressiveness.

Currently, the Cumulative Illness Score Rating-Geriatrics (CISR-G; Table 6.7.1) [591] is the best tool for assessing mortality risk unrelated to PCa [592].

Table 6.7.1: Cumulative Illness Score Rating-Geriatrics (CISR-G)

Cumulative Illness Rating Scale	Rating strategy
0	None
1	Mild (or past significant problem)
2	Moderate (moderate disability or morbidity, requires first-line therapy)
3	Severe (constant significant disability/uncontrollable chronic problems)
4	Extremely severe (immediate treatment required/end organ failure/severe impairment in function)
	Score
Heart	
Vascular	
Respiratory	
Eyes, ears, nose, throat and larynx	
Upper GI	
Lower GI	
Hepatic	
Renal	
Genitourinary	
Musculoskeletal/integument	
Neurological	
Endocrine/metabolic	
Psychiatric illness	
Total score	

Patients are considered fit if they have no Grade 3 score

Frail: one or two Grade 3 scores

Disabled: > 2 Grade 3, or any Grade 4 scores

Too sick: multiple Grade 4 scores

6.7.1.2.2 Dependence in daily activities

The level of dependence in daily activities influences survival in senior adults [593-595]. The Activities of Daily Living (ADL) scale rates accomplishment of basic activities of daily living, while the Instrumental Activities of Daily Living (IADL) scale rates activities requiring higher cognition and judgement.

6.7.1.2.3 Malnutrition

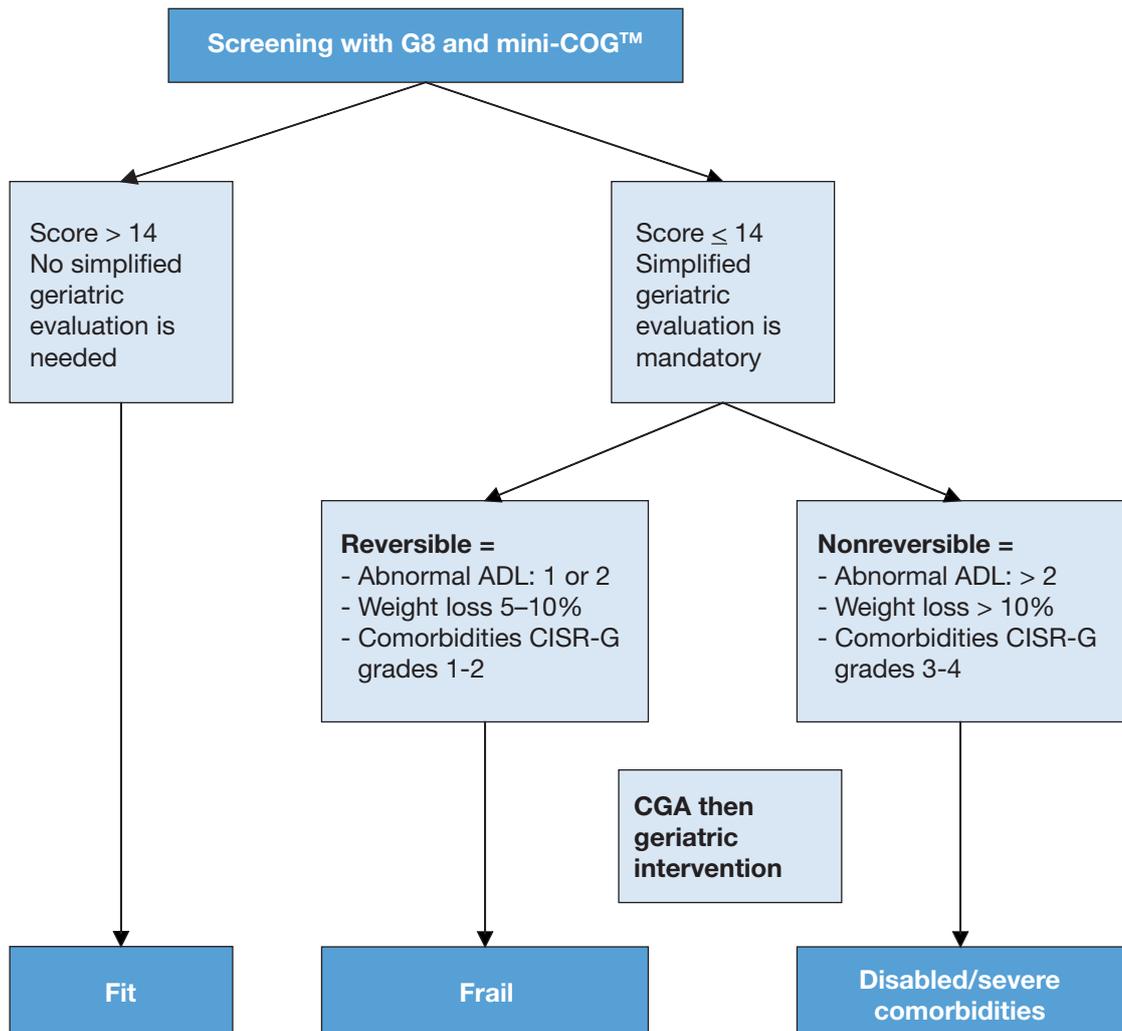

Malnutrition is associated with increased mortality in senior patients [596]. Nutritional status can be estimated from body weight during the previous three months:

- Good nutritional status < 5% weight loss;
- Risk of malnutrition: 5-10% weight loss;
- Severe malnutrition: > 10% weight loss.

6.7.1.2.4 Cognitive impairment

Cognitive impairment is associated with increased mortality risk in senior adults [597]. In patients undergoing major elective surgery, there is an association between baseline cognitive impairment and long-term post-operative complications and mortality [598]. Intervention is unlikely to reverse cognitive impairment, except in depression [599]. The mini-COG is the best available tool to evaluate cognitive function in order to assess the patient's ability to make an informed decision [600].

Figure 6.7.1: Decision tree to determine patient health status* [599]

*Reproduced with permission of Elsevier, from Droz J-P, et al. *Eur Urol* 2017 (prior to press) [599].
 Mini-COG™ = mini-COG™ cognitive test; ADL = activities of daily living; CIRS-G = cumulative illness rating score-geriatrics; CGA = comprehensive geriatric assessment.

6.7.1.2.5 Baseline screening using the G8 screening tool

The International Society of Geriatric Oncology (SIOG) PCa Working Group (PCWG) recommends that treatment for senior adults should be based on a systematic evaluation of health status [599].

The G8 (Geriatric 8) health status screening tool is described in Table 6.7.2, the Karnofsky and ECOG Scores in Table 6.7.3 [601].

Table 6.7.2: G8 screening tool (Adapted from [602])

	Items	Possible responses (score)
A	Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing, or swallowing difficulties?	0 = severe decrease in food intake
		1 = moderate decrease in food intake
		2 = no decrease in food intake
B	Weight loss during the last 3 months?	0 = weight loss > 3 kg
		1 = does not know
		2 = weight loss between 1 and 3 kg
		3 = no weight loss
C	Mobility?	0 = bed or chair bound
		1 = able to get out of bed/chair but does not go out
		2 = goes out
E	Neuropsychological problems?	0 = severe dementia or depression
		1 = mild dementia
		2 = no psychological problems
F	BMI? (weight in kg)/(height in m ²)	0 = BMI < 19
		1 = BMI 19 to < 21
		2 = BMI 21 to < 23
		3 = BMI ≥ 23
H	Takes more than three prescription drugs per day?	0 = yes
		1 = no
P	In comparison with other people of the same age, how does the patient consider his/her health status?	0.0 = not as good
		0.5 = does not know
		1.0 = as good
		2.0 = better
	Age	0: > 85
		1: 80-85
		2: < 80
	Total score	0-17

A G8 score > 14 shows that patients should receive the same treatment as younger patients. Patients with score $G8 \leq 14$ should undergo a full geriatric evaluation, assessing comorbidity, nutritional status, and cognitive and physical functions, to determine if the impairment is reversible [602]. Patients with reversible impairment (frail patients) should be treated according to the EAU-ESTRO-ESUR-SIOG Prostate Cancer Guidelines. Patients with irreversible impairment (disabled patients) should receive adapted treatment [599].

Table 6.7.3: Performance Scales - Karnofsky & ECOG Scores [601]

Karnofsky Status	Karnofsky Grade	ECOG Grade	ECOG Status
Normal, no complaints.	100	0	Fully active, able to carry on all pre-disease performance without restriction.
Able to carry on normal activities. Minor signs or symptoms of disease.	90	1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light house work, office work.
Normal activity with effort.	80	1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light house work, office work.
Care for self. Unable to carry on normal activity or to do active work.	70	2	Ambulatory and capable of all selfcare but unable to carry out any work activities. Up and about more than 50% of waking hours.
Requires occasional assistance, but able to care for most of his needs.	60	2	Ambulatory and capable of all selfcare but unable to carry out any work activities. Up and about more than 50% of waking hours.
Requires considerable assistance and frequent medical care.	50	3	Capable of only limited selfcare, confined to bed or chair more than 50% of waking hours.
Disabled. Requires special care and assistance.	40	3	Capable of only limited selfcare, confined to bed or chair more than 50% of waking hours.
Severely disabled. Hospitalisation indicated though death non-imminent.	30	4	Completely disabled. Cannot carry on any selfcare. Totally confined to bed or chair.
Very sick. Hospitalisation necessary. Active supportive treatment necessary.	20	4	Completely disabled. Cannot carry on any selfcare. Totally confined to bed or chair.
Moribund.	10	4	Completely disabled. Cannot carry on any selfcare. Totally confined to bed or chair.

6.7.1.2.6 Conclusions

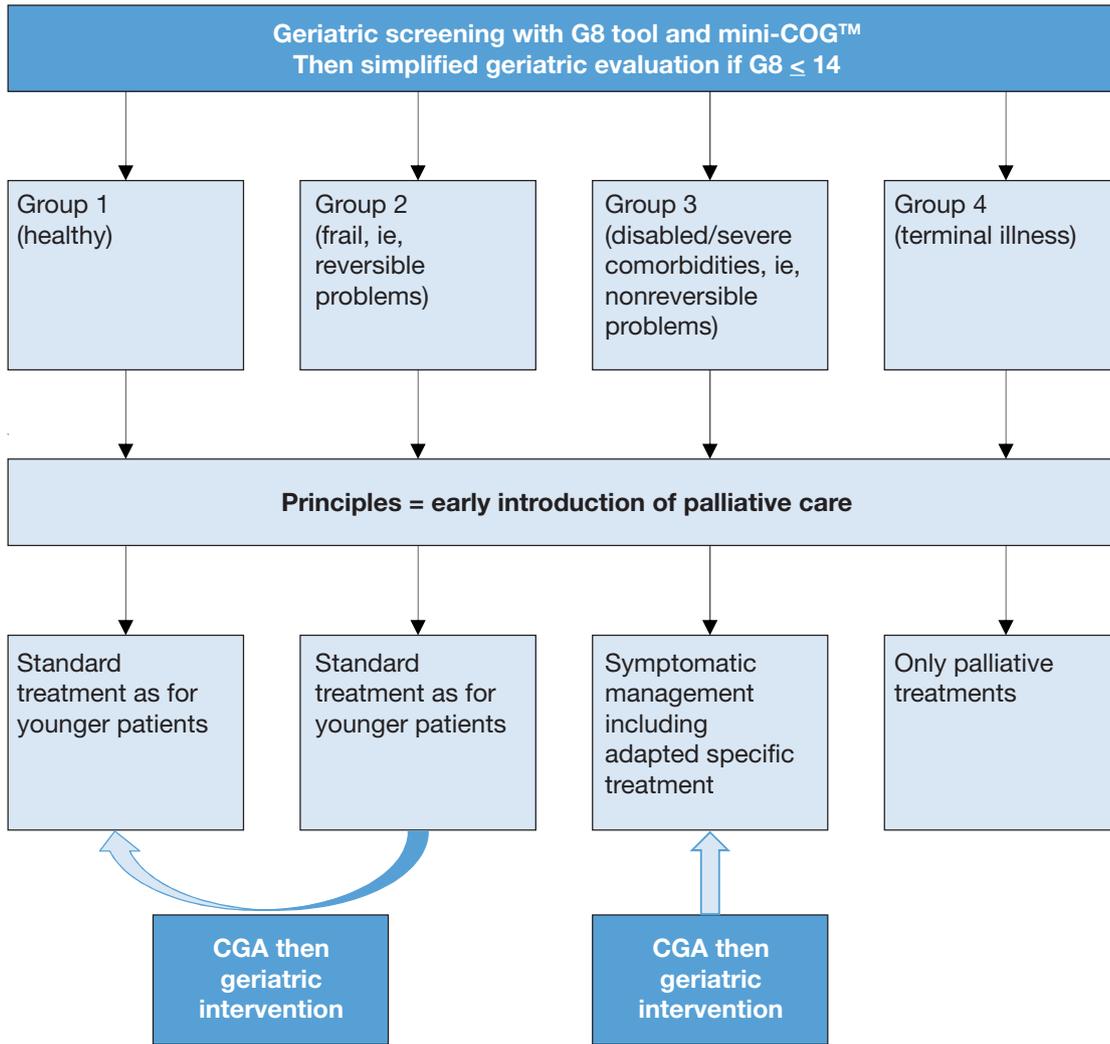

Systematic assessment, using the G8 tool, is recommended by the SIOG PCWG [599]. Patients with G8 score < 14 should undergo complete geriatric assessment to evaluate reversibility of any impairments [599].

Senior adults can be classified into one of four groups regarding health status based on G8 score > 14 (patient considered fit), or score < 14 (patient considered frail or disabled). The treatment policy is then:

- fit or healthy older men should receive standard treatment;
- frail patients may receive standard treatment after resolution of any geriatric problems;
- disabled patients (i.e. non-reversible problems) should receive adapted treatment;
- patients who are too sick with terminal illness should receive only palliative treatment [599].

After resolution of reversible impairments, a similar urological approach should be carried out in fit or frail patients [1, 2]. Older men with PCa should be managed according to their individual health status, which is directed by the presence of any associated comorbidity and not age.

Figure 6.7.2: Decision-making based on health status assessment* [599]

*Reproduced with permission of Elsevier, from Droz J-P, et al. Eur Urol 2017 (prior to press) [599].
Mini-COG™ = mini-COG™ cognitive test; ADL = activities of daily living; CIRS-G = cumulative illness rating score-geriatrics; CGA = comprehensive geriatric assessment.

6.7.1.3 Guidelines for the evaluation of health status in elderly men

Recommendations for assessment	LE	GR
Perform systematic health status screening in senior adults with localised PCa.	1b	A
Use the G8 screening tool for health status screening.	2a	A
Perform a full specialist geriatric evaluation in patients with G8 score ≤ 14.	2a	A
Treatment options for senior adults according to their health status: 1. offer standard treatment to fit or healthy older men; 2. offer standard treatment to frail patients (reversible impairment) after resolution of geriatric problems; 3. offer adapted treatment to disabled patients (irreversible impairment); 4. offer only symptomatic palliative treatment to patients who are too sick with terminal illness.	3	B

6.7.2 Specific aspects of PCa treatment in older men

6.7.2.1 Localised PCa

6.7.2.1.1 Deferred treatment (active surveillance, watchful waiting)

Deferred treatment is addressed in Section 6.1. Active treatment mostly benefits patients with intermediate- or high-risk disease and longest expected survival. A recent study assessed the effect of age, health status and patient preferences on outcomes of surgery vs. AS for low-risk PCa. As expected, older age and worse

baseline health status were associated with a smaller benefit in PCSM and life expectancy with surgery, and increased incremental years with treatment side effects. Older men and men in poor health were likely to have better quality-adjusted life expectancy with AS [603].

6.7.2.1.2 Radical prostatectomy

Senior adults (aged ≥ 75 years) are more likely to present with very advanced disease and have a greater risk of death from PCa, despite higher death rates from competing causes [584]. In the most recent update of the SPCG-4 study, randomising patients with localised PCa to RP vs. WW, the benefit of surgery with respect to death from PCa was largest in men < 65 years of age (RR, 0.45). However, RP was associated with a reduced risk of metastases and use of androgen deprivation therapy among older men (RR: 0.68 and 0.60, respectively) [333]. Risk of short-term complications after RP is related more to comorbidity severity than age. Conversely, risk of long-term incontinence is influenced more by increasing age [604, 605].

6.7.2.1.3 External beam radiotherapy

External beam radiotherapy and RP have similar cancer control and treatment-related comorbidity, regardless of age, assuming a dose of > 72 Gy when using intensity-modulated or image-guided RT [606].

Cardiac status should be assessed because ADT in patients with pre-existing heart conditions is associated with increased morbidity and mortality. Patients with moderate-to-severe comorbidities might not have a significant survival-benefit when combining ADT with EBRT [454].

6.7.2.1.4 Minimally invasive therapies

Minimally invasive energy-ablative therapies are being developed rapidly, but there is still a lack of evidence to support their use.

6.7.2.1.5 Androgen deprivation therapy

In patients with non-metastatic localised PCa not suitable for curative treatment, immediate ADT should be used only in patients requiring symptom palliation. In locally advanced T3-T4 disease, immediate ADT may benefit patients with PSA > 50 ng/mL and PSA-DT < 12 months [328, 607].

6.7.2.2 Advanced PCa

6.7.2.2.1 Hormone-naïve metastatic PCa

Androgen deprivation therapy is the first-line treatment in hormone-sensitive metastatic PCa. The SIOG PCWG recommends evaluation of baseline bone mineral density and prevention of osteoporosis by calcium and vitamin D supplements [599].

Routine bisphosphonates or denosumab to prevent skeletal complications in ADT is not recommended, unless there is a risk of fracture [608].

6.7.2.2.2 Metastatic CRPC

In metastatic CRPC, docetaxel is standard in fit and frail older men [609], with comparable response and tolerance to younger patients [610]. Tolerability has not been specifically studied in disabled older men. In elderly and disabled patients, granulocyte colony-stimulating factor prophylaxis should be considered.

Cabazitaxel, abiraterone acetate, enzalutamide, and sipuleucel-T increase survival in chemotherapy-treated and chemotherapy-naïve senior adults [611-617].

Palliative treatment includes surgery, radiopharmaceuticals, EBRT, and medical treatment for pain and symptoms.

6.7.3 Guidelines for the treatment of senior adults (> 70 years of age)

Recommendations for assessment	GR
Perform systematic health status screening in senior adults with localised PCa.	A
Use the G8 screening tool for health status screening.	A
Perform a full specialist geriatric evaluation in patients with G8 score ≤ 14 .	A
Treatment options for senior adults according to their health status: 1. Offer standard treatment to fit or healthy older men; 2. Offer standard treatment to frail patients (reversible impairment) after resolution of geriatric problems; 3. Offer adapted treatment to disabled patients (irreversible impairment); 4. Offer only symptomatic palliative treatment to patients who are too sick with terminal illness.	B

Recommendations for treatment	LE	GR
Localised disease		
Offer standard treatment to fit and frail senior adults (after status optimisation) with a life expectancy > 10 years.	2b	A
Offer individualised treatment based on life expectancy, symptoms and risk factors to senior adults with a life expectancy < 10 years.	2b	A
In disabled or 'too-sick' senior adults, offer immediate androgen deprivation therapy only for symptom palliation.	1b	A
Offer minimally invasive energy-ablative therapies only to selected fit and frail senior adults with intermediate-risk disease.	3	B
Advanced disease (locally advanced/metastatic disease)		
Evaluate bone mineral status and prevent osteoporosis-related fractures in senior adults.	2b	A
Offer new chemotherapeutic and hormonal agents to fit and frail adults.	1b	B

6.8 Summary of guidelines for the primary treatment of prostate cancer

Table 6.8.1: EAU risk groups for biochemical recurrence of localised and locally advanced prostate cancer

Definition			
Low-risk	Intermediate-risk	High-risk	
PSA < 10 ng/mL and GS < 7 (ISUP grade 1) and cT1-2a	PSA 10-20 ng/mL or GS 7 (ISUP grade 2/3) or cT2b	PSA > 20 ng/mL or GS > 7 (ISUP grade 4/5) or cT2c	any PSA any GS cT3-4 or cN+ any ISUP grade
Localised			Locally advanced

PSA = prostate-specific antigen.

Guidelines overview - Primary treatment of PCa

Primary treatment of prostate cancer - general recommendations	GR
Discuss several treatment modalities (active surveillance [AS], surgery and radiotherapy) with patients suitable for such treatments.	A*
In patients who are surgical candidates for radical prostatectomy (RP), discuss all approaches (i.e. open, laparoscopic or robotic) as acceptable treatment options since none have clearly shown superiority in terms of functional or oncological results.	A
Offer external beam radiotherapy (EBRT) to all risk groups of non-metastatic PCa.	A
Offer intensity-modulated radiation therapy (IMRT) for definitive treatment of PCa by EBRT.	A
Moderate hypofractionation (HFX) with IMRT including image-guided radiation therapy (IGRT) to the prostate can only be offered to carefully selected patients with localised disease.	A
Moderate HFX should adhere to radiotherapy-protocols from trials with equivalent outcome and toxicity, i.e. 60 Gy/20 fractions in four weeks or 70 Gy/28 fractions in six weeks.	A

Recommendations	GR
Low-risk PCa	
Active surveillance	
Offer active surveillance (AS) to patients with the lowest risk of cancer progression: > 10 years life expectancy, cT1/2, prostate-specific antigen (PSA) ≤ 10 ng/mL, biopsy Gleason score ≤ 6, ≤ 2 positive biopsies, minimal biopsy core involvement (≤ 50% cancer per biopsy).	A
Base follow up on digital rectal examination (DRE), PSA and repeated biopsies.	A
Counsel patients about the possibility of needing further treatment in the future.	A
Radical prostatectomy	
Offer both radical prostatectomy (RP) and radiotherapy (RT) in patients with low- and intermediate-risk PCa and a life expectancy > 10 years.	A
Do not perform a lymph node dissection (LND) in low-risk PCa.	A

Radiotherapy	In low-risk PCa, use a total dose of 74 to 78 Gy for external beam radiotherapy (EBRT).	A
	In patients with low-risk PCa, without a previous transurethral resection of the prostate (TURP) and with a good International Prostate Symptom Score (IPSS) and a prostate volume < 50 mL, offer low-dose-rate (LDR) brachytherapy.	A
Cryotherapy, HIFU	Only offer cryotherapy and high-intensity focused ultrasound (HIFU) within a clinical trial setting. The lack of long-term efficacy compared to standard modality must be discussed with patients.	A
Focal treatment	Do not offer focal therapy of PCa as a therapeutic alternative outside clinical trials.	A
Androgen suppression	Unsuitable.	A
Watchful waiting	Offer watchful waiting (WW) to patients not eligible for local curative treatment and with a short life expectancy.	A
Intermediate-risk PCa		
Active surveillance	Not an option.	A
Radical prostatectomy	Offer both RP and RT in patients with low- and intermediate-risk disease and a life expectancy > 10 years.	A
	Offer nerve-sparing surgery in patients with a low risk of extracapsular disease (refer to nomograms).	B
	Use multiparametric magnetic resonance imaging (mpMRI) as a decision tool to select patients for nerve-sparing procedures.	B
	Perform an extended LND (eLND) if the estimated risk for positive lymph nodes (LNs) exceeds 5%.	B
	Do not perform a limited LND.	A
	In patients with pT3,N0M0 PCa and an undetectable PSA following RP, discuss adjuvant EBRT because it at least improves biochemical-free survival.	A
	Inform patients with pT3,N0M0 PCa and an undetectable PSA following RP about salvage irradiation as an alternative to adjuvant irradiation when PSA increases.	A
	Do not offer adjuvant hormonal therapy (HT) after RP for pN0 disease.	A
Radiotherapy	In intermediate-risk PCa use a total dose of 76-78 Gy, in combination with short-term androgen deprivation therapy (ADT) (four to six months).	A
	In selected intermediate-risk patients, without a previous TURP and with a good IPSS and a prostate volume < 50 mL, offer LDR brachytherapy.	A
Androgen suppression monotherapy	No place in asymptomatic patients.	A
Watchful waiting	Offer WW to patients not eligible for local curative treatment and with a short life expectancy.	A
High-risk PCa		
Watchful waiting	High risk localised: Offer WW to patients not eligible for local curative treatment and with a short life expectancy.	A
	High risk locally advanced: In locally advanced M0 patients unwilling or unable to receive any form of local treatment, offer a deferred treatment policy to asymptomatic patients with a PSA-DT > 12 months and a PSA < 50 ng/mL and non-poorly differentiated tumour.	A
Active surveillance	Not appropriate.	A
Radical prostatectomy	Do not offer neoadjuvant hormonal therapy before RP.	A
	Offer RP in selected patients with locally advanced (cT3a) disease and a life expectancy > 10 years only as part of multi-modal therapy	A
	Offer nerve-sparing surgery in patients with a low risk of extracapsular disease (refer to nomograms).	A
	Perform an eLND in high-risk PCa.	A

	High risk localised: Offer RP in patients with high-risk localised PCa and a life expectancy of > 10 years only as part of multi-modal therapy.	A
	In high-risk disease, use mpMRI as a decision-making tool to select patients for nerve-sparing procedures.	B
	High risk locally advanced: Offer RP in highly selected patients with (cT3b-T4 N0 or any T N1) only as part of multi-modal therapy.	C
	In patients with pT3,N0M0 PCa and an undetectable PSA following RP, discuss adjuvant EBRT because it at least improves biochemical-free survival.	A
	Inform patients with pT3,N0M0 PCa and an undetectable PSA following RP about salvage irradiation as an alternative to adjuvant irradiation when PSA increases.	A
Radiotherapy	Inform patients with an undetectable PSA following RP about salvage irradiation as an alternative to adjuvant irradiation when PSA increases (see Section 6.9.5.1).	A
	In patients with high-risk localised PCa and locally advanced cN0 PCa, use EBRT to a dose of 76-78 Gy, or combined EBRT with brachytherapy boost (either high-dose rate [HDR] or LDR). Radiotherapy should be given in combination with long-term ADT (two to three years).	A
	In patients with locally advanced cN0 PCa, offer RT in combination with long-term ADT (two to three years is recommended).	A
Androgen suppression monotherapy	Reserved for those patients unwilling or unable to receive any form of local treatment and that are either symptomatic or asymptomatic with a PSA-DT < 12 months and a PSA > 50 ng/mL and a poorly differentiated tumour.	A
	Do not offer ADT to patients with a PSA-DT > 12 months	A
N1 patients		
cN1	In patients with cN+ PCa, offer pelvic external beam irradiation in combination with immediate long-term ADT.	B
pN1 after extended lymph node dissection (eLND)	Offer adjuvant ADT for node-positive (pN+).	B
	Offer adjuvant ADT with additional radiotherapy.	A
	Offer observation (expectant management) to a patient after eLND and ≤ 2 nodes with microscopic involvement, and a PSA < 0.1 ng/mL and absence of extranodal extension.	B
Metastatic PCa		
Active surveillance	Unsuitable.	A
Radical prostatectomy	Unsuitable outside clinical trial.	A
Radiotherapy to the prostate	Unsuitable outside clinical trial.	A
Androgen suppression	Offer surgical or medical castration (luteinising-hormone-releasing hormone [LHRH] agonist or antagonist) as androgen deprivation therapy.	A
	Offer castration combined with chemotherapy (docetaxel) to all patients whose first presentation is M1 disease and who are fit enough for chemotherapy.	A
	Offer castration alone, with or without an anti-androgen, to patients unfit for, or unwilling to consider, castration combined with chemotherapy.	A
	Do not prescribe abiraterone acetate or enzalutamide outside of a clinical trial.	A
	In M1 symptomatic patients, offer immediate castration to palliate symptoms and reduce the risk for potentially catastrophic sequelae of advanced disease (spinal cord compression, pathological fractures, urethral obstruction, extra-skeletal metastases).	A
	In M1 asymptomatic patients, offer immediate castration to defer progression to a symptomatic stage and prevent serious disease progression-related complications.	A
	In M1 asymptomatic patients, discuss deferred castration with a well-informed patient since it lowers the treatment side effects, provided the patient is closely monitored.	B

	Do not routinely offer ADT to asymptomatic men with biochemical recurrence.	A
	In M1 patients treated with an LHRH agonist, offer short-term administration of anti-androgens to reduce the risk of the 'flare-up' phenomenon.	A
	Start anti-androgens used for 'flare-up' prevention on the same day as an LHRH analogue is started or for up to seven days before the first LHRH analogue injection if the patient has symptoms). Treat for four weeks.	A
	Do not offer anti-androgen monotherapy in M1 patients.	A
	Offer LHRH antagonists, especially in patients with an impending spinal cord compression or bladder outlet obstruction.	B
	In asymptomatic M1 patients, offer intermittent treatment to highly motivated patients, with a major PSA response after the induction period.	B
	In M1 patients follow the schedules used in published clinical trials on timing of intermittent treatment. Stop treatment when the PSA level is < 4 ng/mL after six to seven months of treatment. Resume treatment when the PSA level is > 10-20 ng/mL (or back to the original level, if < 20 ng/mL).	C

Guidelines for the treatment of senior adults (> 70 years of age)

Recommendations for assessment	GR
Perform systematic health status screening in senior adults with localised PCa.	A
Use the G8 screening tool for health status screening.	A
Perform a full specialist geriatric evaluation in patients with G8 score ≤ 14.	A
Treatment options for senior adults according to their health status: 1. offer standard treatment to fit or healthy older men; 2. offer standard treatment to frail patients (reversible impairment) after resolution of geriatric problems; 3. offer adapted treatment to disabled patients (irreversible impairment); 4. offer only symptomatic palliative treatment to patients who are too sick with terminal illness	B

Recommendations for treatment	LE	GR
Localised disease		
Offer standard treatment to fit and frail senior adults (after status optimisation) with a life expectancy > 10 years.	2b	A
Offer individualised treatment based on life expectancy, symptoms and risk factors to senior adults with a life expectancy < 10 years.	2b	A
In disabled or 'too-sick' senior adults, offer immediate androgen deprivation therapy only for symptom palliation.	1b	A
Offer minimally invasive energy-ablative therapies only to selected fit and frail senior adults with intermediate-risk disease.	3	B
Advanced disease (locally advanced/metastatic disease)		
Evaluate bone mineral status and prevent osteoporosis-related fractures in senior adults.	2b	A
Offer new chemotherapeutic and hormonal agents to fit and frail adults.	1b	B

6.9 Treatment - Management of PSA-only recurrence after treatment with curative intent

6.9.1 Background

Between 27% and 53% of all patients undergoing RP or RT develop PSA-recurrence (see Sections 6.2 and 6.3). Whilst a rising PSA level universally precedes metastatic progression, physicians must inform the patient that the natural history of PSA-only recurrence may be prolonged and that a measurable PSA may not necessarily lead to clinically apparent metastatic disease. Physicians treating patients with PSA-only recurrence face a difficult set of decisions in attempting to delay the onset of metastatic disease and death while avoiding over-treating patients whose disease may never affect their OS or QoL. It should be emphasised that the treatment recommendations for these patients should be given after discussion in a multidisciplinary team.

6.9.2 Definitions

6.9.2.1 Definition of biochemical recurrence

The PSA level that defines treatment failure depends on the primary treatment. After RP, recurrent cancer is defined by two consecutive PSA values of > 0.2 ng/mL and rising [618-620].

After primary RT, with or without short-term hormonal manipulation, the RTOG-ASTRO Phoenix Consensus Conference definition of PSA failure (with an accuracy of $> 80\%$) is any PSA increase ≥ 2 ng/mL higher than the PSA nadir value, regardless of the serum concentration of the nadir [621].

Importantly, patients with PSA-recurrence after RP or primary RT have different risks of subsequent symptomatic metastatic disease. Therefore, physicians should carefully interpret BCR endpoints when comparing treatments.

6.9.3 Natural history of biochemical recurrence

Once a PSA relapse has been diagnosed, it is important to determine, as far as possible, whether the recurrence has developed at local or distant sites. The risk of subsequent metastases and PCSM may be predicted by the initial clinical and pathologic factors (e.g. T-category, PSA, Gleason score) and PSA kinetics (PSA-DT and interval to PSA failure).

6.9.3.1 Post-radical prostatectomy biochemical recurrence

Not all patients with BCR after RP will develop clinical recurrences. In two studies of 1,997 and 2,400 men treated by RP, only 23-34% of those with BCR develop a clinical recurrence and 6% died of PCa [378, 622].

Several studies have attempted to identify risk factors for metastases and PCSM in patients experiencing PSA-only recurrence following RP. A PSA-DT < 3 months, SVI (pT3b), specimen Gleason score 8-10, or time to PSA-recurrence < 3 years indicate a high risk of metastases and PCSM. Conversely, a PSA-recurrence > 3 years following surgery, specimen Gleason score < 7 , pathologic organ-confined disease or limited extracapsular extension (pT3a), and PSA-DT > 12 months indicate a low risk of metastases and PCSM [623-626]. Patients in the low-risk subgroup typically respond very well to SRT with a high probability of PSA being undetectable [627]. However, it must be stressed that most patients within the low-risk subgroup have an excellent outcome even without any salvage treatment. Patients within the high-risk subgroup need early and aggressive salvage treatment [628]. Trock *et al.* demonstrated that SRT was associated with a significant three-fold increase in PCa-specific survival relative to those who received no salvage treatment. The increase in PCa-specific survival associated with SRT was limited to men with a PSA-DT of < 6 months and remained after adjustment for pathological stage and other established prognostic factors. Salvage RT initiated > 2 years after recurrence provided no significant increase in PCa-specific survival [628].

6.9.3.2 Post-radiotherapy biochemical recurrence

In patients experiencing PSA-recurrence after RT, PSA-DT < 3 months, time to biochemical progression < 3 years, biopsy Gleason score 8-10 or clinical stage cT3b-T4 also indicate a high risk of metastases and PCSM. Conversely, PSA-DT > 15 months, biopsy Gleason score < 7 , clinical stage $< cT3a$ and time to BCR > 3 years indicate a low risk of metastases and PCSM [625, 629, 630].

Zumsteg *et al.* have designed a risk score to further subdivide patients who develop PSA recurrence following RT. Those with > 2 high-risk factors (PSA-DT < 3 months, time to BCR < 3 years, biopsy Gleason score 8-10 and clinical stage cT3b-T4) have an increased risk of developing metastases and PCSM as compared to those with 0 or 1 risk factor [630].

6.9.4 Assessment of metastases

6.9.4.1 Bone scan and abdominopelvic computed tomography

Biochemical recurrence after RP or RT precedes clinical metastases by seven to eight years on average, and consequentially the diagnostic yield of common imaging techniques is poor in asymptomatic patients [631]. In men with PSA-only relapse after RP, the probability of a positive BS is $< 5\%$, when the PSA level is < 7 ng/mL [632, 633].

Only 11-14% of patients with BCR after RP have a positive CT and rarely in situations when salvage treatment might be considered [632]. In a series of 132 men with BCR after RP, the mean PSA level and PSA velocity associated with a positive CT was 27.4 ng/mL and 1.8 ng/mL/month, respectively [634]. Therefore, bone scan and abdominopelvic CT should only be considered in patients with BCR after RP who have a high baseline PSA (> 10 ng/mL) or high PSA kinetics (PSA-DT < 6 months or PSA velocity > 0.5 ng/mL/month) or in patients with symptoms of bone disease [632, 634].

6.9.4.2 Choline PET/CT

In two different meta-analyses, the combined sensitivities and specificities of choline PET/CT for all sites of recurrence in patients with BCR were 86-89% and 89-93%, respectively [635, 636]. Choline PET/CT may detect multiple bone metastases in patients showing a single metastasis on BS [637] and may be positive for bone metastases in up to 15% of patients with BCR after RP and negative BS [638]. The specificity of choline PET/CT is also higher than BS with less false-positive and indeterminate findings [257]. Detection of LN metastases using choline PET/CT remains limited by the relatively poor sensitivity of the technique (see Section 5.3.4.1.)

Choline PET/CT sensitivity is strongly dependent on the PSA level and kinetics [249, 639-641]. In patients with BCR after RP, PET/CT detection rates are only 5-24% when the PSA level is < 1 ng/mL, but rises to 67-100% when the PSA level is > 5 ng/mL. In a meta-analysis, choline PET/CT detection rates were 65% (95% CI: 58%-71%) when the PSA-DT was < 6 months, and were 71% (95% CI: 66%-76%) and 77% (95% CI: 71%-82%) when the PSA velocity was > 1 and > 2 ng/mL/year, respectively [639].

Despite these limitations, choline PET/CT may change medical management in 18-48% of patients with BCR after primary treatment [642-644]. In a retrospective bi-centric study of 150 patients, 14 of the 55 (25.5%) patients scheduled for palliative treatment were switched to salvage therapy based on choline PET/CT results. Salvage therapy induced a complete biochemical response in 35.7% of these patients at the end of a median follow-up of 18.3 months (range, 10-48 months) [644] suggesting it continues to miss small volume metastasis. In patients not considered fit enough for curative salvage treatments choline PET/CT should be avoided.

After RP, the optimal PSA cut-off level for choline PET/CT analysis seems to be between 1 and 2 ng/mL. Choline PET/CT detection rate was 26% in patients showing PSA < 1 ng/mL but raised up to 44% in the population with PSA values between 1 and 2 (moreover 37% of them were oligo-metastatic) [645]. It has been suggested that a PSA-DT < 6 months and a PSA velocity > 2 ng/mL/year might also select men in whom choline PET/CT could be recommended [646].

After RT, the PSA cut-off level is unclear due to the lack of sufficient data and because the PSA level is more difficult to interpret due to the “physiological” amount of measurable PSA produced by the non-tumoural prostate [640]. In a study of 46 patients with PSA relapse after RT or brachytherapy, the choline PET/CT detection rate was 54.5%, 81%, 89% and 100% when the PSA level was 1-2 ng/mL, 2-4 ng/mL, 4-6 ng/mL and > 6 ng/mL, respectively [647]. In another study of 140 patients the choline PET/CT detection rate was not influenced by the PSA level, but only by PSA kinetics [648].

6.9.4.3 Other radionuclide techniques

¹⁸F-Fluoride PET and PET/CT have a higher sensitivity than BS in detecting bone metastases [649]. However, ¹⁸F-Fluoride PET and PET/CT is limited by a relative lack of specificity and by the fact that it does not assess soft-tissue metastases [650].

⁶⁸Ga-PSMA PET/CT has shown promising potential in patients with BCR. Detection rates of 58% and 76% have been reported for PSA ranges of 0.2-1 and 1-2 ng/mL, respectively [256]. This suggests that ⁶⁸Ga-PSMA is substantially more sensitive at low PSA levels than choline PET/CT. Two head-to-head comparisons confirmed this finding [651, 652]. However, studies incorporated varying proportions of initial therapy (RP or RT) and a majority of studies included patients on current ADT. Further prospective studies on homogeneous populations are needed to better define the role of ⁶⁸Ga-PSMA PET/CT in patients with BCR. Therefore it cannot yet be considered as a standard evaluation tool. However, in case local salvage treatment is planned and ⁶⁸Ga-PSMA PET/CT is available, it should be considered as a valuable assessment option.

6.9.4.4 Whole-body and axial magnetic resonance imaging

Little is known regarding the accuracy of whole-body or axial MRI in patients with BCR after RP or RT [653]. Therefore, the role of these techniques in detecting occult bone or LN metastases in the case of BCR remains to be assessed.

6.9.4.5 Assessment of local recurrences

6.9.4.5.1 Local recurrence after radical prostatectomy

The precise localisation of the local recurrence by imaging techniques is needed only if the localisation could change treatment planning. Transrectal US is neither sensitive nor specific in detecting local recurrences after RP. Even with TRUS guidance, the sensitivity of anastomotic biopsies remains low: 40-71% for PSA levels > 1 ng/mL and 14-45% for PSA levels < 1 ng/mL [631].

Choline PET/CT can detect local recurrences, but is less sensitive than MRI [654] and although ⁶⁸Ga-PSMA PET/CT has improved sensitivity at low PSA levels, it is still unknown if it can reliably detect local

recurrences in the prostate bed, an area that is frequently obscured by tracer excretion in the bladder [655].

Several studies have reported promising results in the detection of local recurrences using MRI, particularly dynamic contrast-enhanced MRI which showed sensitivities and specificities of 76-90% and 82-100%, respectively [656-659]. However, the mean PSA level in these studies was 0.7-1.9 ng/mL, which is higher than the 0.5 ng/mL threshold usually used for salvage therapy. Two studies evaluated mpMRI in patients with a PSA level < 0.5 ng/mL. One found a sensitivity of only 13% in men with PSA level < 0.3 ng/mL [660], while the other reported a sensitivity of 86% in patients with a PSA level < 0.4 ng/mL [661]. It remains to be seen whether MRI can correctly detect local recurrences in patients with a PSA level < 0.5 ng/mL in order to allow a stereotaxic boost to the recurrence site during SRT. Therefore, SRT is usually decided on the basis of BCR, without histological proof of the local recurrence. The dose delivered to the prostatic bed also tends to be uniform as it has not been demonstrated that a focal dose escalation at the site of recurrence improves the outcome. Thus, most patients undergo SRT without local imaging.

6.9.4.5.2 Local recurrence after radiation therapy

In patients with BCR after RT, the biopsy status is a major predictor of outcome, provided the biopsies are obtained 18-24 months after treatment. Given the morbidity of local salvage options, it is thus mandatory to obtain histological proof of the local recurrence before treating the patient [631] especially if a local salvage curative treatment is considered.

Transrectal US is not reliable in depicting local recurrences after RT. In contrast, mpMRI has yielded excellent results [631, 662-664] and can be used for biopsy targeting and guiding local salvage treatment. Detection of recurrent cancer is also feasible with choline PET/CT [648], and a nomogram able to predict the probability of extra pelvic disease has been proposed [665]. It is also too soon to know if ⁶⁸Ga-PSMA PET/CT could play a role in the detection of local recurrences after RT [256].

6.9.4.6 Guidelines for imaging in patients with biochemical recurrence

Prostate-specific antigen (PSA) recurrence after radical prostatectomy	LE	GR
PSA < 1 ng/mL: no imaging is recommended.	3	A
PSA ≥ 1 ng/mL: positron emission tomography (PET)/computed tomography (CT) imaging is recommended using choline or prostate-specific membrane antigen (PMSA).	2b	A
Perform bone scan and/or abdominopelvic CT only in patients with PSA > 10 ng/mL, or with adverse PSA kinetics (PSA-doubling time (DT) < 6 months, PSA velocity > 0.5 ng/mL/month).	3	A
PSA recurrence after radiotherapy		
Perform prostate multiparametric magnetic resonance imaging (mpMRI) only in patients who are considered candidates for local salvage therapy, use mpMRI to localise abnormal areas and guide biopsies.	3	B
Choline PET/CT imaging is recommended to rule out lymph nodes or distant metastases in patients fit enough for curative salvage treatment.	2b	B
Perform bone scan and/or abdominopelvic CT only in patients with PSA > 10 ng/mL, or with adverse PSA kinetics (PSA-DT < 6 months, PSA velocity > 0.5 ng/mL/month).	3	A

6.9.5 Treatment of PSA-only recurrences

The timing and mode of treatment for PSA-only recurrences after RP or RT are still controversial.

After RP, the therapeutic options are:

- radiotherapy at least to the prostatic bed;
- (complete) androgen deprivation;
- intermittent androgen deprivation;
- observation.

After RT, the therapeutic options are:

- salvage RP;
- HIFU
- cryotherapy;
- brachytherapy;
- androgen deprivation;
- observation.

6.9.5.1 Radiotherapy (salvage radiotherapy - with or without androgen-deprivation therapy for PSA-only recurrence after radical prostatectomy)

Early SRT provides a possibility of cure for patients with an increasing or persistent PSA after RP. More than 60% of patients who are treated before the PSA level rises to > 0.5 ng/mL will achieve an undetectable PSA level [505, 666-668], providing patients with a ~80% chance of being progression-free five years later [506]. A retrospective analysis of 635 patients who were followed after RP and experienced BCR and/or local recurrence and either received no salvage treatment (n = 397) or SRT alone (n = 160) within two years of BCR, showed that salvage RT was associated with a three-fold increase in PCa-specific survival relative to those who received no salvage treatment (p < 0.001). Salvage RT has also been effective in patients with a short PSA-DT [628]. Despite the indication for salvage RT, a “wait and see” strategy is an option in patients with a long PSA-DT of > 12 months [622]. For an overview see Table 6.9.1.

Table 6.9.1: Selected studies on post-prostatectomy salvage radiotherapy, sorted by pre-salvage radiotherapy PSA level*

Reference	n	HT (%)	pre-SRT PSA (ng/mL) median	Median dose (Gy)	bNED/PFS (yr)	5-yr results
Siegmann, <i>et al.</i> 2011 [669]	301	0	0.28	66.6/70.2	74% (2)	55% vs. 88% @ 66.6 vs. 70.2 Gy
Wiegel, <i>et al.</i> 2009 [506]	162	0	0.33	66.6	54% (3.5)	60% vs. 33% @ PSA ≤ 0.5 vs. > 0.5
Goenka, <i>et al.</i> 2011 [670]	285	31	0.4	> 70 (72%)	37% (7)	39%
Cremers, <i>et al.</i> 2010 [671]	197	0	0.59	63 /2.25 frct. (88%)	59% (5)	
Bernard, <i>et al.</i> 2010 [672]	364	0	0.6	64.8	50% (5)	
Buskirk, <i>et al.</i> 2006 [673]	368	15	0.7	64.8	46% (5)	63% vs. 51% @ PSA < 0.5 vs. 0.5 - 1.0
Pazona, <i>et al.</i> 2005 [674]	223	4.5	0.8	63	40/25% (5/10)	42% vs. 30% @ < 1.3 vs. ≥ 1.3
Pisansky, <i>et al.</i> 2000 [675]	166	4	0.9	64	46% (5)	61% vs. 36% @ PSA ≤ 1 vs. > 1
Soto, <i>et al.</i> 2012 [676]	441	24	< 1 (58%)	68	63/55% (3) HT/no HT	44/40% HT/no HT
Stephenson, <i>et al.</i> 2007 [505]	1,540	14	1.1	64.8	32% (6)	37%

* Hormone suppression treatment (HT) can influence the outcome ‘biochemically no evidence of disease (bNED)’ or ‘progression-free survival’ (PFS). Therefore, data sets without HT are highlighted. To facilitate comparisons, 5-year bNED/PFS read-outs from Kaplan-Meier plots are included.

bNED/PFS = biochemically no evidence of disease/progression-free survival; HT = hormone suppression treatment; n = number of patients; SRT = salvage radiotherapy.

Addition of androgen deprivation to SRT improves outcomes. The Radiation Therapy Oncology Group RTOG 96-01 comparing RT + placebo vs. a combination of RT + bicalutamide (150 mg daily) for 24 months in the post-operative setting reported improved overall all survival (82% vs 78% at ten years) [677]. The investigators concluded that 24 months of HT also, significantly reduces metastatic disease, reduces death from CaP (from 7.5% to 2.3%, NNT = 17), reduced overall death (from 22% to 18%) and reduced tumour progression. They found that toxicity was similar in both arms, and that gynaecomastia was extremely common in the bicalutamide group. The GETUG-AFU 16 study [678] confirmed improved bPFS and clinical progression at five years when combining six months of goserelin with SRT, but survival remained unchanged.

6.9.5.1.1 Dose and toxicity

The optimal SRT dose has not been well defined. It should be at least 66 Gy to the prostatic fossa (plus/minus the bed of the seminal vesicles dependent upon the pathological stage at RP) [666]. Similarly, a joint AUA/ASTRO Guideline Panel regarded 64-65 Gy as the minimum dose that should be delivered post-RP [679]. However, more recent data suggest that higher total doses can achieve higher rates of biochemical control

at three to five years [672]. In a SR, the pre-salvage RT PSA level and SRT- dose were correlated with BCR, showing that the relapse-free survival decreased by 2.6% per 0.1 ng/mL PSA and improved by 2% per Gy, suggesting that a treatment dose above 70 Gy should be administered at the lowest possible PSA level [666, 680, 681]. However, with dose escalation (72 Gy) or up to a median of 76 Gy, the rate of severe side effects especially for the genitourinary system clearly increases, even with newer planning and treatment techniques [682, 683]. Of note, compared with 3D-CRT, IMRT was associated with a reduction in Grade 2 GI toxicity from 10.2 to 1.9% ($p = 0.02$), while RT technique had no differential effect on the relatively high level of GU toxicity (five-year: 3D-CRT 15.8% vs. IMRT 16.8%) [682]. After a median salvage IMRT dose of 76 Gy, the five-year risk of Grade 2-3 toxicity rose to 22% for GU and 8% for GI symptoms, respectively [683].

6.9.5.1.2 Comparison of adjuvant radiotherapy (ART) and salvage radiotherapy

The largest retrospective case-matching study to evaluate ART vs. early SRT included pT3N0 R0/R1 patients only (HT was excluded), 390 out of 500 observation-plus-early-SRT patients (median pre-SRT PSA was 0.2 ng/mL) were propensity matched with 390 ART patients. Two and five years after surgery, biochemically no evidence of disease (bNED) rates were 91% and 78% for ART vs. 93% and 82% after salvage RT, respectively. Subgroup analyses did not yield significant differences for the two approaches. It was concluded that early SRT does not impair PCa control, but clearly helps to reduce over-treatment which is a major issue in ART [684]. Both approaches (ART and SRT) together with the efficacy of neoadjuvant HT are currently being compared in three prospective RCTs: the Medical Research Council (MRC) Radiotherapy and Androgen Deprivation In Combination After Local Surgery (RADICALS) in the United Kingdom, the Trans-Tasman Oncology Group (TROG) Radiotherapy Adjuvant Versus Early Salvage (RAVES), and Groupe d'Etude des Tumeurs Uro-Génitales (GETUG 17).

Decision-making on whether to proceed with adjuvant RT for high-risk PCa - pT3-4 pN0 M0 with undetectable PSA after RP, or to postpone RT as an early salvage procedure in the case of biochemical relapse, remains difficult. In everyday practice, the urologist should explain to the patient before RP that adjuvant RT may be administered if the patient has negative prognostic risk factors.

6.9.5.2 Hormonal therapy

Currently there is only one underpowered still unpublished RCT comparing the effect of salvage ADT, although retrospective comparative studies are available. The EAU Guidelines Panel conducted a SR including studies published from 2000 onwards [685]. The key findings are summarised below:

Conflicting results on the clinical effectiveness of HT after previous curative therapy of the primary tumour were found. Some studies reported a favourable effect of HT, including the only RCT addressing the research question of this review (86% vs. 79% advantage in OS in the early HT group) [686]. Other studies did not find any differences between early vs. delayed, or no, HT. One study found an unfavourable effect of HT [687]. This may be the result of selecting clinically unfavourable cases for (early) HT and more intensive diagnostic work-up and follow-up in these patients.

The studied population is highly heterogeneous regarding their tumour biology and therefore clinical course. The following factors were found predictive for poor outcomes (CRPC, distant metastases [DM], CSS, OS): short PSA-DT, high Gleason score, high PSA, increased age and comorbidities. In some studies, such as the Boorjian, *et al.* study [622], high-risk patients, mainly defined by a high Gleason score and a short PSA-DT (most often < 6 months), seem to benefit most from (early) HT, especially in men with a long life expectancy.

No data were found on the effectiveness of different types of HT, although it is unlikely that this will have a significant impact on survival outcomes in this setting. Non-steroidal anti-androgens have been claimed to be inferior compared to castration, but this difference was not seen in M0 patients [628]. One of the included RCTs suggested that intermittent HT is not inferior to continuous HT in terms of OS and CSS [688]. A small advantage was found in some QoL domains but not overall QoL outcomes. An important limitation of this RCT is the lack of any stratifying criteria such as PSA-DT or initial risk factors.

Based on the lack of definitive efficacy and the undoubtedly associated significant side effects, not all patients with recurrence after primary curative therapy should receive standard HT. Only a minority of them will progress to metastases or PCa-caused death. The objective of HT should be to improve OS, postpone DM, and improve QoL. Biochemical response to only HT holds no clinical benefit for a patient. For older patients and those with comorbidities, the side effects of HT may even decrease life expectancy; in particular, cardiovascular risk factors need to be considered [689, 690]. Early HT should be reserved for those at highest risk of disease progression, defined mainly by a short PSA-DT at relapse (< 6-12 months) or a high initial Gleason score (> 7), and a long life expectancy. In all other situations, the potential benefits of salvage HT should be judiciously considered and balanced against its potential harms.

6.9.5.3 Observation

Observation until the development of clinically evident metastatic disease may represent a viable option for patients with low-risk features (PSA-DT > 12 months, time to BCR > 3 years, GS ≤ 7 and stage ≤ T3a) or unfit patients with a life expectancy < 10 years and/or are unwilling to undergo salvage treatment. In unselected relapsing patients, the median actuarial time to the development of metastasis will be eight years and the median time from metastasis to death will be a further five years [378].

6.9.6 Management of PSA failures after radiation therapy

Therapeutic options in these patients are ADT or local procedures such as SRP, cryotherapy, interstitial brachytherapy and HIFU [691-700]. Strong recommendations regarding the choice of any of these techniques cannot be made as the available evidence for these treatment options is of (very) low quality. The following is an overview of the most important findings regarding each of these techniques with a proposal for their indications.

6.9.6.1 Salvage radical prostatectomy

Salvage RP (SRP) after RT has the longest history and best likelihood of local control relative to other salvage treatments. However, this must be weighed against the possible adverse events, which are increased compared to primary surgery because of the risk of fibrosis and poor wound healing due to radiation.

6.9.6.1.1 Oncological outcomes

In a recent SR of the literature, Chade, *et al.* showed that SRP gave five- and ten-year BCR-free survival (BCR-FS) estimates ranging from 47-82% and from 28-53%, respectively. The ten-year CSS and OS rates ranged from 70-83% and from 54-89%, respectively. The pre-SRP PSA value and prostate biopsy Gleason score were the strongest predictors of the presence of organ-confined disease, progression, and CSS [701].

In most contemporary series, organ-confined disease, negative surgical margins (SM), and the absence of seminal vesicle and/or LN metastases were favourable prognostic indicators associated with a better DFS of approximately 70-80%, in comparison with 40-60% in patients with locally advanced PCa [700].

Table 6.9.2: Oncological results of selected salvage radical prostatectomy case series, including at least 30 patients

Reference	n	Median FU (mo)	Pathologic organ-confined (%)	PSM (%)	Lymph-node involvement (%)	BCR-free probability (%)	CSS (%)	Time probability (yr)
Sanderson, <i>et al.</i> 2006 [702]	51	-	25	36	28	47	-	5
Leonardo, <i>et al.</i> 2009 [703]	32	35	53	34	0	75	-	3
Heidenreich, <i>et al.</i> 2010 [699]	55	23 (2-56)	73	11	20	87	-	2
Chade, <i>et al.</i> 2011 [704]	404	55	55	25	16	37	83	10

BCR = biochemical recurrence; FU = follow-up; mo = months; n = number of patients; PSM = positive surgical margin; CSS = cancer-specific survival.

6.9.6.1.2 Morbidity

Compared to primary open RP, SRP is associated with a higher risk of later anastomotic stricture (47 vs. 5.8%), urinary retention (25.3% vs 3.5%), urinary fistula (4.1% vs 0.06%), abscess (3.2% vs 0.7%) and rectal injury (9.2 vs. 0.6%) [705]. In more recent series, these complications appear to be less common [698, 701]. Functional outcomes are also worse compared to primary surgery, with urinary incontinence ranging from 21% to 90% and ED in nearly all patients [701].

Table 6.9.3: Perioperative morbidity in selected salvage radical prostatectomy case series, including at least 30 patients

Reference	n	Rectal injury (%)	Anastomotic stricture (%)	Clavien 3-5 (%)	Blood loss, mL, mean, range
Stephenson, <i>et al.</i> 2004 [698]	100	15 vs. 2*	30	33 vs. 13*	-
Ward, <i>et al.</i> 2005 [706]	138	5	22	-	-
Sanderson, <i>et al.</i> 2006 [702]	51	2	41	6	-
Gotto, <i>et al.</i> 2010 [705]	98	9	41	25	-
Heidenreich, <i>et al.</i> 2010 [699]	55	2	11	3.6	360 (150-1450)

* SRP performed before vs. after 1993.

n = number of patients.

6.9.6.2 Summary of salvage radical prostatectomy

In general, SRP should be considered only for patients with low comorbidity, a life expectancy of at least ten years, a pre-SRP PSA < 10 ng/mL and biopsy Gleason score ≤ 7, no LN involvement or evidence of distant metastatic disease pre-SRP, and who's initial clinical staging was T1 or T2 [701]. A meta-regression analysis suggested that SRP may be associated with worse continence outcomes than non-surgical approaches [707].

6.9.7 Salvage cryoablation of the prostate

6.9.7.1 Oncological outcomes

In cases in which RT fails, salvage cryoablation of the prostate (SCAP) has been proposed as an alternative to SRP, as it has a potentially lower risk of morbidity and equal efficacy. However, the very few studies available have shown disappointing results. In a review of the use of SCAP for recurrent cancer after RT, the five-year BDFS estimates ranged from 50-70%. A durable response can be achieved in ~50% of patients with a pre-SCAP PSA < 10 ng/mL [708]. In a multicentre study reporting the current outcome of SCAP in 279 patients, the five-year BCR-free survival (BCR-FS) estimate according to the Phoenix criteria was 54.5 ± 4.9%. Positive biopsies were observed in 15/46 patients (32.6%) who underwent prostate biopsy after SCAP [709].

A case-matched control study comparing SRP and SCAP was performed in men with recurrent PCA after RT. The authors compared the oncological outcomes of the two salvage treatment options after mean follow-up periods of 7.8 (SRP group) and 5.5 years (SCAP group). The five-year BCR-FS was 61% following SRP, significantly better than the 21% detected after SCAP. The five-year OS was also significantly higher in the SRP group (95% vs. 85%) [710].

Table 6.9.4: Oncological results of selected salvage cryoablation of the prostate case series, including at least 50 patients

Reference	n	Median FU (mo)	BCR-free probability (%)	Time probability (yr)	Definition of failure
Pisters, <i>et al.</i> 1997 [710]	150	17	44	-	Nadir + 0.2
Bahn, <i>et al.</i> 2003 [711]	59	82	59	7	PSA > 0.5
Ismail, <i>et al.</i> 2007 [708]	100	33	73 (low risk)	5	ASTRO
Pisters, <i>et al.</i> 2008 [709]	279	22	58	5	ASTRO and Phoenix
Williams, <i>et al.</i> 2011 [712]	187	7.46 yr	39	10	Nadir +2
Spies, <i>et al.</i> 2010 [713]	450	40.8	34	-	PSA > 0.5

BCR = biochemical recurrence; FU = follow-up; mo = months; n = number of patients.

6.9.7.2 Morbidity

According to Cespedes, *et al.* [714], the risks of urinary incontinence and ED at least twelve months after SCAP were as high as 28% and 90%, respectively. In addition, 8-40% of patients reported persistent rectal pain, and an additional 4% of patients underwent surgical procedures for the management of treatment-associated complications. In a recent study by Pisters, *et al.*, the urinary incontinence rate was 4.4%. The rectal fistulae rate was 1.2% and 3.2% of patients required a TURP for removal of sloughed tissue [709]. With the use of third-generation technology, complications such as urinary incontinence and obstruction/retention have significantly decreased during the last decade (see Table 6.9.5) [715].

Table 6.9.5: Perioperative morbidity, erectile function and urinary incontinence in selected salvage cryoablation of the prostate case series, including at least 50 patients

Reference	n	Incontinence (%)	Obstruction/Retention (%)	Rectourethral fistula (%)	ED (%)
Pisters, <i>et al.</i> 1997 [716]	150	73	67	1	72
Bahn, <i>et al.</i> 2003 [711]	59	8	-	3.4	-
Ismail, <i>et al.</i> 2007 [708]	100	13	4	1	-
Pisters, <i>et al.</i> 2008 [709]	279	4.4	3.2	1.2	-
Ahmad, <i>et al.</i> 2013 [717]	283	12	7	1.8	83

ED = erectile dysfunction; n = number of patients.

6.9.7.3 Summary of salvage cryoablation of the prostate

In general, SCAP should be considered only for patients with low comorbidity, a life expectancy of at least ten years, an initial organ-confined PCa cT1c to cT2, initial Gleason score ≤ 7 , a pre-salvage PSA-DT ≥ 16 months and a pre-salvage PSA < 10 ng/mL.

6.9.8 Salvage brachytherapy for radiotherapy failure

Although there is no role for salvage EBRT following local recurrence after previous definitive RT, for carefully selected patients with primary localised PCa and histologically proven local recurrence, HDR- or LDR brachytherapy remain effective treatment options with an acceptable toxicity profile [718-720]. However, the published series are relatively small and consequently this treatment should be offered in experienced centres only. Fifty-two patients were treated at the Scripps Clinic with HDR-brachytherapy over a period of nine years [718]. With a median follow-up of 60 months the five-year biochemical control was 51% and only 2% Grade 3 GU toxicities were reported. Comparable with these data, 42 patients were treated in a phase-II-trial at MSKCC in New York [721]. Of note, the median pre-treatment dose was 81 Gy given with IMRT and the prescription HDR-dose of 32 Gy was delivered in four fractions over 30 hours. The biochemical relapse-free survival after five years was 69% (median follow-up 36 months). Grade 2 late side effects were seen in 15% and one patient developed Grade 3 incontinence. However, older data with higher rates of side effects have been reported [722].

Using LDR-brachytherapy with 103 palladium (Pd), long-term outcome was reported in 37 patients with a median follow-up of 86 months [719]. The biochemical control rate after ten years was 54%. However, the crude rate of \geq Grade 2 toxicity was 46% and \geq Grade 3 toxicity was 11%. These side effects were comparable with a series of 31 patients treated with salvage I-125 brachytherapy in the Netherlands. Therefore, in these small series, late side effects seem to be lower with HDR-brachytherapy [723]. In conclusion, freedom from BCR after salvage HDR and LDR-brachytherapy is promising and the rate of severe side effects in experienced centres seem to be acceptable. Salvage brachytherapy remains a treatment option for selected patients with histologically proven local recurrence after RT.

6.9.9 Salvage high-intensity focused ultrasound

6.9.9.1 Oncological outcomes

Salvage HIFU has more recently emerged as an alternative thermal ablation option for radiation-recurrent PCa. Most of the data were generated by one high-volume centre. Median follow-up was very short, and outcome measures were non-standardised.

Table 6.9.6: Oncological results of selected salvage high-intensity focused ultrasound case series, including at least 20 patients

Reference	n	Median FU (mo)	BCR-free probability (%)	Negative biopsy rate
Colombel, <i>et al.</i> 2006 [724]	224	15-18	-	80
Gelet, <i>et al.</i> 2000 [725]	-	-	-	-
Gelet, <i>et al.</i> 2004 [726]	-	-	-	-
Uchida, <i>et al.</i> 2011 [727]	22	24	59 (Phoenix) (24 mo.)	92 (only 12 biopsied)
Berge, <i>et al.</i> 2011 [728]	46	9	60.9 (9 mo)	-

FU = follow-up; mo = months; n = number of patients.

6.9.9.2 Morbidity

Again, most of the data were generated by one high-volume HIFU centre. Important complication rates were mentioned and are at least comparable to other salvage treatment options.

6.9.9.3 Summary of salvage high-intensity focused ultrasound

There is a lack of data which prohibits any recommendation regarding the indications for salvage HIFU.

6.9.10 Observation

Patients who have signs of only local recurrence (i.e., low-risk patients with late recurrence and a slow PSA rise) who do not wish to undergo second-line curative options are best managed by observation alone. A retrospective cohort analysis of HT vs. WW in 248 men with PSA failure after RT showed no advantage for HT in the subgroup of men with a PSA-DT of > 12 months after RT. The five-year metastasis-free survival rate was 88% with HT vs. 92% with WW ($p = 0.74$) [729].

6.9.11 Salvage lymph node dissection

Novel imaging modalities improve the early detection of nodal metastases [730]. The surgical management of (recurrent) nodal metastases in the pelvis has been the topic of several retrospective analyses [730-732]. The majority of treated patients showed biochemical recurrence but clinical recurrence-free and cancer specific ten-year survival over 70% has been reported [731, 733]. Neither the template nor the real value of nodal salvage dissection is available. It must however be remembered that the imaging modalities under-evaluate the real nodal involvement. Biochemical recurrence rates were found to be dependent on PSA at surgery and location and number of positive nodes [576]. Addition of RT to the lymphatic template after salvage LND may improve the BCR rate [734]. The real efficacy of this salvage procedure remains unproven, as is its impact on survival [735].

6.9.11.1 Guidelines for salvage lymph node dissection

Recommendation	GR
Discuss salvage lymph node dissection (LND) with men experiencing nodal recurrence after local treatment but it should be considered experimental and biochemical recurrence after salvage LND occurs in the majority of cases.	C

6.9.12 Guidelines for second-line therapy after treatment with curative intent

Local salvage treatment	LE	GR
Recommendations for biochemical recurrence after radical prostatectomy		
Offer patients with a prostate-specific antigen (PSA) rise from the undetectable range and favourable prognostic factors ($\leq pT3a$, time to biochemical recurrence > 3 year, PSA-doubling time [DT] > 12 months, Gleason score ≤ 7), active surveillance and possibly delayed salvage radiotherapy.	3	B
Treat patients with a PSA rise from the undetectable range with salvage radiotherapy (SRT). The total dose of SRT should be at least 66 Gy and should be given early (PSA < 0.5 ng/mL).	2	A
Recommendations for biochemical recurrence after radiotherapy		
Treat highly selected patients with localised PCa and a histologically proven local recurrence with salvage radical prostatectomy (SRP).	3	B
Due to the increased rate of side effects, perform SRP in experienced centres.	3	A
Offer/discuss high intensity focused ultrasound, cryosurgical ablation and salvage brachytherapy to/with patients without evidence of metastasis and with histologically proven local recurrence. Inform patients about the experimental nature of these approaches.	3	B
Recommendations for systemic salvage treatment		
Do not routinely offer androgen-deprivation therapy (ADT) to asymptomatic men with biochemical recurrence.	3	A
Do not offer ADT to patients with a PSA-DT > 12 months.	3	B
If salvage ADT (post-primary radiotherapy) is started, offer intermittent therapy to responding patients.	1b	A

6.10 Treatment: Castration-resistant PCa (CRPC)

Table 6.10.1: Definition of Castration-resistant PCa (CRPC)

Castrate serum testosterone < 50 ng/dL or 1.7 nmol/L plus either;	
a)	Biochemical progression: Three consecutive rises in PSA one week apart resulting in two 50% increases over the nadir, and a PSA > 2 ng/mL or,
b)	Radiological progression: The appearance of new lesions: either two or more new bone lesions on bone scan or a soft tissue lesion using RECIST (Response Evaluation Criteria in Solid Tumours) [736]. Symptomatic progression alone must be questioned and subject to further investigation. It is not sufficient to diagnose CRPC.

6.10.1 Non-metastatic castration-resistant PCa

Frequent post-treatment PSA surveillance has resulted in earlier detection of progression. Although approximately one-third of men with a rising PSA will develop bone metastases within two years [737], there are no available studies suggesting a benefit for immediate treatment.

In men with CRPC and no detectable clinical metastases, baseline PSA level, PSA velocity and PSA-DT have been associated with time to first bone metastasis, bone metastasis-free and OS [737, 738]. These factors may be used when deciding which patients should be evaluated for metastatic disease. A consensus statement by the PCa Radiographic Assessments for Detection of Advanced Recurrence (RADAR) group [739] suggested a bone scan and a CT scan when the PSA reached 2 ng/mL and if this was negative it should be repeated when the PSA reached 5 ng/mL and again after every doubling of the PSA based on PSA-testing every three months for asymptomatic men. Symptomatic patients should undergo relevant investigation regardless of PSA level.

6.10.2 Metastatic castration-resistant PCa

The remainder of this Section focuses on the management of men with proven metastatic CRPC (mCRPC).

6.10.2.1 Conventional androgen deprivation in castration-resistant PCa

Eventually men with PCa show evidence of disease progression despite castration. Two trials have shown only a marginal survival benefit for patients remaining on LHRH analogues during second- and third-line therapies [740, 741]. However, in the absence of prospective data, the modest potential benefits of a continuing castration outweigh the minimal risk of treatment. In addition, all subsequent treatments have been studied in men with ongoing androgen suppression and therefore it should be continued indefinitely in these patients.

Table 6.10.2: Randomised phase III controlled trials - first-line treatment of metastatic castration-resistant PCa*

Author	Intervention	Comparison	Selection Criteria	Main outcomes
DOCETAXEL				
SWOG 99-16 2004 [742]	docetaxel/EMP, every 3 weeks, 60 mg/m ² , EMP 3 x 280 mg/day	mitoxantrone, every 3 weeks, 12 mg/m ² prednisone 5 mg BID		OS: 17.52 vs. 15.6 mo. (p = 0.02, HR: 0.80; 95% CI: 0.67-0.97) PFS: 6.3 vs. 3.2 mo. (p < 0.001)

OS: 32.4 vs. 30.2 mo. (p < .001). FU: 22 mo. (p < 0.001 HR: 0.71, 95% CI: 0.60-0.84) rPFS: 20.0 mo. vs. 5.4 mo. HR: 0.186 (95% CI: 0.15-0.23) p < 0.0001)
SIPULEUCEL-T				
Kantoff, <i>et al.</i> 2010 [748]	sipuleucel-T [615]	placebo [615]	- Some with previous docetaxel. - ECOG 0-1. - Asymptomatic or minimally symptomatic.	OS: 25.8 vs. 21.7 mo. (p = 0.03 HR: 0.78, 95% CI: 0.61-0.98). FU: 34.1 mo. PFS: 3.7 vs. 3.6 mo. (no difference)
Small, <i>et al.</i> 2006 [749]	sipuleucel-T [749]	Placebo [96]	- ECOG 0-1. - No visceral metastases. - No bone or cancer pain. - No corticosteroids.	OS: 25.9 vs. 21.4 mo (p. 01). FU: 36 mo. PFS: 11.7 vs. 10.0 wk.

BID = twice a day; *ECOG* = Eastern Cooperative Oncology Group; *EMP* = estramustine; *FU* = follow-up; *PFS* = progression-free survival; *rPFS* = radiographic progression free survival; *OS* = overall survival.

6.10.3 First-line treatment of metastatic castration-resistant PCa

6.10.3.1 Abiraterone

Abiraterone was evaluated in 1,088 chemo-naïve mCRPC patients in the phase III trial COU-AA-302. Patients were randomised to abiraterone acetate or placebo, both combined with prednisone [744]. The main stratification factors were Eastern Cooperative Oncology Group (ECOG) PS 0 or 1 and asymptomatic or mildly symptomatic disease. Overall survival and radiographic PFS (rPFS) were the co-primary endpoints. After a median follow-up of 22.2 months, there was significant improvement of rPFS (median 16.5 vs. 8.2 months, HR: 0.52, p < 0.001) and the trial was unblinded. At the final analysis with a median follow-up of 49.2 months the OS endpoint was significantly positive (34.7 vs. 30.3 months, HR: 0.81, 95% CI: 0.70-0.93, p = 0.0033) [746]. Adverse events (AEs) related to mineralocorticoid excess and liver function abnormalities were more frequent with abiraterone, but mostly Grade 1-2. Sub-set analysis of this trial showed the drug to be equally effective in an elderly population (> 75 years) [750].

6.10.3.2 Enzalutamide

A randomised phase III trial (PREVAIL) [747] included a similar patient population and compared enzalutamide and placebo. Men with visceral metastases were accepted although the numbers were small. Corticosteroids were allowed but not mandatory. PREVAIL was conducted in a chemo-naïve mCRPC population of 1,717 men and showed a significant improvement in both co-primary endpoints, rPFS (HR: 0.186; CI: 0.15-0.23, p < 0.0001), and OS (HR: 0.706; CI: 0.6-0.84, p < 0.001). A ≥ 50% decrease in PSA was seen in 78% of patients. The most common clinically relevant AEs were fatigue and hypertension and again it was equally well tolerated in men > 75 years [751] as well as in those with or without visceral metastases [752]. For the subgroup of visceral metastases, there seems to be limited benefit concerning OS [752]. Enzalutamide has also been compared with bicalutamide in a phase II study [753] revealing a significant improvement in PFS (15.7 months vs. 5.8 months, HR 0.44, p < 0.0001).

6.10.3.3 Docetaxel regimen

A significant improvement in median survival of 2-2.9 months occurred with docetaxel-based chemotherapy

compared to mitoxantrone + prednisone therapy [742, 743]. The standard first-line chemotherapy is docetaxel 75 mg/m² three-weekly doses combined with prednisone 5 mg BID, up to ten cycles. Prednisone can be omitted if there are contraindications or no major symptoms.

Several poor prognostic factors have been described before docetaxel treatment: PSA > 114 ng/mL, PSA-DT < 55 days, or the presence of visceral metastases [754]. A better risk group definition was subsequently presented, again based on the TAX 327 study cohort: the independent prognostic factors were visceral metastases, pain, anaemia (Hb < 13 g/dL), bone scan progression, and prior estramustine. Patients were categorised into three risk groups: low risk (0 or 1 factor), intermediate (2 factors) and high risk (3 or 4 factors), showing three significantly different median OS estimates of 25.7, 18.7 and 12.8 months, respectively [755].

Age by itself is not a contraindication to docetaxel [610] but attention must be paid to closer monitoring and comorbidities as discussed in Section 6.7.2.2.2 [756]. In men with mCRPC who are thought to be unable to tolerate the standard regime the data shows that docetaxel 50 mg/m² every two weeks seems well tolerated with less Grade 3-4 AEs and suggest a prolonged time to treatment failure [757].

6.10.3.4 Sipuleucel-T

In 2010, a phase III trial of sipuleucel-T showed a survival benefit in 512 asymptomatic or minimally symptomatic mCRPC patients [738]. After a median follow-up of 34 months, the median survival was 25.8 months in the sipuleucel-T group compared to 21.7 months in the placebo group, leading to a significant HR of 0.78 (p = 0.03). No PSA decline was observed and PFS was equivalent in both arms. The overall tolerance was very good, with more cytokine-related AEs Grade 1-2 in the sipuleucel-T group, but the same Grade 3-4 AEs in both arms. In Europe, sipuleucel-T is not available.

Table 6.10.3: Randomised controlled phase III - second-line trials in metastatic castration-resistant PCa*

Author	Intervention	Comparison	Selection criteria	Main outcomes
ABIRATERONE				
Fizazi, <i>et al.</i> 2012 [614]	abiraterone + prednisone HR	placebo + prednisone	Previous docetaxel. ECOG 0-2. PSA or radiographic progression.	OS: 15.8 vs. 11.2 mo (p < 0.0001). FU: 20.2 mo.
de Bono, <i>et al.</i> 2011 [611]				Radiologic PFS: no change OS: 14.8 vs. 10.9 mo. (p < 0.001 HR: 0.65; 95% CI: 0.54-0.77). FU: 12.8 mo. Radiologic PFS: 5.6 vs. 3.6 mo.
Radium-223				
Parker, <i>et al.</i> 2013 [758]	radium-223	Placebo	Previous or no previous docetaxel. ECOG 0-2. Two or more symptomatic bone metastases. No visceral metastases.	OS: 14.9 vs. 11.3 mo. (p = 0.002, HR: 0.61; 95% CI: 0.46-0.81). All secondary endpoints show a benefit over best standard of care
CABAZITAXEL				
Bahl, <i>et al.</i> 2013 [617]	cabazitaxel + prednisone	mitoxantrone + prednisone	Previous docetaxel. ECOG 0-2.	OS: 318/378 vs. 346/377 events (odds ratio 2.11; 95% CI: 1.33-3.33). FU: 25.5 months OS ≥ 2y 27% vs. 16% PFS: -
deBono, <i>et al.</i> 2010 [613]				OS: 15.1 vs. 12.7 mo. (p < 0.0001, HR: 0.70; 95% CI: 0.59-0.83). FU: 12.8 mo. PFS: 2.8 vs. 1.4 mo. (p < 0.0001, HR: 0.74; 95% CI: 0.64-0.86)

ENZALUTAMIDE				
Scher, <i>et al.</i> 2012 [612]	enzalutamide	Placebo	Previous docetaxel. ECOG 0-2.	OS: 18.4 vs. 13.6 mo. ($p < 0.001$) HR: 0.63; 95% CI: 0.53-0.75). FU: 14.4 mo. Radiologic PFS: 8.3 vs. 2.9 mo. HR: 0.40; 95% CI: 0.35-0.47 $p < 0.0001$)

*Only studies reporting survival outcomes as primary endpoints have been included.

OS = overall survival; PFS = progression-free survival.

6.10.4 Second-line treatment for mCRPC

All patients who receive treatment for mCRPC will eventually progress. All treatment options in this setting are presented in Table 6.10.3.

6.10.4.1 Cabazitaxel

Cabazitaxel is a novel taxane with activity in docetaxel-resistant cancers. It was studied in a large prospective, randomised, phase III trial (TROPIC trial) comparing cabazitaxel + prednisone vs. mitoxantrone + prednisone in 755 patients with mCRPC, who had progressed after or during docetaxel-based chemotherapy [613]. Patients received a maximum of ten cycles of cabazitaxel (25 mg/m²) or mitoxantrone (12 mg/m²) + prednisone (10 mg/day), respectively. Overall survival was the primary end-point, which was significantly longer with cabazitaxel (median: 15.1 vs. 12.7 months $p < 0.0001$). There was also a significant improvement in PFS (median: 2.8 vs. 1.4 months, $p < 0.0001$), objective RECIST response (14.4% vs. 4.4%, $p < 0.005$), and PSA response rate (39.2% vs. 17.8%, $p < 0.0002$). Treatment-associated WHO Grade 3-4 AEs developed significantly more often in the cabazitaxel arm, particularly haematological (68.2% vs. 47.3%, $p < 0.0002$) but also non-haematological (57.4 vs. 39.8%, $p < 0.0002$) toxicity [759]. In two post marketing randomised phase 3 trials, firstly, cabazitaxel was shown not to be superior to docetaxel in the first line setting and, secondly, it was seen that in the second line setting, 20 mg/m² cabazitaxel is not inferior to 25 mg/m² in terms of OS, but less toxic. Therefore, the lower dose should be preferred [760, 761]. In any case, cabazitaxel should be administered by physicians with expertise in handling neutropenia and sepsis, preferably with prophylactic granulocyte colony-stimulating factor at least in the high-risk patient population [762].

6.10.4.2 Abiraterone acetate after prior docetaxel

Positive preliminary results of the large phase III COU-AA-301 trial were reported after a median follow-up of 12.8 months [611] and the final results have been reported more recently [614]. A total of 1,195 patients with mCRPC were randomised 2:1 to abiraterone acetate + prednisone or placebo + prednisone. All patients had progressive disease based on the PCWG2 criteria after docetaxel therapy (with a maximum of two previous chemotherapeutic regimens). The primary end-point was OS, with a planned HR of 0.8 in favour of abiraterone. After a median follow-up of 20.2 months, the median survival in the abiraterone group was 15.8 months compared to 11.2 months in the placebo arm (HR: 0.74, $p < 0.0001$). The benefit was observed in all subgroups and all the secondary objectives were in favour of abiraterone (PSA, radiologic tissue response, time to PSA or objective progression). The incidence of the most common Grade 3-4 AEs did not differ significantly between the arms, but mineralocorticoid-related side effects were more frequent in the abiraterone group, mainly Grade 1-2 (fluid retention, oedema and hypokalaemia).

6.10.4.3 Enzalutamide after docetaxel

The planned preliminary analysis of the AFFIRM study was published in 2012 [612]. This trial randomised 1,199 patients with mCRPC in a 2:1 fashion to enzalutamide or placebo. The patients had progressed after docetaxel treatment, according to the PCWG2 criteria. Corticosteroids were not mandatory, but could be prescribed, and were received by 30% of the population. The primary end-point was OS, with an expected HR benefit of 0.76 in favour of enzalutamide. After a median follow-up of 14.4 months, the median survival in the enzalutamide group was 18.4 months compared to 13.6 months in the placebo arm (HR: 0.63, $p < 0.001$). This led to the recommendation that the study be halted and unblinded. The benefit was observed irrespective of age, baseline pain intensity, and type of progression. All the secondary objectives were in favour of enzalutamide (PSA, soft tissue response, QoL, time to PSA or objective progression). No difference in terms of side effects was observed in the two groups, with a lower incidence of Grade 3-4 AEs in the enzalutamide arm. There was a 0.6% incidence of seizures in the enzalutamide group compared to none in the placebo arm.

6.10.4.4 Radium-223

The only bone-specific drug that is associated with a survival benefit is radium-223, an α -emitter. In a large

phase III trial (ALSYMPCA), 921 patients with symptomatic mCRPC, who failed or were unfit for docetaxel, were randomised to six injections of 50 kBq/kg radium-223 or placebo, plus standard of care. The primary end-point was OS. Radium-223 significantly improved median OS by 3.6 months (HR: 0.70; $p < 0.001$) [758]. It was also associated with prolonged time to first skeletal event, improvement in pain scores and improvement in QoL. The associated toxicity was mild and, apart from slightly more haematologic toxicity and diarrhoea with radium-223, this did not differ significantly from that in the placebo arm [758]. Radium-223 was effective and safe no matter if the patients were docetaxel pre-treated, or not [763].

6.10.5 **Treatment after docetaxel and one line of hormonal treatment for mCRPC**

The choice of further treatment after docetaxel and one line of hormonal treatment for mCRPC is open. Either further HT (enzalutamide or abiraterone) or second-line chemotherapy (cabazitaxel) are reasonable options albeit with low levels of evidence. PARP inhibitors have shown high rates of response in men with somatic homologous recombination deficiency (HRD) in initial studies. Men previously treated with both docetaxel and at least one novel hormonal agent and whose tumours demonstrated homozygous deletions or deleterious mutations in DNA-repair genes showed an 88% response rate [764]. Patients without HRD did not clearly benefit from olaparib. Although not yet available they offer an exciting opportunity to tailor therapy based on the mutation profile contained within a tumour.

In general however, and in unselected patients, subsequent treatments can be expected to have a smaller response [765, 766] with evidence of cross-resistance between enzalutamide and abiraterone [767].

6.10.6 **Monitoring of treatment**

Baseline examinations should include history and clinical examination as well as baseline bloods (PSA, FBC, renal function, LFTs, ALP), bone scan and CT of chest abdomen and pelvis [768]. Prostate-specific antigen alone is not reliable enough [769] for monitoring disease activity in advanced CRPC, since visceral metastases may develop in men without rising PSA [770]. Instead PCWG2 recommends a combination of bone scintigraphy and CT scans, PSA measurements and clinical benefit in assessing men with CRPC [742]. A majority of experts at a recent consensus meeting suggested regular review and repeat blood profile every two to three months with bone scintigraphy and CT scans at least every six months, even in the absence of a clinical indication [768]. This reflects that the agents with a proven OS survival benefit all have potential toxicity and considerable cost and patients with no objective benefit should have treatment modified. This panel stressed that such treatments should not be stopped for PSA progression alone. Instead at least two of three criteria (PSA progression, radiographic progression and clinical deterioration) should be fulfilled to stop treatment. For trial purposes, the updated PCWG3 put more weight on the importance of documenting progression in existing lesions and introduced the concept of “no longer clinically benefiting” to underscore the distinction between first evidence of progression and the clinical need to terminate or change treatment [771]. These recommendations also seem valid for clinical practice outside trials.

6.10.7 **When to change treatments**

The timing of mCRPC treatment change remains a matter of debate in mCRPC although it is clearly advisable to start or change treatment immediately in men with symptomatic progressing metastatic disease. As the number of effective treatments increases and without head to head trials or data assessing the effectiveness of different sequencing options, it is not clear how to choose the appropriate “second-line” treatment. In the absence of other data, the inclusion criteria from licensing trials have been used to prioritise treatment sequencing.

The Eastern Cooperative Oncology group PS have been used to stratify patients. Generally men with a PS of 0-1 are likely to tolerate treatments and those with PS of 2 or more are less likely to benefit. However, it is important that treatment decisions are individualised. This applies particularly where symptoms related to disease progression are determining PS. In such cases it may be appropriate to trial novel treatments to establish if treatment would improve PS. A summary of the issues regarding sequencing are discussed in a paper published following the St. Gallen Consensus Conference [768].

6.10.8 **Symptomatic management in metastatic castration-resistant PCa**

Castration-resistant PCa is usually a debilitating disease, often affecting the elderly male. A multidisciplinary approach is often required with input from urologists, medical oncologists, radiation oncologists, nurses, psychologists and social workers [772]. Critical issues of palliation must be addressed when considering additional systemic treatment, including management of pain, constipation, anorexia, nausea, fatigue and depression, which often occur.

6.10.8.1 **Common complications due to bone metastases**

Most patients with CRPC have painful bone metastases. External beam radiotherapy is highly effective [773],

even as a single fraction [774]. A single infusion of a third generation bisphosphonate could be considered when RT is not available [775]. Common complications due to bone metastases include vertebral collapse or deformity, pathological fractures and spinal cord compression. Cementation can be an effective treatment for painful spinal fracture, whatever its origin, clearly improving both pain and QoL [776]. However, it is still important to offer standard palliative surgery, which can be effective for managing osteoblastic metastases [777, 778]. Impending spinal cord compression is an emergency. It must be recognised early and patients should be educated to recognise the warning signs. Once suspected, high-dose corticosteroids must be given and MRI performed as soon as possible. A systematic neurosurgery consultation should be planned to discuss a possible decompression, followed by EBRT [779]. Otherwise, EBRT, with or without systemic therapy, is the treatment of choice.

6.10.9 Preventing skeletal-related events

6.10.9.1 Bisphosphonates

Zoledronic acid has been evaluated in mCRPC to reduce skeletal-related events (SRE). This study was conducted when no active anticancer treatments but docetaxel were available. 643 patients who had CRPC [780] with bone metastases were randomised to receive zoledronic acid, 4 or 8 mg every three weeks for fifteen consecutive months, or placebo. The 8 mg dose was poorly tolerated and reduced to 4 mg but did not show a significant benefit. However, at fifteen and 24 months of follow-up, patients treated with 4 mg zoledronic acid had fewer skeletal-related events (SREs) compared to the placebo group (44 vs. 33%, $p = 0.021$) and in particular fewer pathological fractures (13.1 vs. 22.1%, $p = 0.015$). Furthermore, the time to first SRE was longer in the zoledronic acid group. No survival benefit has been seen in any prospective trial with bisphosphonates.

6.10.9.2 RANK ligand inhibitors

Denosumab is a fully human monoclonal antibody directed against RANKL (receptor activator of nuclear factor κ B ligand), a key mediator of osteoclast formation, function, and survival. In M0 CRPC, denosumab has been associated with increased bone-metastasis-free survival compared to placebo (median benefit: 4.2 months, HR: 0.85, $p = 0.028$) [779]. This benefit did not translate into a survival difference (43.9 compared to 44.8 months, respectively) and neither the FDA nor the EMA have approved denosumab for this indication [781].

The efficacy and safety of denosumab ($n = 950$) compared with zoledronic acid ($n = 951$) in patients with metastatic CRPC was assessed in a phase III trial. Denosumab was superior to zoledronic acid in delaying or preventing SREs, as shown by time to first on-study SRE (pathological fracture, radiation or surgery to bone, or spinal cord compression) of 20.7 vs. 17.1 months, respectively (HR: 0.82; $p = 0.008$). Both urinary N-telopeptide (NTX) and bone-specific alkaline phosphatase (BAP) were significantly suppressed in the denosumab arm compared with the zoledronic acid arm ($p < 0.0001$ for both). However, these findings were not associated with any survival benefit and in a recent *post-hoc* re-evaluation of endpoints, denosumab showed identical results when comparing skeletal-related events and symptomatic skeletal events [782].

The potential toxicity (e.g., osteonecrosis of the jaw) of these drugs, must always be kept in mind [773, 779]. Patients should have a dental examination before starting therapy as the risk of jaw necrosis is increased by a history of trauma, dental surgery or dental infection [783].

6.10.10 Summary of evidence and guidelines for life-prolonging treatments of castrate-resistant PCa

Summary of evidence	LE
No definitive strategy regarding first treatment choice (which drug/drug family first) can be devised.	4
No clear-cut recommendation can be made for the most effective drug for secondary treatment (i.e. hormone therapy, chemotherapy or radium-223) as no clear predictive factors exist.	3

Recommendations	LE	GR
Ensure that testosterone levels are confirmed to be < 50 ng/mL, before diagnosing castration-resistant PCa (CRPC).	4	A
Do not treat patients for non-metastatic CRPC outside of a clinical trial.	3	A
Counsel, manage and treat patients with metastatic (m)CRPC in a multidisciplinary team.	3	A
Treat patients with mCRPC with life prolonging agents. Base the choice of first line treatment on the performance status, symptoms, comorbidities, location and extent of disease (alphabetical order: abiraterone, docetaxel, enzalutamide, radium-223, sipuleucel-T).	1b	A

6.10.11 **Guidelines for cytotoxic treatment in castrate-resistant PCa**

Recommendations	LE	GR
Counsel, manage and treat patients with metastatic castration-resistant PCa (mCRPC) in a multidisciplinary team.	3	A
Offer patients with mCRPC who are candidates for cytotoxic therapy docetaxel with 75 mg/m ² every three weeks.	1a	A
In patients with mCRPC and progression following docetaxel chemotherapy offer further life-prolonging treatment options, which include cabazitaxel, abiraterone, enzalutamide and radium-223.	1a	A
Base second-line treatment decisions of mCRPC on pre-treatment performance status, comorbidities and extent of disease.		B

6.10.12 **Guidelines for supportive care of castrate-resistant PCa**

These recommendations are in addition to appropriate systemic therapy.

Recommendations	LE	GR
Offer bone protective agents to patients with metastatic castration-resistant PCa (mCRPC) and skeletal metastases to prevent osseous complications.	1a	B
Offer calcium and vitamin D supplementation when prescribing either denosumab or bisphosphonates.	1b	A
Treat painful bone metastases early on with palliative measures such as external beam radiotherapy, and adequate use of analgesics.	1a	B
In patients with spinal cord compression start immediate high-dose corticosteroids and assess for spinal surgery followed by irradiation. Offer radiation therapy alone if surgery is not appropriate.	1b	A

7. FOLLOW-UP

7.1 Follow-up: After local treatment

7.1.1 Definition

Local treatment is defined as RP or RT, either by EBRT or low- or high-dose brachytherapy, or any combination of these. Unestablished alternative treatments, such as HIFU and cryosurgery do not have a well-defined, validated PSA cut-off to define BCF, but do follow the general principles as presented in this section.

7.1.2 Why follow-up?

Recurrence occurs after primary therapy in many patients who have previously received treatment with intent to cure. Reasons for follow-up vary depending on treatment, patient age, comorbidity and the patient's own wishes. Patients who receive curative therapy are followed up to:

- assess immediate- and long-term oncological results, side effects or complications of therapy, functional outcomes and to provide psychological support to PCa survivors;
- discuss the possibility of second-line treatment with curative intent; early HT or WW with the patient.

7.1.3 How to follow-up?

The procedures indicated at follow-up visits vary according to clinical situation. The examinations discussed below are routinely used to detect PCa progression or residual disease. Prostate specific antigen level and DRE are the only tests that should be performed routinely. A disease-specific history is mandatory at every follow-up visit and includes psychological aspects, signs of disease progression, and treatment-related complications. Evaluation of treatment-related complications must be individualised, which is beyond the scope of these Guidelines. The examinations used most often for cancer-related follow-up after curative surgery or RT are discussed below.

7.1.3.1 Prostate-specific antigen monitoring

Measurement of PSA is a cornerstone in follow-up after local treatment. Expectations differ after RP and RT, but PSA recurrence often precedes clinical recurrence [784, 785]. A single, elevated, serum PSA level should

be confirmed before starting second-line therapy based solely on PSA elevation.

7.1.3.2 *Definition of prostate-specific antigen progression*

The PSA level for definition of treatment failure differs between RP and RT. International consensus defines recurrent cancer after RP by two consecutive PSA rises ≥ 0.2 ng/mL [786]. However, others have argued for a higher cut-off of 0.4 ng/mL for patients at high risk of clinical progression [785].

Ultrasensitive PSA assay remains controversial for routine follow-up after RP. Men with a ultrasensitive PSA nadir < 0.01 ng/mL have a 4% likelihood of early biochemical relapse [787]. Detectable post-operative ultrasensitive PSA does not predict BCR in all cases, although it adds prognostic value. In men with ultrasensitive PSA > 0.05 ng/mL, 66.8% remained free of biochemical disease at five years [788]. If survival is improved by early adjuvant treatment after RP (before PSA reaches > 0.2 ng/mL), higher PSA nadir levels may help identify suitable candidates.

At the 2006 RTOG-ASTRO Consensus conference, a new definition of radiation failure was proposed to establish better correlation between definition and clinical outcome, namely, an increase of 2 ng/mL above the post-treatment PSA nadir [621]. It applies to patients with or without HT.

After HIFU or cryotherapy, no endpoints have been validated against clinical progression or survival; therefore, it is not possible to give a firm recommendation of BCF after these alternative local treatments.

7.1.3.3 *Prostate-specific antigen monitoring after radical prostatectomy*

Prostate-specific antigen is expected to be undetectable within six weeks after successful RP [789]. Persistently elevated PSA in patients treated with RP is thought to be due to residual cancer, either micro-metastases or residual pelvic disease.

A rapidly increasing PSA level suggests distant metastases, whereas a later, slowly increasing, level most likely suggests local recurrence. Time to PSA recurrence and tumour differentiation are important predictive factors distinguishing local and systemic recurrence [790]. Local treatment failure and distant metastases occur with undetectable PSA levels. This is rare and occurs mostly in patients with undifferentiated tumours [791].

Thus, in patients with favourable pathology ($< pT3$, $pN0$, Gleason score < 8), PSA measurement and disease-specific history could be a single test in follow-up after RP.

7.1.3.4 *PSA monitoring after radiotherapy*

Prostate-specific antigen level falls slowly after RT compared with RP. A nadir < 0.5 ng/mL is associated with a favourable outcome after RT [792], although the optimal value is controversial. The interval before reaching the nadir can be up to 3 years or more. After RT, PSA-DT is correlated with site of recurrence: patients with local recurrence have a doubling time of thirteen months compared to three months for those with distant failure [793].

7.1.3.5 *Digital rectal examination*

Local recurrence after curative treatment is possible without a concomitant rise in PSA level [791]. However, this has only been proven in patients with unfavourable pathology, namely, undifferentiated tumours. Prostate-specific antigen measurement and DRE comprise the most useful combination for first-line examination in follow-up after RT or RP, but PSA measurement may be the only test in cases with favourable pathology ($< pT3$, $pN0$, Gleason < 8) after RP [794].

7.1.3.6 *Transrectal ultrasound, bone scintigraphy, computed tomography, magnetic resonance imaging, and ^{11}C -choline positron emission tomography computed tomography*

Imaging techniques have no place in routine follow-up of localised PCa. They are only justified in patients with BCF or in patients with symptoms for whom the findings affect treatment decisions. (See Section 6.9.4.5 for a more detailed discussion).

7.1.3.6.1 *Transrectal ultrasonography/magnetic resonance imaging guided biopsy.*

Biopsy of the prostate bed and urethrovesical anastomosis or of the remaining prostate after radiotherapy, are only indicated if local recurrence affects treatment decisions.

7.1.4 **When to follow-up?**

Most patients who fail treatment for PCa do so early, even if failure only becomes clinically obvious after years. Patients should be followed up more closely during the initial post-treatment period when risk of failure is highest. Prostate-specific antigen measurement, disease-specific history and DRE are recommended at three, six and twelve months post-operatively, every six months thereafter until three years, and then annually.

The first post-treatment clinic visit mainly focusses on detecting treatment-related complications

and assist patients in coping with their new situation. Tumour or patient characteristics may allow alterations to this schedule. Patients with poorly differentiated and locally advanced tumours or with positive margins may be followed-up more closely than those with a well-differentiated, intracapsular or specimen-confined tumour. Advanced age or associated comorbidity may make further follow-up in asymptomatic patients superfluous.

7.1.5 **Summary of evidence and guidelines for follow-up after treatment with curative intent**

Summary of evidence	LE
After radical prostatectomy serum prostate-specific antigen (PSA) level > 0.2 ng/mL is associated with residual or recurrent disease.	2a
After radiotherapy, an increase in PSA > 2 ng/mL above the nadir, rather than a specific threshold value, is the most reliable sign of recurrence.	2a
Palpable nodules and increasing serum PSA are signs of local recurrence.	2a

Recommendations	GR
Routinely follow-up asymptomatic patients, by obtaining a disease-specific history and serum prostate-specific antigen (PSA) measurement supplemented by digital rectal examination (DRE). These should be performed at three, six and twelve months after treatment, then every six months until three years, and then annually.	B
Imaging to detect local recurrence is only recommended if it affects treatment planning. Biopsy is usually not necessary before second-line therapy.	B
Do not routinely offer bone scans and other imaging modalities to asymptomatic patients if there are no signs of biochemical relapse. In case patients have bone pain or other symptoms of progression, re-staging should be considered irrespective of serum PSA level.	B

7.2 **Follow-up: During hormonal treatment**

7.2.1 **Introduction**

Follow up must be individualised as BCF might be associated with rapid symptomatic progression or evolve without progression on imaging or symptoms over years.

7.2.2 **Purpose of follow-up**

The main objectives of follow-up in these patients are to ensure treatment compliance, to monitor treatment response and side effects, and to guide the treatment at the time of CRPC.

Complementary investigations must be restricted to those that are clinically helpful to avoid unnecessary examinations and costs. Based on current knowledge, it is not possible to formulate level 1 evidence guidelines for follow-up during HT.

7.2.3 **Methods of follow-up**

7.2.3.1 **Clinical follow-up**

Clinical follow-up is mandatory on a regular basis, and cannot be replaced, neither by laboratory test biology nor imaging modalities. Of utmost importance in metastatic situations is to advise patients about early signs of spinal cord compression, check for occult cord compression, urinary tract complications (ureteral obstruction, bladder outlet obstruction) or bone lesions that are at an increased fracture risk.

7.2.3.1.1 **Prostate-specific antigen monitoring**

Prostate-specific antigen is a key marker for following the course of androgen sensitive PCa. Treatment response may be assessed using the change in serum PSA level as a surrogate endpoint for survival in patients with newly diagnosed metastatic PCa in locally advanced and metastatic PCa [795], as in salvage ADT for relapse following treatments with curative intent [796].

For intermittent ADT Section 6.6.4.3 may be consulted.

A rise in PSA level usually precedes the onset of clinical symptoms by several months. Importantly, taking into account the PSA level alone is insufficient to define progression as clinical progression (usually bone pain) with a stable PSA has been reported.

7.2.3.1.2 **Creatinine, haemoglobin and liver function monitoring**

Creatinine monitoring is good clinical practice as an increase may be linked to bilateral ureteral obstruction or bladder retention. Liver function tests may suggest treatment toxicity (especially NSAA), or rarely disease

progression. A decline in haemoglobin after three months of ADT is independently associated with a shorter progression-free and OS rate [797] and might explain significant fatigue. Alkaline phosphatase may increase secondary to bone metastases and androgen-induced osteoporosis [798]. Therefore, it may be helpful to determine bone-specific isoenzymes as none are directly influenced by HT.

7.2.3.1.3 Bone scan, ultrasound and chest X-ray

Asymptomatic patients with a stable PSA level should not undergo imaging at regular intervals [799]. New symptomatic bone lesions require a bone scan, as well as a PSA progression suggesting CRPC status, if a treatment modification is considered. The Prostate Cancer Clinical Trials Working Group has clarified the definition of bone scan progression as the appearance of at least two new lesions [742], later confirmed.

Suspicion of disease progression indicates the need for additional imaging modalities, guided by symptoms or possible subsequent treatments. In CRPC, imaging must be individualised with the aim of maintaining the patient's QoL.

7.2.3.1.4 Testosterone monitoring

This should be considered part of clinical practice for men on LHRH therapy. Most patients receiving LHRH analogues will achieve castrate serum testosterone levels (< 50 ng/mL). However, approximately 13-38% of patients fail to achieve this goal and up to 24% of men may experience temporary testosterone surges (testosterone > 50 ng/dL) during long-term treatment [525], known as the 'acute on-chronic effect' or 'breakthrough response'.

The timing of measurements is not clearly defined. A three to six-month testosterone level assessment is suggested to ensure castration is achieved and maintained. If not, switching to another agonist or antagonist, or to an orchiectomy should be considered. In patients with rising PSA and/or clinical progression, serum testosterone must be evaluated in all cases to confirm a castrate-resistant state.

7.2.3.1.5 Monitoring of metabolic complications

Androgen deprivation therapy has a greater range of complications than might be expected. The most severe are metabolic syndrome, cardiovascular morbidity and bone problems, (see Section 8.2.4.5). The patient's general practitioner should probably be more involved at this stage.

All patients should be screened for diabetes by checking fasting glucose and HbA1c (at baseline and regularly), as for blood lipid levels. Men with impaired glucose tolerance and/or diabetes should be referred for an endocrine consultation. A cardiology consultation should be considered in men with a history of cardiovascular disease and men older than 65 years prior to starting ADT. Monitoring serum levels of vitamin D and calcium is important (see Section 6.7.2.2.1). It is suggested that routine bone monitoring should be performed every two years during castration [800], or yearly if there are other risk factors [801, 802]. However, there is no high level evidence that this recommendation improves bone complications due to ADT, and prospective trials are needed.

Patients on ADT should be given advice on modifying their lifestyle (e.g. diet, exercise, smoking cessation, etc.) and should be treated for any existing conditions, such as diabetes, hyperlipidaemia, and/or hypertension [797, 798]. Furthermore, the risk-to-benefit ratio of ADT must be considered in patients with a higher risk of cardiovascular complications, especially if it is possible to delay starting ADT.

7.2.4 **When to follow-up**

After the initiation of ADT, it is recommended that patients are followed at three to six months intervals. This must be individualised and each patient should be advised to contact his physician in the event of troublesome symptoms.

7.2.4.1 *Stage M0 - M1 patients*

If there is a good treatment response, i.e. PSA response (< 4 ng/mL), symptomatic improvement, good psychological coping, good treatment compliance, follow-up visits are scheduled every three to six months.

7.2.4.2 *Castration-refractory PCa*

Patients whose disease progresses, or who do not respond according to the criteria mentioned above, warrant an individualised follow-up scheme.

7.2.5 **Guidelines for follow-up during hormonal treatment**

Recommendations	GR
Evaluate patients at three to six months after the initiation of treatment.	A
As a minimum, tests should include serum prostate-specific antigen (PSA) measurement, digital rectal examination (DRE), serum testosterone, and careful evaluation of symptoms in order to assess the treatment response and side effects.	A
In patients undergoing intermittent androgen deprivation, monitor PSA and testosterone at fixed intervals during the treatment pause (monthly or at three-month intervals).	A
Adapt follow-up to the individual patient, according to stage of disease, prior symptoms, prognostic factors and the treatment given.	A
In patients with stage M0 disease with a good treatment response, schedule follow-up every six months. As a minimum requirement, include a disease-specific history, DRE and serum PSA determination in the diagnostic work-up.	A
In patients with stage M1 disease with a good treatment response, schedule follow-up every three to six months. As a minimum requirement, include a disease-specific history, DRE, serum PSA, haemoglobin, serum creatinine and alkaline phosphatase measurements in the diagnostic work-up. The testosterone level should be checked, especially during the first year.	A
Counsel patients (especially with M1b status) about the clinical signs suggestive of spinal cord compression.	A
When disease progression occurs, or if the patient does not respond to treatment, adapt/individualise follow up.	A
In patients with suspected progression, assess the testosterone level. By definition, castration-resistant PCa (CRPC) requires a testosterone level < 50 ng/mL (< 1 mL/L).	B
Do not offer routine imaging to otherwise stable patients.	B

8. QUALITY OF LIFE OUTCOMES IN PROSTATE CANCER

This chapter is presented in two parts. The first will summarise consequences of therapies for PCa. Based on two SRs, the second will evaluate the evidence for adverse effects of treatments over the longer-term (twelve months +) and also make evidence-based recommendations for supportive interventions aimed at improving disease-specific QoL across all stages of disease.

8.1 Introduction

Quality of life and personalised care go hand in hand. Treating prostate cancer can affect an individual both physically and mentally, as well as his close relations and his work or vocation. These multifaceted issues all have a bearing on his perception of 'quality of life' [803]. Approaching care from a holistic point of view requires the intervention of a multi-disciplinary team ranging from urologist, medical oncologist, radiation oncologist, oncology nurse to psychologists and many others. Attention to the psychosocial concerns of men with prostate cancer is integral to quality clinical care, and this includes the needs of carers and partners [762]. Prostate cancer care should not be reduced to focusing on the organ in isolation: side effects or late adverse effects of treatment can manifest systemically and have a major influence on the patient's QoL. Taking QoL into consideration relies on understanding the patient's wishes and preferences so that optimal treatment proposals can be formulated and discussed.

8.2 Adverse effects of prostate cancer therapies

8.2.1 Surgery

Post-operative incontinence and ED are common problems following surgery for PCa. A key consideration is whether these problems are reduced by using newer techniques such as RALP. Recent SRs have documented complication rates after RALP [388, 390-393], and can be compared with contemporaneous reports after RRP [398]. From these reports, the mean continence rates at twelve months were 89-100% for patients treated with RALP and 80-97% for patients treated with RRP. There is, as yet, no evidence from retrospective studies of differences in urinary incontinence at twelve months and there was insufficient evidence to draw conclusions on differences in cancer-related, patient-driven or ED outcomes. The major limitations of the included studies

were the retrospective study design and the use of different assessment tools preventing comparison between techniques and series. Recently, a prospective, controlled, non-randomised trial of patients undergoing RP in fourteen centres using RALP or RRP was published. At twelve months after RALP, 21.3% were incontinent, as were 20.2% after RRP. The adjusted OR was 1.08 (95% CI: 0.87-1.34). Erectile dysfunction was observed in 70.4% after RALP and 74.7% after RRP. The adjusted OR was 0.81 (95% CI: 0.66-0.98) [394]. A recent RCT comparing RALP and RRP, has reported outcomes at twelve weeks in 326 patients [334]. Functional outcomes were similar in the two groups, but longer follow up is needed to report on longer term effects. The intra- and peri-operative complications of retropubic RP and RALP are listed in Table 8.2.1.

Table 8.2.1: Intra- and peri-operative complications of retropubic RP and RALP (Adapted from [388])

Predicted probability of event	RALP (%)	Laparoscopic RP (%)	RRP (%)
Bladder neck contracture	1.0	2.1	4.9
Anastomotic leak	1.0	4.4	3.3
Infection	0.8	1.1	4.8
Organ injury	0.4	2.9	0.8
Ileus	1.1	2.4	0.3
Deep-vein thrombosis	0.6	0.2	1.4
Predicted rates of event	RALP (%)	Laparoscopic RP (%)	RRP (%)
Clavien I	2.1	4.1	4.2
Clavien II	3.9	7.2	17.5
Clavien IIIa	0.5	2.3	1.8
Clavien IIIb	0.9	3.6	2.5
Clavien IVa	0.6	0.8	2.1
Clavien V	< 0.1	0.2	0.2

RALP = robot-assisted laparoscopic prostatectomy; RP = radical prostatectomy; RRP = radical retropubic prostatectomy.

8.2.1.1 Early complications of extended lymph node dissection

Pelvic eLND increases morbidity in the treatment of PCa. Overall complication rates of 19.8% vs. 8.2% were noted for eLND vs. limited LND, respectively, with lymphoceles (10.3% vs. 4.6%) being the most common adverse event. Other authors have reported more acceptable complication rates [804]. Similar rates of lymphoceles have been observed in RALP series, however, in one subgroup analysis, lymphoceles were more common with the extraperitoneal approach (19%) vs. the transperitoneal approach (0%) [805, 806]. Briganti *et al.* [807] also showed more complications after extended compared to limited LND. 20% of men suffer a complication of some sort after eLND. Thromboembolic events occur in less than 1% of cases.

8.2.2 Radiotherapy

8.2.2.1 Side effects of external beam radiotherapy

Retrospective studies suggest that RT affects erectile function to a lesser degree than surgery of patients [808], and this has been borne out by the recent ProtecT study results (see below). A meta-analysis has shown that the one-year probability rates for maintaining erectile function were 0.76 after brachytherapy, 0.60 after brachytherapy + EBRT, 0.55 after EBRT, 0.34 after nerve-sparing RP, and 0.25 after standard RP. When studies with more than two years of follow-up were selected (i.e. excluding brachytherapy), the rates became 0.60, 0.52, 0.25, and 0.25, respectively, with a greater spread between the radiation techniques and surgical approaches [809].

Studies have demonstrated a significantly increased risk of developing secondary malignancies of the rectum and bladder following EBRT [810, 811]. In a retrospective evaluation of 30,552 and 55,263 men, who had undergone either EBRT or RP, the risk of being diagnosed with rectal cancer increased by 1.7-fold in comparison with the surgery group [810]. Another analysis [811] showed that the relative risk of developing bladder cancer increased by 2.34-fold in comparison with a healthy control population. On the other hand, a re-analysis of SEER data including more than 100,000 patients, demonstrated a risk of about 0.16% (i.e. 160 cases per 100,000 patients) of radiation-induced malignant tumours [812]. The Memorial Sloan-Kettering Cancer Center group have also reported corresponding data on late toxicity from their experience in 1,571 patients with T1-T3 disease treated with either 3D-CRT or IMRT at doses of between 66 Gy and 81 Gy, with a median follow-up of ten years [813]. Both acute gastrointestinal and GU toxicity appeared to be predictive for corresponding late toxicity. The overall rate of NCIC/Common Toxicity Criteria (CTC) Grade 2 or more

gastrointestinal toxicity was 5% with IMRT vs. 13% with 3D-CRT. The incidence of Grade 2 or higher late GU toxicity was 20% in patients treated with 81 Gy vs. 12% in patients treated with lower doses. The overall incidences of Grade 3 toxicity were 1% for gastrointestinal toxicity and 3% for GU toxicity. These data suggest that IMRT can successfully protect against late gastrointestinal toxicity. Interestingly, with dose escalation, GU toxicity may become the predominant type of morbidity [813].

8.2.2.2 Side effects from brachytherapy

Some patients experience significant urinary complications following implantation, such as urinary retention (1.5-22%), with post-implantation TURP reported as being required in up to 8.7% of cases, and incontinence (0-19%) [814]. A small RCT has suggested that prophylactic tamsulosin does not reduce the rates of acute urinary retention, but may improve urinary morbidity [815]. This observation requires further study in a larger number of patients. Chronic urinary morbidity can occur in up to 20% of patients, depending on the severity of the symptoms before brachytherapy. Previous TURP for BPH increases the risk of post-implantation incontinence and urinary morbidity. Prevention of morbidity depends on careful patient selection, and expert assessment of IPSS score, backed up by urodynamic studies if needed is key to this.

A small RCT has suggested that using stranded rather than loose seeds is associated with better seed retention and less seed migration, and this should be the standard choice [816].

Table 8.2.2: Acute gastrointestinal and genitourinary complications according to the Radiation Therapy Oncology Group (RTOG)/European Organisation for Research and Treatment of Cancer morbidity scale (adaptations with regard to the original RTOG scale in italics) according to Huang *et al.* [817]*.

	Grade 1	Grade 2	Grade 3	Grade 4
GI	Increased frequency or change in quality of bowel habits not requiring medication. Rectal discomfort not requiring analgesics.	Diarrhoea requiring parasympatholytic drugs. Mucous discharge not necessitating sanitary pads. Rectal or abdominal pain requiring analgesics.	Diarrhoea requiring parenteral support. Severe mucous or blood discharge necessitating sanitary pads. Abdominal distension (flat plate radiograph demonstrates distended bowel loops).	Obstruction, fistula, or perforation GI bleeding requiring transfusion; Abdominal pain or tenesmus requiring tube decompression or bowel diversion.
GU	Frequency of urination or nocturia twice pretreatment habit. Dysuria or urgency not requiring medication.	Frequency of urination is less frequent than every hour (<i>day: 12-16 times; nocturia 5-8 times</i>). Dysuria, urgency, bladder spasm requiring local anaesthetic.	Frequency of urination is more frequent than every hour (<i>day: >16 times; nocturia: > 8 times</i>). Dysuria, bladder spasm, urgency requiring frequent regular narcotic. Gross haematuria <i>complaints requiring permanent or suprapubic catheter.</i>	Haematuria requiring transfusion Obstruction not resulting from Clots. Ulceration Necrosis

*Reproduced with permission of Elsevier, from Budäus L *et al.* *Eur Urol* 2012 Jan;61(2):112-7.

GI = gastrointestinal; GU = genito-urinary.

Table 8.2.3: Late gastrointestinal and genitourinary complications according to the Radiation Therapy Oncology Group (RTOG)/European Organisation for Research and Treatment of Cancer (EORTC) morbidity scale (adaptations with regard to the original RTOG/EORTC scale in italics) according to Huang *et al.* [817]*

	Grade 1	Grade 2	Grade 3	Grade 4
GI*	Mild diarrhoea Mild cramping Bowel movements 2-5 per day Slight rectal discharge or bleeding	Moderate diarrhoea Intermittent, severe cramping. Bowel movements (5 per day). Moderate excessive, rectal discharge. Intermittent, frequent bleeding (3 single laser treatments or transfusion).	Watery diarrhoea Obstruction requiring surgery. Bleeding requiring surgery or 2 laser treatments or transfusions.	Necrosis Perforation Fistula Abdominal pain or tenesmus requiring tube decompression or bowel diversion.
GU	<i>Frequency during day 0.5-1 h Nocturia 2-3/night Slight dysuria or microscopic haematuria requiring no medication Slight epithelial atrophy, minor telangiectasia Bladder capacity > 300 mL</i>	<i>1-2 h Nocturia 4-6/night Moderate dysuria or intermittent (mild, moderate) haematuria requiring medication† Moderate telangiectasia Bladder capacity: 150-300 mL</i>	<i>Frequency during day: 2 h Nocturia 6/night Severe dysuria Frequent (severe) haematuria Severe telangiectasia Bladder capacity: 100-150 mL Benign urethral strictures requiring TURP, dilation, or suprapubic or permanent catheter</i>	<i>Frequency during day: Necrosis Severe haemorrhagic cystitis Bladder capacity > 100 mL</i>

* The difference between grade 1 and grade 2 GI pain, mucosal loss, or bleeding is most easily made when grade 2 is defined as morbidity requiring specific medication: grade 1 = stool softener, diet modification, occasional (< 2/wk) non-narcotic drug, occasional antidiarrhoeal agent (2/wk), occasional use of incontinence pads (1-2 d/wk); grade 2 = regular (>2/wk) use of (non)narcotic drugs for pain, regular (2/wk) antidiarrhoeals, steroid suppositories, one laser.

† With the exception of antibiotics.

*Reproduced with permission of Elsevier, from Budäus L *et al.* *Eur Urol* 2012 Jan;61(2):112-7.

GI = gastrointestinal; GU = genito-urinary; TURP = transurethral resection of the prostate.

8.2.3 Local treatments other than surgery or radiotherapy

8.2.3.1 Cryosurgery

In Ramsay *et al.*'s systematic review and meta-analysis [511], there was evidence that the rate of urinary incontinence at one year was lower for CSAP than for RP, but the size of the difference decreased with longer follow-up. There was no significant difference between CSAP vs. EBRT in terms of urinary incontinence at one year (< 1%), CSAP had a similar ED rate (range 0-40%) to RP at one year. There was insufficient data to compare CSAP vs. EBRT in terms of ED. There was a general trend for CSAP to have fewer procedural complications, apart from urinary retention. The only difference that reached statistical significance was for urethral stricture, which was less frequent after CSAP than after RP. However, the data underlying this comparison are weak and are, of course, not based on a RCT.

8.2.3.2 High-intensity focused ultrasound

In terms of toxicity, there are insufficient data on urinary incontinence, ED or bowel dysfunction to draw any conclusions, although at one year HIFU had lower statistically significant incontinence rates than RP [511]. The safety profile for HIFU was generally good, the commonest reported complications being dysuria (22-30%), acute urinary retention (range 2-24%), urethral sloughing (up to 22%) and UTI (up to 17%). However, HIFU appeared to have a slightly higher incidence of urethral stricture than EBRT which was statistically significant. The quality of the evidence was poor, due to high risks of bias across studies and heterogeneity of outcome definition, measurement and reporting.

The incontinence rates at one year for focal CSAP were very low. Procedural complication rates were generally low, with the commonest complication being acute urinary retention (range 1.2-8.0%).

8.2.4 **Hormonal therapy**

There is a lack of data on the effects of HT on QoL, with only a single, large, prospective, RCT comparing orchiectomy + flutamide or placebo in M1 patients. Combined therapy resulted in a lower QoL in the first six months, with more frequent diarrhoea and worse emotional functioning, compared with castration alone [818]. A small RCT evaluated the HRQoL at one-year follow-up in patients with non-localised PCa, between various ADT regimens, or no treatment. Both sexual and cognitive function significantly declined with ADT, while emotional distress significantly increased in the no treatment patient group [819]. A prospective observational study of non-metastatic PCa, found that immediate ADT was associated with a lower overall QoL compared to deferred treatment [820]. Another retrospective, non-randomised study suggested that men receiving LHRH agonists reported more worry and physical discomfort and poorer overall health, and were less likely to believe themselves free of cancer than orchiectomised patients. The stage at diagnosis had no effect on health outcomes [821].

Using a specific non-validated questionnaire, bicalutamide monotherapy showed a significant advantage over castration in the domains of physical capacity and sexual interest (not sexual function) at twelve months [822]. A *post-hoc* analysis, including only patients with sexual interest suggested that bicalutamide was associated with better sexual preservation, including maintained sexual interest, feeling sexually attractive [823], preserved libido and erectile function [824].

Intermittent androgen deprivation has been discussed elsewhere (see Section 6.6 - Metastatic PCa - Hormonal therapy).

8.2.4.1 *Sexual function*

Loss of libido and ED are common. The management of acquired ED is mostly non-specific [825].

8.2.4.2 *Hot flushes*

Hot flushes are the most common side-effect of ADT. They appear three months after starting ADT, usually persist long-term and have a significant impact on QoL.

Oestrogen-receptor modulators or low-dose oestrogen therapies, e.g. DES, 0.5-1 mg/day, reduce the frequency and severity of hot flushes. Both treatments carry a risk of cardiovascular complications. Soy phytoestrogens have shown an efficacy in breast cancer patients, but have not been evaluated in men. Progesterone-based treatments have demonstrated efficacy with 80% of patients showing an improvement [826].

Serotonin re-uptake inhibitors (e.g. venlafaxine or sertraline) appear to be effective in men, but less than HT based on a prospective randomised trial comparing venlafaxine, 75 mg daily, with medroxyprogesterone, 20 mg daily, or CPA, 100 mg daily [827]. After six months of LHRH (n = 919), 311 men had significant hot flushes and were randomised to one of the treatments. Venlafaxine was clearly inferior compared to the hormonal agents, which showed similar efficacy to each other.

With a placebo effect influencing up to 30% of patients [828], the efficacy of clonidine, veralipride, gabapentine [829] and acupuncture [830] must be compared in prospective RCTs.

8.2.4.3 *Other systemic side-effects of androgen-deprivation therapy*

Androgen-deprivation therapy is associated with significant side effects which may lead to significantly increased morbidity or even mortality.

8.2.4.4 *Non-metastatic bone fractures*

Due to increased bone turnover and decreased BMD in a time-dependent manner, ADT use is linked to an increased risk of fracture (up to 45% relative risk with long-term ADT) [831]. Hip fractures in men are associated with a significant risk of death [832]. A precise evaluation of BMD should be performed by dual emission X-ray absorptiometry (DEXA) before starting long-term ADT. An initial low BMD (T-score < -2.5 or < -1, with other risk factors) indicates a high risk of subsequent non-metastatic fracture. The WHO FRAX tool (<http://www.shef.ac.uk/FRAX>) should be used to evaluate individual risk. Obesity (increase in body fat mass by up to 10%) and sarcopenia (decrease in lean tissue mass by up to 3%) are common and occur during the first year of ADT [833]. Both changes increase the fracture risk.

8.2.4.4.1 *Lifestyle changes before starting long-term androgen-deprivation therapy*

Patients should be encouraged to adopt lifestyle changes, e.g. increased physical activity, cessation of smoking, decreased alcohol consumption, and to normalise their BMI. Calcium and vitamin D supplements

should be considered if low values are detected (normal values: calcium: 2.2-2.6 nmol/L, vitamin D: 100-160 nmol/L). A daily intake of at least 1,200 mg/day of calcium and 1,000 UI of vitamin D is useful.

8.2.4.4.2 Hormonal treatment modalities

Bicalutamide monotherapy could be a bone-protective treatment [834, 835], but is limited by its suboptimal efficacy (see Section 6.6 - Metastatic PCa - Hormonal Therapy). The intermittent modality might be associated with less bone impact [565].

8.2.4.4.3 Bisphosphonates

Bisphosphonates increase BMD in the hip and spine by up to 7% in 1 year. The optimal regimen for zoledronic acid remains unclear: quarterly [836] or yearly [837] injections. The question is relevant as the risk of jaw necrosis is both dose- and time-related [838]. A quarterly regimen could be considered for a BMD \leq 2.5 as a yearly injection is unlikely to provide sufficient protection [839].

In contrast to breast cancer, a significant benefit in OS has only been demonstrated in PCa in a *post-hoc* analysis for the oral first-generation clodronate with an absolute 8% OS increase after eight years of follow-up [840]. This benefit has never been observed with more recent bisphosphonates.

Denosumab (a fully human monoclonal antibody against receptor activator of NF- κ B ligand [RANKL])

In M0 patients, denosumab has been shown to increase the lumbar BMD by 5.6% compared to a 1% decrease in the placebo arm after two years, using a 60 mg subcutaneous regimen every six months [841]. This was associated with a significant decrease in vertebral fracture risk (1.5% vs. 3.9%, $p = 0.006$). The benefits were similar whatever the age ($<$ or $>$ 70 years), the duration or type of ADT, the initial BMD, the patient's weight or the initial BMI. This benefit was not associated with any significant toxicity, e.g. jaw osteonecrosis or delayed healing in vertebral fractures. In M0 patients, with the use of a higher dosage (120 mg every four weeks), a delay in bone metastases of 4.2 months has been shown [782] without any impact on OS, but with an increase in side effects. Therefore, this later regimen cannot be recommended.

8.2.4.5 Metabolic effects

Lipid alterations are common and may occur as early as the first 3 months of treatment [833]. ADT also decreases insulin sensitivity and increases fasting plasma insulin levels, which is a marker of insulin resistance. Once again, exercise is strongly recommended for its protective effect. In diabetic patients, metformin appears to be an attractive option for protection against metabolic effects based on retrospective analysis [842], but there is insufficient data to recommend its use in non-diabetic patients.

Metabolic syndrome is an association of independent cardiovascular disease risk factors, often associated with insulin resistance. The definition requires at least three of the following criteria [843]:

- waist circumference $>$ 102 cm;
- serum triglyceride $>$ 1.7 mmol/L;
- blood pressure $>$ 130/80 mmHg or use of medication for hypertension;
- high-density lipoprotein (HDL) cholesterol $<$ 1 mmol/L;
- glycaemia $>$ 5.6 mmol/L or the use of medication for hyperglycaemia.

The prevalence of a metabolic-like syndrome is higher during ADT compared with men not receiving ADT [844].

8.2.4.6 Cardiovascular morbidity

Cardiovascular mortality is now the most common cause of death in PCa patients, even exceeding PCa mortality [845]. Several studies showed that ADT, after only six months, was associated with an increased risk of diabetes mellitus, cardiovascular disease, and myocardial infarction [846]. The RTOG 92-02 [847] and 94-08 [415] trials confirmed an increased cardiovascular risk, unrelated to the duration of ADT and not accompanied by an overall increased cardiovascular mortality. No increase in cardiovascular mortality has been reported in a systematic meta-analysis of trials RTOG 8531, 8610, 9202, EORTC 30891 or EORTC 22863 [848]. However, an increase in cardiovascular mortality has been reported in patients suffering from previous congestive heart failure or myocardial infarction in a retrospective database analysis [849] or presenting with a metabolic syndrome [850].

It has been suggested that LHRH antagonists might be associated with less cardiovascular morbidity compared to agonists [851]. However, the methodology used in these studies does not provide convincing evidence to show a clear superiority of these compounds.

These data resulted in an FDA warning and consensus paper from the American Heart, Cancer Society and Urological Associations [689]. Preventive advice includes non-specific measures such as loss of

weight, increased exercise, improved nutrition and smoking cessation.

8.2.4.7 Fatigue

Fatigue often develops as a side-effect of ADT. Regular exercise appears to be the best protective measure [852, 853], with prolonged efficacy [854] and improved specific survival [855].

Anaemia may be a cause of fatigue. Anaemia requires an etiological diagnosis (medullar invasion, mainly inflammatory, renal insufficiency, iron deficiency, chronic bleeding) and individualised treatment. Iron supplementation (using injectable formulations only) must be systematic if deficiency is observed. Regular blood transfusions are required if severe anaemia is present. Erythropoiesis-stimulating agents might be considered in dedicated cases, taking into account the possible increased risk of thrombovascular events [856].

8.2.4.8 neurological side effects

Castration seems also to be associated with an increased risk of stroke [857], and is suspect to be associated with an increased risk for depression and cognitive decline such as Alzheimer disease [858].

8.3 Overall quality of life in men with prostate cancer

Living longer with prostate cancer, does not necessarily equate to living well [803, 762]. There is clear evidence of unmet needs and ongoing support requirements for some men after diagnosis and treatment for prostate cancer [859]. Radical treatment for prostate cancer can negatively impact long-term QoL (e.g. sexual, urinary and bowel dysfunction), as can ADT used in short or long-term treatment e.g. loss of muscle mass, sexual problems, fatigue, psychological morbidity, adverse metabolic sequelae increased cardiovascular and bone fracture risk [860, 861]. Direct symptoms from advanced or metastatic cancer e.g. pain, hypercalcaemia, spinal cord compression, pathological fractures, also adversely affect health [862, 863]. Men's QoL including domains such as sexual function, urinary function and bowel function is worse after treatment for PCa compared to non-cancer controls [864, 865].

The concept of 'quality of life' is subjective and can mean different things to different men, but there are some generally common features across virtually all patients. Drawing from these common features, specific tools or 'patient reported outcome measures' (PROMs) have been developed and validated for men with prostate cancer. These questionnaires assess common issues that affect men after prostate cancer diagnosis and treatment and generate scores which reflect the impact on perceptions of HRQoL. During the process of undertaking two dedicated SRs around cancer-specific QoL outcomes in men with PCa as the foundation for our guideline recommendations, the following validated PROMs were found in our searches (see Table 8.3.1).

Table 8.3.1: PROMs assessing cancer specific quality of life

Questionnaire	Domains / items
Functional Assessment of Cancer Therapy-General (FACT-G) [866]	Physical well-being, Social/family well-being, Emotional well-being, and Functional well-being.
Functional Assessment of Cancer Therapy-Prostate (FACT-P) [867]	12 cancer site specific items to assess for prostate related symptoms. Can be combined with FACT-G or reported separately.
European Organisation for Research and Treatment of Cancer QLQ-C30 (EORTC QLQ-C30) [868]	Five functional scales (physical, role, cognitive, emotional, and social); Three symptom scales (fatigue, pain, and nausea and vomiting); Global health status / QoL scale; and a number of single items assessing additional symptoms commonly reported by cancer patients (dyspnoea, loss of appetite, insomnia, constipation and diarrhoea) and perceived financial impact of the disease.
European Organisation for Research and Treatment of Cancer QLQ-PR 25 (EORTC QLQ-PR 25) [869]	Urinary, bowel and treatment-related symptoms, as well as sexual activity and sexual function.
Expanded prostate cancer index composite (EPIC) [870]	Urinary, bowel, sexual, and hormonal symptoms.
Expanded prostate cancer index composite short form 26 (EPIC 26) [871]	Urinary, sexual, bowel, and hormonal domains.
UCLA Prostate Cancer Index (UCLA PCI) [872]	Urinary, bowel, and sexual domains.

Prostate Cancer Quality of Life Instrument (PCQoL) [873]	Urinary, sexual, and bowel domains, supplemented by a scale assessing anxiety.
Prostate Cancer Outcome Study Instrument [874]	Urinary, bowel, and sexual domains.

8.3.1 Long-term (≥ 12 months) quality of life outcomes in men with localised disease.

Men undergoing local treatments

Recently the results of the Prostate Testing for Cancer and Treatment (ProtecT) trial ($n = 1,643$ men) were published [875]. The study reported no difference in EORTC QLQ-C30 assessed global QoL, up to five years of follow-up in men aged 50-69 years with T1-T2 disease randomised for treatment with AM, RP or RT [875]. However, EPIC urinary summary scores (at 6 years) were worse in men treated with RP compared to AM or RT (88.7 vs. 89.0 vs. 91.4, respectively) as were urinary incontinence (80.9 vs. 85.8 vs. 89.4, respectively) and sexual summary, function and bother scores (32.3 vs. 40.6 vs. 41.3 for sexual summary, 23.7 vs. 32.5 vs. 32.7 for sexual function and 51.4 vs. 57.9 vs. 60.1 for sexual bother, respectively) at six years of follow-up. Minimal clinically important differences for the 50 item EPIC questionnaire are not to our knowledge available. For men receiving RT, EPIC bowel scores were poorer compared to AM and RP in all domains: function (90.8 vs. 92.3 vs. 92.3, respectively), bother (91.7 vs. 94.2 vs. 93.7, respectively) and summary (91.2 vs. 93.2 vs. 93.0, respectively) at six years of follow-up in the ProtecT trial.

The findings regarding RP and RT are supported by other observational studies, the most important being The Prostate Cancer Outcomes Study (PCOS) [876] that studied a cohort of 1,655 men, of whom 1,164 had undergone RP and 491 RT. The study reported that at five years of follow-up, men who underwent RP had a higher prevalence of urinary incontinence and ED, while men treated with RT had a higher prevalence of bowel dysfunction. However, despite these differences detected at five years, there were no significant differences in the adjusted odds of urinary incontinence, bowel dysfunction or ED between RP and RT at fifteen years.

With respect to brachytherapy cancer-specific QoL outcomes, the best available evidence come from one small RCT ($n = 200$) evaluating bilateral nerve sparing RP and brachytherapy in men with localised disease (up to T2a), which reported worsening of physical functioning as well as irritative urinary symptomatology in 20% of brachytherapy patients at one year of follow-up. However, there were no significant differences in EORTC-QLQ-C30/PR-25 scores at five years of follow-up when comparing to pre-treatment values [877]. It should be noted of this trial within group tests only were reported.

Recommendations	LE	GR
Advise eligible patients for active surveillance, that global quality of life is equivalent for up to five years compared to radical prostatectomy or radiotherapy.	1b	A
Discuss the negative impact of surgery on urinary and sexual function, as well as the negative impact of radiotherapy on bowel function with patients.	1b	A
Advise patients treated with brachytherapy of the negative impact on irritative urinary symptomatology at one year but not after five years.	1b	C

8.3.2 Improving quality of life in men who have been diagnosed with prostate cancer

Men undergoing local treatments

In men with localised disease, nurse led multi-disciplinary rehabilitation (addressing sexual functioning, cancer worry, dyadic adjustment, depression, managing bowel and urinary function problems) provided positive short-term effects (four months) on sexual function (effect size 0.45) and long-term (twelve months) positive effects on sexual limitation (effect size 0.5) and cancer worry (effect size 0.51) [878].

The use of PDE5 inhibitors in penile rehabilitation has been subject to some debate. A single centre, double blind RCT of 100 men undergoing nerve-sparing surgery reported no benefit of nightly sildenafil (50 mg) compared to on-demand use [405]. However, a multi-centre double blind RCT ($n = 423$) in men aged < 68 years, with normal pre-treatment erectile function undergoing either open, conventional or robot assisted laparoscopic nerve-sparing RP, Tadalafil (5 mg) once per day improved participants EPIC sexual domain-scores (least squares mean difference +9.6; 95% CI: 3.1-16.0) when compared to 20 mg 'on demand' or placebo at nine months of follow-up [406]. Therefore, based on discordant results, no clear recommendation is possible, even if a trend exists for early use of PDE5 inhibitors after RP for penile rehabilitation. A detailed discussion can be found in the EAU Male Sexual Dysfunction Guidelines [879].

Men undergoing systemic treatments

Similar to men treated with a radical approach (see above) men with T1-T3 disease undergoing RT and ADT a combined nurse led psychological support and physiotherapist led multi-disciplinary rehabilitation has reported

improvements in QoL. Specifically this intervention involved action planning around patients' needs related to lifestyle changes, weight control, toilet habits, sexuality, and psychological problems. This was complemented with pelvic floor muscle therapy. Improvements in urinary (adjusted mean 4.5: 95% CI 0.6-8.4), irritative (adjusted mean 5.8: 95% CI: 1.4-10.3) and hormonal (adjusted mean 4.8: 95% CI: 0.8-8.8) EPIC domains were found up to 22 weeks of follow-up [880].

Providing supervised aerobic and resistance exercise training of a moderate intensity improves EORTC QLQ-C30 role (adjusted mean 15.8: 95% CI: 6.6-24.9) and cognitive domain outcomes (adjusted mean 11.4: 95% CI: 3.3-19.6) as well as symptom scales for fatigue (adjusted mean -11.0: 95% CI: -20.2,-1.7), nausea (adjusted mean -4.0: 95% CI: -7.4,-0.25), and dyspnoea (adjusted mean -12.4: 95% CI: -22.5,-2.3) up to three months in men treated with ADT [852]. Such interventions have also reported clinically relevant improvements in FACT-P (mean difference 8.9: 95% CI: 3.7-14.2) in men on long-term ADT [881, 882]. These findings are supported by a recent SR which reported improvements up to twelve weeks in cancer-specific QoL in a meta-analysis of high quality trials (SMD 0.33: 95% CI: 0.08-0.58) [883].

Recommendations	LE	GR
Offer men on androgen deprivation therapy, twelve weeks of supervised (by trained exercise specialists) combined aerobic and resistance exercise.	1a	A
Offer men with T1-T3 disease specialist nurse led, multi-disciplinary rehabilitation based on the patients' personal goals addressing incontinence, sexuality, depression and fear of recurrence, social support and positive lifestyle changes after any radical treatment.	1b	A

10. CONFLICT OF INTEREST

All members of the EAU - ESTRO – ESUR – SIOG Prostate Cancer Guidelines working panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website: <http://www.uroweb.org/guidelines/>.

This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

TABLE OF CONTENTS	PAGE
1. INTRODUCTION	5
1.1 Aims and scope	5
1.2 Panel composition	5
1.3 Available publications	5
1.4 Publication history and summary of changes	5
1.4.1 Publication history	5
1.4.2 Summary of changes	5
2. METHODS	7
2.1 Data identification	7
2.2 Review	8
2.3 Future goals	8
3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY	9
3.1 Epidemiology	9
3.1.1 Summary of evidence and recommendation	9
3.2 Histological diagnosis	9
3.2.1 Clear cell renal cell cancer	9
3.2.2 Papillary renal cell cancer	10
3.2.3 Chromophobe (chRCC)	10
3.3 Other renal tumours	10
3.3.1 Carcinoma associated with end-stage renal disease; acquired cystic disease-associated RCC	10
3.3.2 Papillary adenoma	10
3.3.3 Hereditary kidney tumours	10
3.3.4 Angiomyolipoma	11
3.3.4.1 Treatment	11
3.3.4.2 Summary	13
3.4 Summary of evidence and recommendations for the management of other renal tumours	13
4. STAGING AND CLASSIFICATION SYSTEMS	13
4.1 Staging	13
4.2 Anatomic classification systems	14
5. DIAGNOSTIC EVALUATION	15
5.1 Symptoms	15
5.1.1 Physical examination	15
5.1.2 Laboratory findings	15
5.2 Imaging investigations	15
5.2.1 Presence of enhancement	15
5.2.2 Computed tomography or magnetic resonance imaging	15
5.2.3 Other investigations	16
5.2.4 Radiographic investigations to evaluate RCC metastases	16
5.2.5 Bosniak classification of renal cystic masses	16
5.3 Renal tumour biopsy	16
5.4 Summary of evidence and recommendations for the diagnostic assessment of renal cell cancer	17
6. PROGNOSTIC FACTORS	18
6.1 Classification	18
6.2 Anatomical factors	18
6.3 Histological factors	18
6.4 Clinical factors	19
6.5 Molecular factors	19
6.6 Prognostic systems and nomograms	20
6.7 Summary of evidence and recommendations for prognostic factors	20

7.	DISEASE MANAGEMENT	22
7.1	Treatment of localised RCC	22
7.1.1	Introduction	22
7.1.2	Surgical treatment	22
7.1.2.1	Nephron-sparing surgery vs. radical nephrectomy	22
7.1.2.2	Associated procedures	23
7.1.2.2.1	Adrenalectomy	23
7.1.2.2.2	Lymph node dissection for clinically negative lymph nodes (cN0)	23
7.1.2.2.3	Embolisation	23
7.1.2.2.4	Summary of evidence and recommendations	24
7.1.3	Radical and partial nephrectomy techniques	24
7.1.3.1	Radical nephrectomy techniques	24
7.1.3.2	Partial nephrectomy techniques	24
7.1.3.3	Positive margins on histopathological specimens of resected tumours	25
7.1.3.4	Summary of evidence and recommendations	25
7.1.4	Therapeutic approaches as alternatives to surgery	26
7.1.4.1	Surgical versus non-surgical treatment	26
7.1.4.2	Surveillance	26
7.1.4.3	Ablative therapies	26
7.1.4.3.1	Cryoablation	26
7.1.4.3.2	Cryoablation versus partial nephrectomy	26
7.1.4.3.3	Radiofrequency ablation	27
7.1.4.3.4	Radiofrequency ablation versus partial nephrectomy	27
7.1.4.3.5	Cryoablation versus radiofrequency ablation	27
7.1.4.3.6	Other ablative techniques	27
7.1.4.3.7	Summary of evidence and recommendation for therapeutic approaches as alternative to surgery	27
7.2	Treatment of locally advanced RCC	28
7.2.1	Introduction	28
7.2.2	Management of clinically positive lymph nodes (cN+)	28
7.2.3	Management of locally advanced unresectable RCC	28
7.2.4	Management of RCC with venous tumour thrombus	28
7.2.4.1	The evidence base for surgery in patients with venous tumour thrombus	28
7.2.4.2	The evidence base for different surgical strategies	28
7.2.4.3	Summary of evidence and recommendations for the management of RCC with venous tumour thrombus	28
7.2.5	Adjuvant therapy	29
7.2.5.1	Summary of evidence and recommendations for adjuvant therapy	29
7.3	Advanced/metastatic RCC	29
7.3.1	Local therapy of advanced/metastatic RCC	29
7.3.1.1	Cytoreductive nephrectomy	29
7.3.1.1.1	Embolisation of the primary tumour	29
7.3.1.1.2	Summary of evidence and recommendation for local therapy of advanced/metastatic RCC	30
7.3.2	Local therapy of metastases in mRCC	30
7.3.2.1	Complete versus no/incomplete metastasectomy	30
7.3.2.2	Local therapies for RCC bone metastases	30
7.3.2.3	Local therapies for RCC brain metastases	30
7.3.2.4	Embolisation of metastases	31
7.3.2.5	Summary of evidence and recommendations for local therapy of metastases in metastatic RCC	31
7.4	Systemic therapy for advanced/metastatic RCC	31
7.4.1	Chemotherapy	31
7.4.1.1	Summary of evidence and recommendation for systemic therapy for advanced/metastatic renal cell cancer	31
7.4.2	Immunotherapy	32
7.4.2.1	IFN- α monotherapy and combined with bevacizumab	32

7.4.2.2	Interleukin-2	32
7.4.2.3	Vaccines and targeted immunotherapy	32
7.4.2.4	Immune checkpoint blockade	32
7.4.2.5	Summary of evidence and recommendations for immunotherapy in mRCC	33
7.4.3	Targeted therapies	33
7.4.3.1	Tyrosine kinase inhibitors	34
7.4.3.1.1	Sorafenib	34
7.4.3.1.2	Sunitinib	34
7.4.3.1.3	Pazopanib	34
7.4.3.1.4	Axitinib	34
7.4.3.1.5	Cabozantinib	35
7.4.3.1.6	Lenvatinib	35
7.4.4	Monoclonal antibody against circulating VEGF	35
7.4.4.1	Bevacizumab monotherapy and bevacizumab + IFN- α	35
7.4.5	mTOR inhibitors	35
7.4.5.1	Temsirolimus	35
7.4.5.2	Everolimus	35
7.4.6	Therapeutic strategies	36
7.4.6.1	Therapy for treatment-naïve patients with clear-cell mRCC	36
7.4.6.1.1	Sequencing targeted therapy	36
7.4.6.1.1.1	Following progression of disease with one or more lines of VEGF-targeted therapy	36
7.4.6.1.1.2	Treatment after progression of disease with mTOR inhibition	36
7.4.6.1.1.3	Treatment after progression of disease with cytokines	36
7.4.6.1.1.4	Treatment after second-line targeted therapy	36
7.4.6.1.1.4.1	Treatment after two VEGF-targeted therapies	36
7.4.6.1.1.4.2	Treatment after VEGFR- and mTOR inhibition	37
7.4.6.1.1.4.3	Combination of targeted agents	37
7.4.6.2	Non-clear-cell renal cancer	37
7.4.6.3	Summary of evidence and recommendations for systemic therapy in metastatic renal cell cancer	39
7.5	Recurrent RCC	40
7.5.1	Introduction	40
7.5.2	Summary of evidence and recommendation for advanced/metastatic RCC	40
8.	FOLLOW-UP IN RCC	41
8.1	Introduction	41
8.2	Which investigations for which patients, and when?	41
8.3	Summary of evidence and recommendations for surveillance following RN or PN or ablative therapies in RCC	42
8.4	Research priorities	42
9.	REFERENCES	43
10.	CONFLICT OF INTEREST	66

1. INTRODUCTION

1.1 Aims and scope

The European Association of Urology (EAU) Renal Cell Cancer (RCC) Guidelines Panel has compiled these clinical guidelines to provide urologists with evidence-based information and recommendations for the management of RCC.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise and judgement when making treatment decisions for individual patients, but rather help to focus decisions whilst also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The RCC Guidelines Panel is an international group of clinicians consisting of urological surgeons, oncologists, methodologists, a pathologist and a radiologist, with particular expertise in the field of renal cancer care. Since 2015, the panel has incorporated a patient advocate to provide a consumer perspective for its guidelines.

All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU website Uroweb: <http://uroweb.org/guideline/renal-cell-carcinoma/>.

Acknowledgement

The RCC Guidelines Panel is most grateful for the methodological and scientific support provided by Prof. Dr. O. Hes (pathologist, Pilzen, Czech Republic) for two sections of this document: Histological diagnosis and Other renal tumours.

1.3 Available publications

A quick reference document (Pocket Guidelines) is available, both in print and in a number of versions for mobile devices, presenting the main findings of the RCC Guidelines. These are abridged versions which may require consultation together with the full text version. Several scientific publications are available, as are a number of translations of all versions of the EAU RCC Guidelines [1, 2]. All documents can be accessed on the EAU website: <http://uroweb.org/guideline/renal-cell-carcinoma/>.

1.4 Publication history and summary of changes

1.4.1 Publication history

The EAU RCC Guidelines were first published in 2000. This 2017 RCC Guidelines document presents a limited update of the 2016 publication.

1.4.2 Summary of changes

All chapters of the 2017 RCC Guidelines have been updated, based on the 2016 version of the guideline. References have been added throughout the document.

Key changes in this 2017 print:

- Section 3.3.3 - Hereditary kidney tumours: This section has been expanded
- Section 5.2 - Imaging evaluations: The findings of a systematic review have been incorporated.

New data and recommendations have been included in the following sections:

5.4 Summary of evidence and recommendations for the diagnostic assessment of renal cell cancer

Summary of evidence	LE
Contrast enhanced multi-phasic CT has a high sensitivity and specificity for characterisation and detection of RCC, invasion, tumour thrombus and metastatic RCC.	2
MRI has a slightly higher sensitivity and specificity for small renal masses and tumour thrombus as compared to CT.	2
CEUS has a high sensitivity and specificity for characterisation of renal masses.	2
US, Power-Doppler US and PET-CT have a low sensitivity and specificity for detection and characterisation of RCC.	2

Recommendations	grade	
Use multi-phasic contrast-enhanced computed tomography (CT) for general staging and detection of renal cell cancer (RCC).	strong	↑↑
Use axial abdominal imaging and CT of the chest for staging of RCC.	strong	↑↑
Use non-ionising modalities, mainly contrast enhanced ultrasound (CEUS), for further characterisation of small renal masses, tumour thrombus and differentiation of unclear renal masses.	weak	↑
Do not use bone scan and/or positron-emission tomography (PET)-CT for staging of RCC.	weak	↓
Perform a renal tumour biopsy before ablative therapy and systemic therapy without previous pathology.	strong	↑↑
Perform a percutaneous biopsy in select patients who are considered for active surveillance.	weak	↑
When performing a renal tumour biopsy technique, use a coaxial technique.	strong	↑↑
Do not perform a renal tumour biopsy of cystic renal masses.	weak	↓

7.2.5.1 Summary of evidence and recommendations for adjuvant therapy

Summary of evidence	LE
Adjuvant cytokines do not improve survival after nephrectomy.	1b
Adjuvant sunitinib improved disease-free survival in one of the two available studies, but not overall survival, after nephrectomy in selected high-risk patients.	1b

Recommendations	grade	
Do not offer adjuvant therapy with sorafenib.	strong	↓↓
Do not offer adjuvant sunitinib following surgically resected high-risk clear-cell renal cell cancer.	weak	↓

7.3.2.5 Recommendations for local therapy of metastases in metastatic RCC

Recommendation	grade	
Consider local therapy for metastatic disease (including metastasectomy) in patients with a favourable risk profile in whom complete resection is achievable or when local symptoms need to be controlled.	weak	↑

7.4.1.1 Summary of evidence and recommendation for systemic therapy for advanced/metastatic renal cell cancer

Summary of evidence	LE
In metastatic RCC, 5-FU combined with immunotherapy has equivalent efficacy to INF- α .	1b
In metastatic RCC, chemotherapy is otherwise not effective with the exception of gemcitabine and doxorubicin in sarcomatoid and rapidly progressive disease.	3

Recommendations	grade	
Do not offer chemotherapy as first-line therapy in patients with metastatic clear-cell renal cell cancer (RCC).	strong	↓↓
Consider offering a combination of gemcitabine and doxorubicin to patients with sarcomatoid or rapidly progressive RCC.	weak	↑

7.4.6.3 Summary of evidence and recommendations for systemic therapy in metastatic renal cell cancer

Summary of evidence	LE
First line pazopanib is not inferior to sunitinib in clear-cell mRCC patients.	1b
Cabozantinib is superior to everolimus in terms of PFS and OS in patients failing one or more lines of VEGF-targeted therapy.	1b
Everolimus prolongs PFS in patients who have previously failed or are intolerant of VEGF-targeted therapy when compared to placebo.	1b
No combination has proven to be better than single-agent therapy, with the exception of the combination of lenvatinib plus everolimus.	1a

Recommendations	grade	
Offer sunitinib or pazopanib as first-line therapy for metastatic clear-cell renal cell cancer (ccRCC).	strong	↑↑
Consider offering bevacizumab + Interferon (IFN)-α as first-line therapy for metastatic RCC in favourable-risk and intermediate-risk ccRCC.	weak	↑
Consider offering temsirolimus as first-line treatment in poor-risk RCC patients.	weak	↑
Offer cabozantinib for ccRCC after one or two lines of vascular endothelial growth factor (VEGF)-targeted therapy in metastatic RCC.	strong	↑↑
Sunitinib can be offered as first-line therapy for non-clear cell mRCC.	weak	↑

2. METHODS

2.1 Data identification

For the 2017 Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature for the chapters as listed in Table 2.1.

A broad and comprehensive scoping exercise was performed. The search was limited to studies representing high levels of evidence (i.e. systematic reviews [SRs] with meta-analysis [MA], randomised controlled trials (RCTs), and prospective non-randomised comparative studies only) published in the English language. The search was restricted to articles published between July 30th 2015 and June 30th 2016. Databases covered included Medline, EMBASE, and the Cochrane Library. A total of 1,602 unique records were identified, retrieved and screened for relevance. A search strategy is published online: <https://uroweb.org/guideline/renal-cell-carcinoma/?type=appendices-publications>.

Specific chapters were updated by way of SRs, commissioned and undertaken by the panel in conjunction with the EAU Guidelines Office, based on topics or questions prioritised by the Guidelines Panel. These reviews were performed using standard Cochrane SR methodology <http://www.cochranelibrary.com/about/about-cochrane-systematic-reviews.html>.

A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.

The EAU Guidelines Office are in the process of introducing modified GRADE methodology across all 20 guidelines [3, 4]. This will be a phased introduction, with the RCC Guidelines Panel already incorporating these changes in their 2017 Guidelines print.

The Summary of Evidence (SOE) tables provided for each recommendation within the guidelines address a number of key elements:

1. the overall quality of the evidence which exists for the recommendation;
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength of each recommendation. The strength of each recommendation is represented by the words 'strong' or 'weak' and is directional, either 'do it' (as represented by arrows pointing upwards) or 'do not do it' (arrows pointing downwards) [5]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences. The SOE tables will be posted online for consultation.

Table 2.1: Description of update and summary of review methodology

Chapter	Brief description of review methodology
1. Introduction	Not applicable
2. Methods	Not applicable
3. Epidemiology, aetiology and pathology	This chapter was updated by a traditional narrative review, based on a structured literature assessment.
4. Staging and grading classification systems	This chapter was updated by a traditional narrative review, based on a structured literature assessment.
5. Diagnostic evaluation	Section 5.2 (Diagnostic imaging) was revised based on a SR [6]. The remainder of the chapter was updated by a structured literature assessment.
6. Prognosis	This chapter was updated by a traditional narrative review, based on a structured literature assessment.
7. Treatment (Disease management)	Chapters 7.1.2 and 7.2.4 (Treatment of localised and locally advanced disease) were revised based on an updated SR. The remainder of the chapter was updated using a structured literature assessment. Systemic therapy for metastatic disease: this section was updated by a SR.
8. Surveillance following radical or partial nephrectomy or ablative therapies	This chapter was updated by a traditional narrative review, based on a structured literature assessment.

The findings of a number of SR topics have been incorporated in this 2017 update:

- Imaging in Suspected Renal Cell Carcinoma: A Systematic Review [6]
- What is the best surgical treatment option for clinical > T2, N0M0 tumours? What is the best way of performing this procedure? [7];
- A Systematic Review and Meta-analysis Comparing the Effectiveness and Adverse Effects of Different Systemic Treatments for Non-clear Cell Renal Cell Carcinoma [8].

2.2 Review

Chapter 7 'Disease management' was peer reviewed prior to publication. Publications ensuing from SRs have all been peer reviewed. The other sections of the RCC Guidelines were peer reviewed prior to publication in 2015.

2.3 Future goals

For their future updates, the RCC Guideline Panel aims to focus on patient-reported outcomes.

The use of clinical quality indicators is an area of interest for the RCC Panel. A number of key quality indicators for this patient group have been selected:

- thorax computed tomography (CT) for staging of pulmonary metastasis;
- proportion of patients with T1aN0M0 tumours undergoing nephron-sparing surgery as first treatment;
- the proportion of patients treated within six weeks after diagnosis;
- the proportion of patients with metastatic RCC offered treatment with targeting agents;
- proportion of patients who undergo minimally invasive or operative treatment as first treatment who die within 30 days;

Panel members have set up a database to capture current practice of follow-up of RCC patients in a number of European Centres. Assessing patterns of recurrence and use of imaging techniques are primary outcomes for this project.

The results of ongoing and new SRs will be included in the 2018 update of the RCC Guidelines.

Topics of ongoing SRs:

- What is the best treatment option for T1-T2 tumours? (updated review);
- What is the best treatment option for T1a tumours?;
- What is the best treatment option for T1b-T2a tumours? (updated review);
- What is the best treatment option for T2b tumours;
- Systematic review and meta-analysis of systemic therapy of renal tumours (Cochrane Review).

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Renal cell cancer represents 2-3% of all cancers [9], with the highest incidence in Western countries. Over the last two decades the incidence of RCC increased by about 2%, both worldwide and in Europe. In Western European countries this incidence stabilised over the past decade [10]. In 2012, there were approximately 84,400 new cases of RCC and 34,700 kidney-cancer-related deaths in the European Union [11]. In Europe, overall mortality rates for RCC increased up to the early 1990s, and stabilised or declined thereafter [12]. Mortality has decreased since the 1980s in Scandinavian countries and since the early 1990s in France, Germany, Austria, the Netherlands, and Italy. However, in some European countries (Croatia, Estonia, Greece, Ireland, Slovakia), mortality rates still show an upward trend [12]. Data from the United States also show increased incidence [13].

There is a 1.5:1 male predominance, with a peak incidence between 60 and 70 years. Aetiological factors include smoking, obesity [14] and hypertension. Having a first-degree relative with RCC also increases the risk of RCC [15]. A number of other factors associated with higher or lower RCC-risk include specific dietary habits, occupational exposure to specific carcinogens, acetaminophen and non-aspirin non-steroidal anti-inflammatory drugs [16], cruciferous vegetables [17], nephrolithiasis [18], and viral hepatitis [19-23]. However, data from the literature are still inconclusive [24, 25]. Moderate alcohol consumption appears to have a protective effect for unknown reasons [26-28]. Effective prophylaxis includes avoidance of cigarette smoking and obesity.

Due to increased detection of tumours by ultrasound (US) and computed tomography (CT), the number of incidentally diagnosed RCCs has increased. These tumours are usually smaller and of lower stage [29-31].

3.1.1 Summary of evidence and recommendation

Summary of evidence	LE
Several verified risk factors have been identified including smoking, obesity and hypertension. These are considered definite risk factors for RCC.	2a

Recommendation	grade	
For the most important primary prevention of RCC, eliminate cigarette smoking and reduce weight.	strong	↑↑

3.2 Histological diagnosis

Renal cell carcinomas comprise a broad spectrum of histopathological entities described in the 2016 World Health Organization (WHO) classification [32, 33]. There are three main RCC types: clear cell (ccRCC), papillary (pRCC - type I and II) and chromophobe (chRCC). Renal cell cancer type classification has been confirmed by cytogenetic and genetic analyses [32, 33] (LE: 2b). Collecting duct carcinoma and other infrequent renal tumours are discussed in Section 3.3.

Histological diagnosis includes, besides RCC type; evaluation of nuclear grade, sarcomatoid features, vascular invasion, tumour necrosis, and invasion of the collecting system and peri-renal fat, pT or even pN categories. The four-tiered WHO/ISUP (International Society of Urological Pathology) grading system has replaced the Fuhrman grading system [32, 33].

3.2.1 Clear cell renal cell cancer

Overall, clear-cell RCC (ccRCC) is well circumscribed and a capsule is usually absent. The cut surface is golden-yellow, often with haemorrhage and necrosis. Loss of chromosome 3p and mutation of the von Hippel-Lindau (VHL) gene at chromosome 3p25 are frequently found, including additional tumour suppressor genes including SETD2, BAP1, and PBRM1; all genes are identified near the VHL gene within a region that is frequently deleted in ccRCC [34]. In general, ccRCC has a worse prognosis compared to pRCC and chRCC [35, 36] even after stratification for stage and grade [37]. The five-year cancer-specific-survival (CSS) rate was 91%, 74%, 67% and 32% for TNM stages I, II, III and IV (patients treated between 1987-1998) [38]. For more details, see Section 6.3 - Histological factors.

3.2.2 **Papillary renal cell cancer**

Papillary RCC (pRCC) is the second most commonly encountered morphotype of RCC. Papillary RCC has traditionally been subdivided into two types [33]. Type 1 and 2 pRCC, which were shown to be clinically and biologically distinct; pRCC type 1 is associated with activating germline mutations of MET and pRCC type 2 is associated with activation of the NRF2-ARE pathway with at least three subtypes [39]. Macroscopically, pRCC is well circumscribed with pseudocapsule, yellow or brown in colour, and a soft structure. Compared to ccRCC, pRCC has a significantly higher rate of organ-confined tumour (pT1-2N0M0) and a higher five-year CSS rate [40]. Papillary RCC type 1 is more common and generally considered to have a better prognosis than pRCC type 2 [33, 41]. Exophytic spherical growth, pseudo-necrotic changes and pseudo-capsule are typical signs of pRCC type 1. Tumours are fragile. On post-contrast CT, a hypodense central area of tumour surrounded by vital tumour tissue is seen, presented as a serpiginous contrast-enhancing margin on CT [42].

3.2.3 **Chromophobe (chRCC)**

Overall, chRCC is a pale tan, relatively homogenous and tough, well-demarcated mass without a capsule. Chromophobe RCC cannot be graded (by the Fuhrman grading system), because of its innate nuclear atypia. An alternative grading system has been proposed, but has yet to be validated [32, 33]. Loss of chromosomes Y, 1, 2, 6, 10, 13, 17 and 21 are typical genetic changes [32, 33]. The prognosis is relatively good, with high five-year recurrence-free survival (RFS), and ten-year CSS [43]. The new WHO/ISUP Grading system merges former entity hybrid oncocytic chromophobe tumour with chRCC.

3.3 **Other renal tumours**

Other renal tumours constitute the remaining 10-15% of renal cortical tumours. These include a variety of uncommon, sporadic, and familial carcinomas, some only recently described, as well as a group of unclassified carcinomas. A summary of these tumours is provided in Table 3.1, but some clinically relevant tumours and extremely rare entities are mentioned below.

3.3.1 **Carcinoma associated with end-stage renal disease; acquired cystic disease-associated RCC**

Cystic degenerative changes (acquired cystic kidney disease [ACKD]) and a higher incidence of RCC are typical features of ESKD (end-stage kidney disease). Renal cell cancers of native end-stage kidneys are found in about 4% of patients. Their lifetime risk of developing RCCs is at least ten times higher than in the general population. Compared with sporadic RCCs, RCCs associated with ESKD are generally multicentric and bilateral, found in younger patients (mostly male), and are less aggressive [44, 45]. The relatively indolent outcome of tumours in ESKD is due to the mode of diagnosis and a specific ACKD-related molecular pathway which has still to be determined [45]. Although the histological spectrum of ESKD tumours is similar to that of sporadic RCC, the predominant form is pRCC. The remaining tumours are mostly ccRCC [44-46]. A specific subtype of RCC occurring only in end-stage kidneys has been described as Acquired Cystic Disease-associated RCC (ACD-RCC) [47] with indolent clinical behaviour, likely due to early detection in patients with ESKD on periodic follow-up [33].

3.3.2 **Papillary adenoma**

These tumours have a papillary or tubular architecture of low nuclear grade and may be up to 15 mm in diameter, or smaller [48], according to the WHO 2016 classification [33].

3.3.3 **Hereditary kidney tumours**

Five to eight percent of RCC is hereditary; to date there are ten hereditary RCC syndromes known, associated with specific germline mutations, RCC histology, and comorbidities. Hereditary RCC syndromes are often suggested by family history, age of onset and presence of other lesions typical for the respective syndromes. Median age for hereditary RCC is 37 years; 70% of hereditary RCC tumours are found in the lowest decile (≤ 46 years old) of all RCC tumours [49]. Hereditary kidney tumours are found in the following entities: VHL syndrome, hereditary pRCC, Birt-Hogg-Dubé syndrome (see Hybrid oncocytopoma-chromophobe carcinoma), hereditary leiomyomatosis and RCC (HLRCC), tuberous sclerosis (TS), germline succinate dehydrogenase (SDH) mutation, non-polyposis colorectal cancer syndrome, hyperparathyroidism-jaw tumour syndrome, phosphatase and tensin homolog (PTEN) hamartoma syndrome (PHTS), constitutional chromosome 3 translocation, and familial nonsyndromic ccRCC. Renal medullary carcinoma can be included because of its association with hereditary haemoglobinopathies [47, 48, 50, 51].

Patients with hereditary kidney cancer syndromes may require repeated surgical interventions [52, 53]. Appropriately timed nephron-sparing approaches are recommended with the exception of Hereditary Leiomyomatosis and RCC (HLRCC) and succinate dehydrogenase (SDH) syndromes, for which surveillance is recommended until the largest solid tumour reaches 3 cm in diameter, to reduce interventions [54]. Active

surveillance for VHL, BDH and HPRCC should, in individual patients, follow the growth kinetics, size and location of the tumours rather than apply a standardised fixed follow-up interval. Regular screening for both renal and extra-renal lesions should follow international guidelines for these syndromes. Multi-disciplinary and co-ordinated care should be offered, where appropriate [55].

Although not hereditary, somatic fusion translocations of TFE3 and TFEB may affect 15% of patients with RCC younger than 45 years and 20-45% of children and young adults with RCC [56].

3.3.4 **Angiomyolipoma**

Angiomyolipoma (AML) is a benign mesenchymal tumour, which can occur sporadically, and is four times more common in females [57]. Angiomyolipoma also occurs in tuberous sclerosis and accounts for approximately 1% of surgically removed tumours. Ultrasound, CT, and magnetic resonance imaging (MRI) often lead to diagnosis due to the presence of adipose tissue. Biopsy is rarely useful. Pre-operatively, it may be difficult to differentiate between smooth muscle cell tumours and epithelial tumours. Angiomyolipoma can be found in tuberous sclerosis in lymph nodes (LNs), but it is not metastasis, and has a multicentric genesis. Angiomyolipoma can be due to angiotrophic-type growth extending into the renal vein or the inferior vena cava. Angiomyolipoma with LN involvement and tumorous thrombus is benign. Only epithelioid AML is potentially malignant [48, 58]. Angiomyolipoma has a slow and consistent growth rate, and minimal morbidity [59]. The main complications of renal AML are retroperitoneal bleeding or bleeding into the urinary collection system, which can be life-threatening [60]. The bleeding tendency is related to the angiogenic component of the tumour that includes irregular and aneurysmatic blood vessels [60]. The major risk factors for bleeding are tumour size, grade of the angiogenic component, and the presence of tuberous sclerosis [60, 61]. Indications for intervention are pain, bleeding, or suspected malignancy.

3.3.4.1 *Treatment*

Active surveillance (AS) is the most appropriate option for most AMLs [57, 59, 62] (LE: 3). Risk factors for delayed intervention include tumour size > 4 cm and symptoms at diagnosis [62]. Selective arterial embolisation (SAE) seems to be the first-line option used for active treatment after AS is discontinued [62] (LE: 3). Selective arterial embolisation is an efficient treatment for AML devascularisation, but only for volume reduction [63].

Although SAE controls haemorrhage in the acute setting, it has limited value long-term [64, 65]. If surgery is selected, most cases of AML can be managed by conservative nephron-sparing surgery (NSS), although some patients may require complete nephrectomy [61] (LE: 3). Radiofrequency ablation (RFA) can be an option as well [59, 60, 66]. The volume of AML can be reduced by the mammalian target of rapamycin (mTOR) inhibitor everolimus [67]. A clinical phase II trial and its open-label extension of medical management with everolimus in AMLs not requiring surgical intervention, showed a response rate of 81.6 (64.5% (\geq 50% or 30% tumour volume reduction) by week 96, confirming the long-term safety profile of everolimus [67]. Sirolimus can be combined with deferred surgery [68].

Table 3.1: Other renal cortical tumours, and recommendations for treatment (grade: weak) [32, 33]

Entity	Clinical relevant notes	Malignant potential	Treatment of localised tumour/metastatic tumour
Sarcomatoid variants of RCC	Sign of high-grade transformation without being a distinct histological entity.	High	Surgery. Sunitinib, gemcitabine plus doxorubicin is also an option [69].
Multilocular cystic renal neoplasm of low malignant potential	Formerly multilocular cystic RCC	Benign	Surgery, nephron-sparing surgery (NSS).
Carcinoma of the collecting ducts of Bellini	Rare, often presenting at an advanced stage (N+ 44% and M1 33% at diagnosis). The hazard ratio (HR) CSS in comparison with ccRCC is 4.49 [36].	High, very aggressive. Median survival 30 months [70].	Surgery. Response to targeted therapies is poor [71].
Renal medullary carcinoma	Very rare. Mainly young black men with sickle cell trait.	High, very aggressive, median survival is five months [70].	Surgery. Different chemotherapy regimes, radiosensitive.
Translocation RCC (TRCC) Xp11.2	Rare, mainly younger patients < 40, more common in females. It constitutes with TRCC 6p21 MiT translocation RCCs [72].	High	Surgery. Vascular endothelial growth factor (VEGF)-targeted therapy.
Translocation RCC t(6;11)		Low/intermediate	Surgery, NSS. VEGF-targeted therapy.
Mucinous tubular and spindle cell carcinoma	Tumour is associated with the loop of Henle.	Intermediate	Surgery, NSS.
Acquired cystic disease-associated RCC		Low	Surgery.
Clear cell papillary RCC	Also reported as renal angiomyomatous tumour (RAT).	Low	Surgery, NSS.
Hereditary leiomyomatosis and RCC-associated RCC	Rare, new entity in the 2016 WHO classification, caused by a germline mutation of the fumarate hydratase gene [33].	Aggressive	Surgery. No data about treatment of metastatic disease.
Tubulocystic RCC	Mainly men, imaging can be Bosniak III or IV.	Low (90% indolent)	Surgery, NSS.
Succinate dehydrogenase-deficient RCC	Rare.	Low	Surgery.
Metanephric tumours	Divided into metanephric adenoma, adenofibroma, and metanephric stromal tumours.	Benign	Surgery, NSS.
Cystic nephroma/Mixed Epithelial and Stromal Tumour	Term renal epithelial and stromal tumours (REST) is used as well. Imaging – Bosniak type III or II/IV.	Low/benign	Surgery, NSS.
Oncocytoma	3-7% of all renal tumours. Imaging characteristics alone are unreliable when differentiating between oncocytoma and RCC. Histopathological diagnosis remains the reference standard [73, 74].	Benign	Observation (when histologically confirmed) [75-77]. NSS.

Hereditary kidney tumours	Details see above.	High	Surgery, NSS.
Angiomyolipoma	Details see above.	Benign	Consider treatment only in very well selected patients.
Unclassified RCC	RCC that cannot be assigned to any other category of RCC-type carcinoma [48].	Variable	Surgery, NSS.

3.3.4.2 Summary

A variety of renal tumours exist, and about 15% are benign. All kidney lesions require examination for malignant behaviour.

3.4 Summary of evidence and recommendations for the management of other renal tumours

Recommendations	grade	
Treat Bosniak type III or IV cysts the same as RCC.	strong	↑↑
Treat angiomyolipoma (AML) with selective arterial embolisation or nephron-sparing surgery, in: <ul style="list-style-type: none"> large tumours (a recommended threshold of intervention does not exist, the formerly recommended size of > 4 cm wide is disputed); females of childbearing age; patients in whom follow-up or access to emergency care may be inadequate. 	weak	↑
Treat AMLs that are not candidates for active treatment with active surveillance.	weak	↑
In AML > 3 cm not requiring surgical intervention, medical treatment with everolimus can be considered.	weak	↑
Offer active surveillance to patients with biopsy-proven oncocytomas.	weak	↑
For advanced uncommon renal tumours, develop individualised oncological treatment plans for each patient.	strong	↑↑

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Staging

The Tumour Node Metastasis (TNM) classification system is recommended for clinical and scientific use [78], but requires continuous re-assessment [79] with the latest version published in 2017. A supplement was published in 2012 (Table 4.1), and the latter's prognostic value was confirmed in single and multi-institution studies [80, 81]. Tumour size, venous invasion, renal capsular invasion, adrenal involvement, and LN and distant metastasis are included in the TNM classification system (Table 4.1). However, some uncertainties remain:

- The sub-classification of T1 tumours using a cut-off of 4 cm might not be optimal in NSS for localised cancer.
- The value of size stratification of T2 tumours has been questioned [82].
- Since the 2002 version, tumours with renal sinus fat invasion have been classified as pT3a.
- Renal sinus fat invasion might carry a worse prognosis than perinephric fat invasion but is nevertheless included in the same pT3a stage group [83-85] (LE: 3).
- Sub T-stages (pT2b, pT3a, pT3c and pT4) may overlap [81].
- For adequate M staging, accurate pre-operative imaging (chest and abdominal CT) should be performed [86, 87] (LE: 4).

Table 4.1: 2017 TNM classification system [78] and TNM supplement 2012 [88]

T - Primary Tumour			
TX	Primary tumour cannot be assessed		
T0	No evidence of primary tumour		
T1	Tumour ≤ 7 cm or less in greatest dimension, limited to the kidney		
T1a	Tumour ≤ 4 cm or less		
T1b	Tumour > 4 cm but ≤ 7 cm		
T2	Tumour > 7 cm in greatest dimension, limited to the kidney		
T2a	Tumour > 7 cm but ≤ 10 cm		
T2b	Tumours > 10 cm, limited to the kidney		
T3	Tumour extends into major veins or perinephric tissues but not into the ipsilateral adrenal gland and not beyond Gerota fascia		
T3a	Tumour grossly extends into the renal vein or its segmental (muscle-containing) branches, or tumour invades perirenal and/or renal sinus fat (peripelvic fat), but not beyond Gerota fascia		
T3b	Tumour grossly extends into the vena cava below diaphragm		
T3c	Tumour grossly extends into vena cava above the diaphragm or invades the wall of the vena cava		
T4	Tumour invades beyond Gerota fascia (including contiguous extension into the ipsilateral adrenal gland)		
N - Regional Lymph Nodes			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastasis in regional lymph node(s)		
M - Distant Metastasis			
M0	No distant metastasis		
M1	Distant metastasis		
TNM stage grouping			
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
	T1, T2, T3	N1	M0
Stage IV	T4	Any N	M0
	Any T	Any N	M1

A help desk for specific questions about TNM classification is available at <http://www.uicc.org/tnm>.

4.2 Anatomic classification systems

Objective anatomical classification systems, such as the Preoperative Aspects and Dimensions Used for an Anatomical (PADUA) classification system, the R.E.N.A.L. nephrometry score, the C-index, an Arterial Based Complexity (ABC) Scoring System and Zonal NePhRO scoring system, have been proposed to standardise the description of renal tumours [89-91]. These systems include assessment of tumour size, exophytic/endophytic properties, proximity to the collecting system and renal sinus, and anterior/posterior or lower/upper pole location.

The use of such a system is helpful as it allows objective prediction of potential morbidity of NSS and tumour ablation techniques. These tools provide information for treatment planning, patient counselling, and comparison of partial nephrectomy (PN) and tumour ablation series. However, when selecting the most optimal treatment option, anatomic scores must always be considered together with patient features and surgeon experience.

5. DIAGNOSTIC EVALUATION

5.1 Symptoms

Many renal masses remain asymptomatic until the late disease stages. More than 50% of RCCs are detected incidentally by non-invasive imaging investigating various non-specific symptoms and other abdominal diseases [81, 92] (LE: 3). The classic triad of flank pain, visible haematuria, and palpable abdominal mass is rare (6-10%) and correlates with aggressive histology and advanced disease [93, 94] (LE: 3).

Paraneoplastic syndromes are found in approximately 30% of patients with symptomatic RCCs (LE: 4). Some symptomatic patients present with symptoms caused by metastatic disease, such as bone pain or persistent cough [95] (LE: 3).

5.1.1 Physical examination

Physical examination has a limited role in RCC diagnosis. However, the following findings should prompt radiological examinations:

- palpable abdominal mass;
- palpable cervical lymphadenopathy;
- non-reducing varicocele and bilateral lower extremity oedema, which suggests venous involvement.

5.1.2 Laboratory findings

Commonly assessed laboratory parameters are serum creatinine, glomerular filtration rate (GFR), complete cell blood count, erythrocyte sedimentation rate, liver function study, alkaline phosphatase, lactate dehydrogenase (LDH), serum corrected calcium [96], coagulation study, and urinalysis (LE: 4). For central renal masses abutting or invading the collecting system, urinary cytology and possibly endoscopic assessment should be considered in order to exclude urothelial cancer (LE: 4).

Split renal function should be estimated using renal scintigraphy in the following situations [97, 98] (LE: 2b):

- when renal function is compromised, as indicated by increased serum creatinine or significantly decreased GFR;
- when renal function is clinically important - e.g., in patients with a solitary kidney or multiple or bilateral tumours.

Renal scintigraphy is an additional diagnostic option in patients at risk of future renal impairment due to comorbid disorders.

5.2 Imaging investigations

Most renal tumours are diagnosed by abdominal US or CT performed for other medical reasons [92] (LE: 3). Renal masses are classified as solid or cystic based on imaging findings.

5.2.1 Presence of enhancement

With solid renal masses, the most important criterion for differentiating malignant lesions is the presence of enhancement [99] (LE: 3). Traditionally, US, CT and MRI are used for detecting and characterising renal masses. Most renal masses are diagnosed accurately by imaging alone. Contrast-enhanced US can be helpful in specific cases [100-102] (LE: 3).

5.2.2 Computed tomography or magnetic resonance imaging

Computed tomography or MRI are used to characterise renal masses. Imaging must be performed before and after administration of intravenous contrast material to demonstrate enhancement. In CT imaging, enhancement in renal masses is determined by comparing Hounsfield units (HUs) before and after contrast administration. A change of fifteen, or more, HUs demonstrates enhancement [103] (LE: 3). Computed tomography or MRI allow accurate diagnosis of RCC, but cannot reliably distinguish oncocytoma and fat-free AML from malignant renal neoplasms [73, 104-106] (LE: 3). Abdominal CT provides information on [107]:

- function and morphology of the contralateral kidney [108] (LE: 3);
- primary tumour extension;
- venous involvement;
- enlargement of locoregional LNs;
- condition of the adrenal glands and other solid organs (LE: 3).

Abdominal contrast-enhanced CT angiography is useful in selected cases for detailed information on renal vascular supply [109, 110].

If the results of CT are indeterminate, contrast enhanced ultrasound (CEUS) is a valuable alternative to further characterise renal lesions [6] (LE: 1b).

Magnetic resonance imaging may provide additional information on venous involvement if the extent of an inferior vena cava (IVC) tumour thrombus is poorly defined on CT [111-114] (LE: 3).

Magnetic resonance imaging is indicated in patients who are allergic to intravenous CT contrast medium and in pregnancy without renal failure [112, 115] (LE: 3). Advanced MRI techniques such as diffusion-weighted and perfusion-weighted imaging are being explored for renal mass assessment [116].

In patients with hereditary RCC who are worried about the radiation exposure of frequent CT scans, MRI may be offered as alternative.

5.2.3 **Other investigations**

Renal arteriography and inferior venacavography have a limited role in the work-up of selected RCC patients (LE: 3). In patients with any sign of impaired renal function, an isotope renogram and total renal function evaluation should be considered to optimise treatment decision making [97, 98] (LE: 2a).

Positron-emission tomography (PET) is not recommended [6, 117] (LE: 1b).

5.2.4 **Radiographic investigations to evaluate RCC metastases**

Chest CT is accurate for chest staging [86, 87, 118-120] (LE: 3). There is a consensus that most bone metastases are symptomatic at diagnosis; thus, routine bone imaging is not generally indicated [118, 121, 122] (LE: 3). However, bone scan, brain CT, or MRI may be used in the presence of specific clinical or laboratory signs and symptoms [121, 123, 124] (LE: 3).

5.2.5 **Bosniak classification of renal cystic masses**

This classification system classifies renal cysts into five categories, based on CT imaging appearance, to predict malignancy risk [125, 126] (LE: 3). This system also advocates treatment for each category (Table 5.1).

Table 5.1: Bosniak classification of renal cysts [125]

Bosniak category	Features	Work-up
I	Simple benign cyst with a hairline-thin wall without septa, calcification, or solid components. Same density as water and does not enhance with contrast medium.	Benign
II	Benign cyst that may contain a few hairline-thin septa. Fine calcification may be present in the wall or septa. Uniformly high-attenuation lesions < 3 cm in size, with sharp margins without enhancement.	Benign
IIF	These may contain more hairline-thin septa. Minimal enhancement of a hairline-thin septum or wall. Minimal thickening of the septa or wall. The cyst may contain calcification, which may be nodular and thick, with no contrast enhancement. No enhancing soft-tissue elements. This category also includes totally intrarenal, non-enhancing, high attenuation renal lesions ≥ 3 cm. Generally well-marginated.	Follow-up, up to five years. Some are malignant.
III	These are indeterminate cystic masses with thickened irregular walls or septa with enhancement.	Surgery or active surveillance – see Chapter 7. Over 50% are malignant.
IV	Clearly malignant containing enhancing soft-tissue components.	Surgery. Most are malignant.

5.3 **Renal tumour biopsy**

Percutaneous renal tumour biopsy can reveal histology of radiologically indeterminate renal masses and can be considered in patients who are candidates for AS of small masses, to obtain histology before ablative treatments, and to select the most suitable form of medical and surgical treatment strategy in the setting of metastatic disease [127-132] (LE: 3).

Renal biopsy is not indicated for comorbid and frail patients who can be considered only for conservative management (watchful waiting) regardless of biopsy results. Due to the high diagnostic accuracy of abdominal imaging, renal tumour biopsy is not necessary in patients with a contrast-enhancing renal mass for whom surgery is planned (LE: 4).

Percutaneous sampling can be performed under local anaesthesia with needle core biopsy and/or fine needle

aspiration (FNA). Biopsies can be performed with US or CT guidance, with a similar diagnostic yield [130, 133] (LE: 2b). Eighteen-gauge needles are ideal for core biopsies, as they result in low morbidity and provide sufficient tissue for diagnosis [127-131, 134] (LE: 2b). A coaxial technique allowing multiple biopsies through a coaxial cannula should always be used to avoid potential tumour seeding [127-131] (LE: 3).

Core biopsies should be preferred for the characterisation of solid renal masses (LE: 2a). A SR and meta-analysis of the diagnostic performance and complications of renal tumour biopsy (RTB) was recently performed by this Panel. Fifty-seven articles including a total of 5,228 patients were included in the analysis. Needle core biopsies were found to have better accuracy for the diagnosis of malignancy compared with FNA [135]. Other studies showed that solid pattern, larger tumour size and exophytic location are predictors of a diagnostic core biopsy [127, 130, 133] (LE: 2b).

In experienced centres, core biopsies have a high diagnostic yield, specificity, and sensitivity for the diagnosis of malignancy. The above-mentioned meta-analysis showed that sensitivity and specificity of diagnostic core biopsies for the diagnosis of malignancy are 99.1% and 99.7%, respectively [135] (LE: 2b). However, 0-22.6% of core biopsies are non-diagnostic (8% in the meta-analysis) [128-134, 136] (LE: 2a). If a biopsy is non-diagnostic, and radiologic findings are suspicious for malignancy, a further biopsy or surgical exploration should be considered (LE: 4). Repeat biopsies have been reported to be diagnostic in a high proportion of cases (83-100%) [127, 137-139].

Accuracy of RTBs for the diagnosis of tumour histotype is good. The median concordance rate between tumour histotype on RTBs and on the surgical specimen of the following PN or radical nephrectomy (RN) was 90.3% in the pooled analysis [135].

Assessment of tumour grade on core biopsies is challenging. In the pooled analysis the overall accuracy for nuclear grading was poor (62.5%), but significantly improved (87%) using a simplified two-tier system (high grade vs. low grade) [135] (LE: 2a).

The ideal number and location of core biopsies are not defined. However, at least two good quality cores should be obtained, and necrotic areas should be avoided to maximise diagnostic yield [127, 130, 140, 141] (LE: 4). Peripheral biopsies are preferable for larger tumours, to avoid areas of central necrosis [142] (LE: 2b). In cT2 or greater renal masses multiple core biopsies taken from at least four separate solid enhancing areas in the tumour were shown to achieve a higher diagnostic yield and a higher accuracy to identify sarcomatoid features without increasing the complication rate [143].

Core biopsies of cystic renal masses have a lower diagnostic yield and accuracy and are not recommended alone, unless areas with a solid pattern are present (Bosniak IV cysts) [127, 130, 135] (LE: 2b). Combined FNA and core biopsies can provide complementary results, especially for complex cystic lesions [131, 136, 137, 144, 145] (LE: 3).

Overall, percutaneous biopsies have a low morbidity [135]. Tumour seeding along the needle tract is anecdotal. Spontaneously resolving subcapsular/perinephric haematomas are reported in 4.3% of cases in a pooled analysis, but clinically significant bleeding is unusual (0-1.4%; 0.7% in the pooled analysis) and generally self-limiting [135].

5.4 Summary of evidence and recommendations for the diagnostic assessment of renal cell cancer

Summary of evidence	LE
Contrast enhanced multi-phasic CT has a high sensitivity and specificity for characterisation and detection of RCC, invasion, tumour thrombus and metastatic RCC.	2
MRI has a slightly higher sensitivity and specificity for small renal masses and tumour thrombus as compared to CT.	2
CEUS has a high sensitivity and specificity for characterisation of renal masses.	2
US, Power-Doppler US and PET-CT have a low sensitivity and specificity for detection and characterisation of RCC.	2

Recommendations	grade	
Use multi-phasic contrast-enhanced computed tomography (CT) for general staging and detection of RCC.	strong	↑↑
Use axial abdominal imaging and CT of the chest for staging of RCC.	strong	↑↑
Use non-ionising modalities, mainly contrast enhanced ultrasound (CEUS), for further characterisation of small renal masses, tumour thrombus and differentiation of unclear renal masses.	weak	↑
Do not use bone scan and/or positron-emission tomography (PET)-CT for staging of RCC.	weak	↓
Perform a renal tumour biopsy before ablative therapy and systemic therapy without previous pathology.	strong	↑↑
Perform a percutaneous biopsy in select patients who are considered for active surveillance.	weak	↑
Use a coaxial technique when performing a renal tumour biopsy.	strong	↑↑
Do not perform a renal tumour biopsy of cystic renal masses.	weak	↓

6. PROGNOSTIC FACTORS

6.1 Classification

Prognostic factors can be classified into: anatomical, histological, clinical, and molecular.

6.2 Anatomical factors

Tumour size, venous invasion, renal capsular invasion, adrenal involvement, and LN and distant metastasis are included in the TNM classification system [78] (Table 4.1).

6.3 Histological factors

Histological factors include tumour grade, RCC subtype, sarcomatoid features, microvascular invasion, tumour necrosis, and invasion of the collecting system [146]. Fuhrman nuclear grade is the most widely accepted grading system [147]. Although affected by intra- and inter-observer discrepancies, Fuhrman nuclear grade is an independent prognostic factor [148]. A simplified two- or three-strata system may be as accurate for prognostication as the classical four-tiered grading scheme [149, 150] (LE: 3). The new WHO/ISUP (International Society of Urological Pathology) grading system [151] that will replace the Fuhrman grading, needs to be validated for prognostic systems and nomograms.

In a univariate analysis, patients with chRCC vs. pRCC vs. ccRCC had a better prognosis [152, 153]. However, prognostic information provided by the RCC type is lost when stratified to tumour stage [35, 153] (LE: 3).

Differences in tumour stage, grade and CSS between the RCC types are illustrated in Table 6.1.

Table 6.1: Basic characteristics of three main types of RCC [35, 36, 154]

Type	Percentage of RCC	Advanced disease at diagnosis (T3-4, N+, M+)	Fuhrman grade 3 or 4 [155]	CSS (HR)
clear-cell RCC	80-90%	28%	28.5%	Referent
papillary RCC	6-15%	17.6%	28.8%	0.64 - 0.85
chromophobe RCC	2-5%	16.9%	32.7%*	0.24 - 0.56

* The Fuhrman grading system is validated for ccRCC, but is unreliable for chRCC.

HR = hazard ratio.

In all RCC types, prognosis worsens with stage and histopathological grade (Tables 6.2 and 6.3). The five-year overall survival (OS) for all types of RCC is 49%, which has improved since 2006 probably due to an increase in incidentally detected RCCs and the introduction of tyrosine kinase inhibitors (TKIs) [156, 157]. Sarcomatoid changes can be found in all RCC types and are equivalent to high grade and very aggressive tumours.

Table 6.2: Cancer-specific survival by stage and histopathological grade in RCCs - HR (95% CI) [36].

T1N0M0	Referent
T2N0M0	2.71 (2.17-3.39)
T3N0M0	5.20 (4.36-6.21)
T4N0M0	16.88 (12.40-22.98)
N+M0	16.33 (12.89-20.73)
M+	33.23 (28.18-39.18)
Grade 1	Referent
Grade 2	1.16 (0.94-1.42)
Grade 3	1.97 (1.60-2.43)
Grade 4	2.82 (2.08-3.31)

CI = confidential interval. HR = hazard ratio.

Long-term survival in RCC patients treated by RN or PN between 1970 and 2003; for unilateral, sporadic ccRCC, pRCC or chRCC in a cohort study [154] (Table 6.3).

Table 6.3: Cancer-specific survival of surgically treated patients by RCC type (estimated survival rate in percentage [95% CI])

Survival time	5 years (%)	10 years (%)	15 years (%)	20 years (%)
clear-cell RCC	71 (69-73)	62 (60-64)	56 (53-58)	52 (49-55)
papillary RCC	91 (88-94)	86 (82-89)	85 (81-89)	83 (78-88)
chromophobe RCC	88 (83-94)	86 (80-92)	84 (77-91)	81 (72-90)

Two subgroups of pRCC with different outcomes have been identified [158]. Type 1 have a favourable prognosis. Type 2 are mostly high-grade tumours with a propensity for metastases (LE: 3). For more details, see Section 3.2 Histological diagnosis. Renal cell cancer with Xp 11.2 translocation has a poor prognosis [159]. Its incidence is low, but it should be systematically addressed in young patients. Renal cell cancer type classification has been confirmed by cytogenetic and genetic analyses [155, 160, 161] (LE: 2b).

6.4 Clinical factors

These include performance status (PS), local symptoms, cachexia, anaemia, platelet count, neutrophil/lymphocyte ratio, C-reactive protein (CRP) and albumin [95, 162-166] (LE: 3).

6.5 Molecular factors

Numerous molecular markers such as carbonic anhydrase IX (CaIX), vascular endothelial growth factor (VEGF), hypoxia-inducible factor (HIF), Ki67 (proliferation), p53, p21 [167], PTEN (phosphatase and tensin homolog) (cell cycle), E-cadherin, osteopontin [168] CD44 (cell adhesion) [169, 170], CXCR4 [171], and other cell cycle and proliferative markers [64, 172] are being investigated (LE: 3). None of these markers have clearly improved the predictive accuracy of current prognostic systems, none have been externally validated, and their routine use in clinical practice is at present not recommended. Several retrospective studies and large molecular screening programmes have identified mutated genes in ccRCC with distinct clinical outcomes. The expression of the BAP1 and PBRM1 genes, situated on chromosome 3p in a region that is deleted in more than 90% of ccRCCs, have shown to be independent prognostic factors for tumour recurrence [173-175]. These published reports suggest that patients with BAP1-mutant tumours have worse outcomes compared with patients with PBRM1-mutant tumours [174]. Validated data from surgical series can predict relapse using a sixteen gene signature. This signature is likely to be adopted in clinical trials and may be helpful in the clinical setting in due time [176].

The recognition of the potential relevance of immunotherapy as an approach to RCC management is growing. Prognostic information of cytokines and blockade of immune-inhibitory molecules such as PD-L1 have shown promising therapeutic results. Emerging evidence of chromosomal alterations, through Genome-Wide Association Studies (GWAS), miRNA, SNPs and gene methylations all contribute to improving diagnostic and prognostic information. A number of studies have confirmed prognostic information based on gain of chromosomal regions 7q, 8q and 20q, and chromosomal losses of regions 9p, 9q and 14q, which are associated with poor survival. CpG-methylation-based assays also independently predict survival in ccRCC [177, 178]. An international collaboration is currently investigating GWAS loci for prognostic information.

6.6 Prognostic systems and nomograms

Post-operative prognostic systems and nomograms combining independent prognostic factors have been developed and externally validated [179-185]. These may be more accurate than TNM stage or Fuhrman grade alone for predicting survival (LE: 3). An advantage of nomograms is their ability to measure predictive accuracy (PA), allowing all new predictive parameters to be objectively evaluated. Before being adopted, new prognostic variables or systems should demonstrate that its PA is superior to conventional post-operative prognostic schemes [186]. Recently, new pre-operative nomograms with excellent PA have been designed [187, 188].

Table 6.4 summarises the current most relevant prognostic systems.

6.7 Summary of evidence and recommendations for prognostic factors

Summary of evidence	LE
In RCC patients, TNM stage, tumour nuclear grade, and RCC subtype provide important prognostic information [22].	2

Recommendations	grade	
Use the current Tumour, Node, Metastasis classification system.	strong	↑↑
Use grading systems and classify RCC subtype.	strong	↑↑
Use prognostic systems in the metastatic setting.	strong	↑↑
In localised disease do not routinely use integrated prognostic systems or nomograms for patient selection. Prognostic systems or nomograms can provide a rationale for enrolling patients into clinical trials.	weak	↓
Do not use molecular prognostic markers in routine clinical practice.	weak	↓
In patients receiving targeted treatments, use molecular prognostic markers to predict response.	weak	↑

Table 6.4: Anatomical, histological, and clinical variables in the commonly used prognostic models for localised and metastatic RCC

Prognostic Models	Variables	TNM Stage	ECOG PS	Karnofsky PS	RCC related symptoms	Fuhrman grade	Tumour necrosis	Tumour size	Delay between diagnosis and treatment	LDH	Corrected calcium	Haemoglobin	Neutrophil count	Platelet count	
Localised RCC	UISS	x	x			x									
	SSIGN	x				x		x							
	Post-operative Karakiewicz's nomogram	x			x			x							
Metastatic RCC	MSKCC prognostic system			x					x	x	x	x			
	IMDC				x						x		x	x	
	Heng's model			x					x		x	x	x	x	x

ECOG-PS = Eastern Cooperative Oncology Group - performance status; IMDC = International Metastatic Renal Cancer Database Consortium; LDH = lactate dehydrogenase; MSKCC = Memorial Sloan Kettering Cancer Center; PS = performance status; SSIGN = Stage Size Grade Necrosis; UISS = University of California Los Angeles integrated staging system.

7. DISEASE MANAGEMENT

7.1 Treatment of localised RCC

7.1.1 Introduction

A SR underpins the findings of sections 7.1.2 to 7.2.4.2. The review included all relevant published literature comparing surgical management of localised RCC (T1-2N0M0) [189, 190]. Randomised or quasi-RCTs were included. However, due to the very limited number of RCTs, non-randomised studies (NRS), prospective observational studies with controls, retrospective matched-pair studies, and comparative studies from the databases of well-defined registries were also included.

7.1.2 Surgical treatment

7.1.2.1 Nephron-sparing surgery vs. radical nephrectomy

Multiple retrospective series as well as one prospective RCT including patients with organ-confined RCC of limited size, respectively T-stage (pT1), have demonstrated a comparable CSS for PN vs. RN [191-195]. However, trials that directly compared both approaches in terms of their oncological safety are rarely available, therefore, the data presented is based on a comparison of data available from retrospective series that have included patient cohorts of different and, in part, limited size.

In addition, PN vs. RN was demonstrated to better preserve general kidney function, thereby lowering the risk of development of metabolic or cardiovascular disorders.

When compared with a radical surgical approach, for NSS, several retrospective analyses of large databases have suggested a decreased cardiac-specific mortality [196, 197] as well as improved OS as compared to RN. However, in some series this held true only for a younger patient population and/or patients without significant comorbidity at the time of the surgical intervention [198, 199]. An analysis of the Medicare database [200] could not demonstrate an OS benefit for patients > 75 years of age when RN or PN were compared with non-surgical management. Another series that addressed this question and also included Medicare patients suggested an OS benefit in an older RCC patient population (75-80 years) when subjected to surgery rather than non-surgical management. Shuch *et al.* compared patients subjected to PN for RCC with a non-cancer, healthy control group via a retrospective database analysis, showing an OS benefit for the cancer cohort, [201]. These conflicting results indicate that unknown statistical confounders hamper the retrospective analysis of population-based tumour registries.

In contrast, the only prospectively randomised but prematurely closed and heavily underpowered, trial available so far did not demonstrate an inferiority of RN vs. PN in terms of OS. Taken together, the OS advantage suggested for PN vs. RN remains an unresolved issue.

It has been suggested that the more pronounced deterioration of renal function after RN negatively affects patients' OS [98, 202]. Patients with a normal pre-operative renal function and a decreased GFR due to surgical treatment, generally present with a stable renal function longer term [203]. In contrast, adverse OS in patients with a pre-existing GFR reduction does not seem to result from further renal function impairment following surgery, but rather from other medical comorbidities causing pre-surgical CKD. However, in particular in patients with pre-existing CKD, PN is the treatment of choice to limit the risk of development of ESKD which requires haemodialysis.

Only a limited number of studies are available addressing quality of life (QoL) following PN vs. RN irrespective of the surgical approach used (open- vs. minimally invasive). Quality of life was ranked higher following PN as compared to RN, but in general, patients' health status deteriorated following both approaches [191, 192, 194, 204-208].

In terms of the intra- and peri-operative morbidity/complications associated with PN vs. RN, there was no difference in the length of hospital stay [192, 193, 207], the number of red blood cell (RBC) units applied [192, 207, 208], or the mean intra-operative blood loss [192, 207]. Complication rates were inconsistently reported and one intervention was not favoured over another [209]. One study indicated a longer operation time for open PN [209], but this was not confirmed by others [210].

In view of the above and since oncological safety (CSS and FS) of PN has been proven to be similar for RN, PN is the treatment of choice for T1b RCC since it preserves kidney function better and in the long term limits development of metabolic as well as cardiovascular disorders. Whether decreased mortality from any cause can be attributed to PN is still unresolved, but in patients with pre-existing CKD, PN is the preferred surgical treatment option as it avoids further deterioration of kidney function, the latter being associated with a higher risk of development of ESKD and the need for haemodialysis.

Partial nephrectomy is unsuitable in some patients with localised RCC due to:

- insufficient volume of remaining parenchyma to maintain proper organ function;
- renal vein thrombosis;
- unfavourable tumour location e.g. adherence to the renal vessels;
- use of anticoagulants.

In these situations the curative therapy is RN including removal of the tumour-bearing kidney. Complete resection of the primary tumour by open- or laparoscopic surgery offers a reasonable chance of cure.

7.1.2.2 Associated procedures

7.1.2.2.1 Adrenalectomy

One prospective NRS compared the outcomes of RN or PN with, or without, ipsilateral adrenalectomy [211]. Multivariate analysis showed that upper pole location was not predictive of adrenal involvement, but tumour size was. No difference in OS at five or ten years was seen, with, or without, adrenalectomy. Adrenalectomy was justified using criteria based on radiographic and intra-operative findings. Only 48 of 2,065 patients underwent concurrent ipsilateral adrenalectomy of which 42 were for benign lesions.

7.1.2.2.2 Lymph node dissection for clinically negative lymph nodes (cN0)

The indication for lymph node dissection (LND) together with PN or RN is still controversial [212]. The clinical assessment of LN status is based on the detection of an enlargement of LNs; either by CT/MRI or the intra-operative palpability of enlarged nodes. Less than 20% of suspected metastatic nodes (cN+) are positive for metastatic disease at histopathological examination (pN+) [213]. Both CT and MRI are unsuitable for detecting malignant disease in nodes of normal shape and size [214]. For clinically positive LNs (cN+) see Section 7.2.2.

For patients with clinically negative LNs (cN0) six clinical trials have evaluated the clinical value of LND [212], the latter including one RCT [213] and five comparative studies [215-219].

Smaller retrospective studies have suggested a clinical benefit associated with a more or less extensive lymphadenectomy preferably in patients at high risk for lymphogenic spread. The number of LN metastases (< / > 4) as well as the intra- and extracapsular extension of intranodal metastasis correlated with the patients' clinical prognosis in some studies [214, 220-222]. Better survival outcomes were seen in patients with a low number of positive LNs (< 4) and no extranodal extension. On the basis of a retrospective SEER database analysis of > 9,000 patients no effects of an extended LND on the disease-specific survival (DSS) of patients with pathologically confined negative nodes was demonstrated [223]. However, in patients with pathologically proven lymphogenic spread (pN+), an increase of ten for the number of nodes dissected resulted in a 10% absolute increase in DSS. In addition, in a larger cohort of 1,983 patients Capitano *et al.* demonstrated that extended LND results in a significant prolongation of CSS in patients with unfavourable prognostic features (e.g., sarcomatoid differentiation, large tumour size) [224].

Only one prospective RCT evaluating the clinical value of LND combined with surgical treatment of primary RCC has been published so far. With an incidence of only 4%, lymphatic spread appears to be very low. Recognising the latter, only a staging effect was attributed to a (super)extended LND [213]. This trial included a very high percentage of patients with pT2 tumours, which are not at increased risk for LN metastases. Additionally, only 25% of patients with pT3 tumours were subjected to a complete LND. The LN template used by the authors was also not clearly stated.

The most optimal surgical approach remains controversial. Retrospective studies suggest that an extended LND should involve the LNs surrounding the ipsilateral great vessel and the inter-aortocaval region from the crus of the diaphragm to the common iliac artery. Involvement of inter-aortocaval LNs without regional hilar involvement is reported in up to 35-45% of cases [214, 215, 225]. At least fifteen LNs should be removed [224, 226]. Sentinel LND is an investigational technique [227, 228].

7.1.2.2.3 Embolisation

Before routine nephrectomy, tumour embolisation has no benefit [229, 230]. In patients unfit for surgery, or with non-resectable disease, embolisation can control symptoms, including visible haematuria or flank pain [231-233]. These indications will be repeated in Sections 7.2 and 7.3 with cross reference to the summary of evidence and recommendations below.

7.1.2.2.4 Summary of evidence and recommendations

Summary of evidence	LE
The oncological outcome in terms of DSS following PN equals that of a radical approach in patients with c/p T1 RCC.	1b
Ipsilateral adrenalectomy, in the absence of clinical evident adrenal involvement during RN or PN, has no survival advantage.	3
In patients with localised disease without evidence of lymph node metastases, a survival advantage of LND in conjunction with RN is not demonstrated in randomised trials.	1b
In patients unfit for surgery with massive haematuria or flank pain, embolisation can be a beneficial palliative approach.	3

Recommendations	grade	
Offer surgery to achieve cure in localised renal cell cancer.	strong	↑↑
Offer partial nephrectomy to patients with T1 tumours.	strong	↑↑
Do not perform ipsilateral adrenalectomy if there is no clinical evidence of invasion of the adrenal gland.	strong	↓↓
Consider an extended lymph node dissection in patients with adverse clinical features including a large diameter of the primary tumour or sarcomatoid histological features.	weak	↑

7.1.3 **Radical and partial nephrectomy techniques**7.1.3.1 *Radical nephrectomy techniques*

No RCTs have assessed oncological outcomes of laparoscopic vs. open RN. A cohort study [234] and retrospective database reviews are available, mostly of low methodological quality [192, 235, 236]. Similar oncological outcomes for laparoscopic vs. open RN were found. Data from one RCT [237] and two NRSs [192, 234] showed a significantly shorter hospital stay and lower analgesic requirement for the laparoscopic RN group as compared with the open group. Convalescence time was also significantly shorter [234]. No difference in the number of patients receiving blood transfusions was observed, but peri-operative blood loss was significantly less in the laparoscopic arm in all three studies [192, 234, 237]. Surgical complication rates were low with very wide confidence intervals. There was no difference in complications, but operation time was significantly shorter in the open nephrectomy arm. Post-operative QoL scores were similar [192].

Some comparative studies focused on the peri-operative outcomes of laparoscopic vs. RN for renal tumours \geq T2. Overall, patients who underwent laparoscopic RN were shown to have lower estimated blood loss, less post-operative pain, shorter length of hospital stay and convalescence compared to those who underwent open RN [234, 238-240]. Intra-operative and post-operative complications were similar in the two groups [234, 238-241]. No significant differences in CSS, PFS and OS were reported [226, 234, 239, 241, 242] (LE: 2b).

The best approach for RN was the retroperitoneal or transperitoneal approach with similar oncological outcomes in the two RTCs [243, 244] and one quasi-randomised study [245]. Quality of life variables were similar for both approaches.

Hand-assisted vs. standard laparoscopic RN was compared in one RCT [245] and one database review [209]. Estimated five-year OS, CSS, and RFS rates were comparable. Duration of surgery was significantly shorter in the hand-assisted approach, while length of hospital stay and time to non-strenuous activities were shorter for the standard laparoscopic RN cohort [209, 245]. However, the sample size was small.

Robot-assisted laparoscopic RN vs. laparoscopic RN was compared in one study [246]. There were no local recurrences, port-site or distant metastases, but the sample size was small and follow-up was short. Similar results were seen in observational cohort studies comparing 'portless' and 3-port laparoscopic RN [247, 248]. Peri-operative outcomes were similar.

7.1.3.2 *Partial nephrectomy techniques*

Studies comparing laparoscopic PN and open PN found no difference in PFS [249-252] and OS [251, 252] in centres with laparoscopic expertise. The mean estimated blood loss was lower with the laparoscopic approach [249, 251, 253], while post-operative mortality, deep vein thrombosis, and pulmonary embolism events are similar [249, 251]. Operative time is generally longer with the laparoscopic approach [250-252] and warm ischaemia time is shorter with the open approach [249, 251, 253, 254]. In a matched-pair comparison, GFR decline was greater in the laparoscopic PN group in the immediate post-operative period [252], but not after follow-up of 3.6 years. In another comparative study, the surgical approach was not an independent predictor for post-operative CKD [254]. Retroperitoneal and transperitoneal laparoscopic PN have similar peri-operative

outcomes [255]. Simple tumour enucleation also had similar PFS and CSS rates compared to standard PN and RN in a large study [256, 257].

Hand-assisted laparoscopic PN (HALPN) is rarely performed. A recent comparative study of open vs. HALPN showed no difference in OS or RFS at intermediate-term follow-up. The authors observed a lower rate of intra-operative and all-grade post-operative 30-day complications in HALPN than in open PN patients, but there was no significant difference in high Clavien Grade complications. Glomerular filtration rate three months after operation was lower in the HALPN than in the open PN group [258].

The feasibility of off-clamp laparoscopic PN and laparo-endoscopic single-site PN has been shown in selected patients but larger studies are needed to confirm their safety and clinical role [259, 260].

At present, the oncological outcomes of robot-assisted vs. laparoscopic or open PN have been compared only in studies with short-term follow-up. One recent study prospectively compared the peri-operative outcomes of a series of robot-assisted and open PN performed by the same experienced surgeon. Robot-assisted PN was superior to open PN in terms of lower estimated blood loss and shorter hospital stay. Warm ischaemia time, operative time, immediate- early- and short-term complications, variation of creatinine levels, and pathologic margins were similar among the groups [261].

A recent meta-analysis, including a series of NSS, with variable methodological quality compared the peri-operative outcomes of robot-assisted and laparoscopic PN. The robotic group had a significantly lower rate of conversion to open surgery and to radical surgery, shorter warm ischaemia time, smaller change in estimated GFR after surgery and shorter length of stay. No significant difference was observed between the two groups regarding complications, change of serum creatinine after surgery, operative time, estimated blood loss and positive surgical margins (PSMs) [262].

7.1.3.3 Positive margins on histopathological specimens of resected tumours

A positive surgical margin is encountered in about 8% of PNs [263]. Studies comparing different resection techniques (open, laparoscopic, robotic) are inconclusive [264, 265]. Most trials showed that intra-operative frozen section analysis had no influence on the risk of definite PSMs [266]. A PSM status occurs more frequently in cases in which surgery is imperative, including bilateral tumours [267, 268]. Positive surgical margins increase the risk of disease recurrence, primarily in patients with adverse pathological features (pT2a-pT3a, grade III-IV) [263, 267, 268]. The effect of margin status on long-term oncologic outcomes remains to be determined [264], but PSMs need not translate into worse CSS [267, 268]. Therefore, RN or re-resection of margins presents overtreatment in many cases, but a small percentage of patients will harbour residual malignancy [269]. Patients with PSMs should be informed that they will be subjected to a more intense surveillance (imaging) programme and are at increased risk for secondary local therapies [267, 270]. However, protection from recurrence is not ensured by negative surgical margins [271].

7.1.3.4 Summary of evidence and recommendations

Summary of evidence	LE
Laparoscopic radical nephrectomy has lower morbidity than open surgery.	1b
Oncological outcomes for T1-T2a tumours are equivalent between laparoscopic and open radical nephrectomy.	2a
Partial nephrectomy can be performed, either with an open, pure laparoscopic or robot-assisted approach, based on surgeon's expertise and skills.	2b
Partial nephrectomy is associated with a higher percentage of positive surgical margins compared with radical nephrectomy.	3

Recommendations	grade	
Offer laparoscopic radical nephrectomy to patients with T2 tumours and localised masses not treatable by partial nephrectomy.	strong	↑↑
Do not perform radical nephrectomy in patients with T1 tumours for whom partial nephrectomy is indicated.	strong	↓↓

7.1.4 **Therapeutic approaches as alternatives to surgery**

7.1.4.1 *Surgical versus non-surgical treatment*

Population-based studies compared the oncological outcomes of surgery (RN or PN) and non-surgical management for tumours < 4 cm. The analyses showed a significantly lower cancer-specific mortality in patients treated with surgery [200, 272]. However, the patients assigned to the surveillance arm were older and likely to be frailer and less suitable candidates for surgery. Other-cause mortality rates in the non-surgical group significantly exceeded that of the surgical group [272]. Analyses of older patients (> 75 years) failed to show the same benefit in cancer-specific mortality for surgical treatment [273-275].

7.1.4.2 *Surveillance*

Elderly and comorbid patients with incidental small renal masses have a low RCC-specific mortality and significant competing-cause mortality [276, 277]. Active surveillance is defined as the initial monitoring of tumour size by serial abdominal imaging (US, CT, or MRI) with delayed intervention reserved for tumours showing clinical progression during follow-up [278]. The concept of AS differs from the concept of watchful waiting. Watchful waiting is reserved for patients whose comorbidities contraindicate any subsequent active treatment and do not require follow-up imaging, unless clinically indicated.

In the largest reported series of AS, the growth of renal tumours was low and progression to metastatic disease was reported in only a limited number of patients [279, 280].

A single-institutional comparative study evaluating patients aged ≥ 75 years showed decreased OS for those who underwent surveillance and nephrectomy relative to NSS for clinically T1 renal tumours. However, patients selected for surveillance were older with greater comorbidity. At multi-variate analysis, management type was not associated with OS after adjusting for age, comorbidity, and other variables [276]. No statistically significant difference in OS and CSS were observed in another study of RN vs. PN vs. AS for T1a renal masses with a follow-up of 34 months [281].

The initial results of the multi-institutional Delayed Intervention and Surveillance for Small Renal Masses (DISSRM) registry were recently published. This prospective, NRS enrolled 497 patients with solid renal masses < 4 cm in size who chose AS or primary active intervention. Patients who selected AS were older, had worse ECOG scores, more comorbidities, smaller tumours, and more often multiple and bilateral lesions. Overall survival for primary intervention and AS was 98% and 96% at two years, and 92% and 75% at five years, respectively ($p = 0.06$). At five years, CSS was 99% and 100%, respectively ($p = 0.3$). Active surveillance was not predictive of OS or CSS in regression modelling with relatively short follow up [282].

Overall, both short- and intermediate-term oncological outcomes indicate that in selected patients with advanced age and/or comorbidities, AS is appropriate to initially monitor small renal masses, followed, if required, by treatment for progression [278-280, 283-286].

A multicentre study assessed QoL of patients undergoing immediate intervention vs. AS. Patients undergoing immediate intervention had higher QoL scores at baseline, specifically for physical health. The perceived benefit in physical health persisted for at least one year following intervention. Mental health, which includes domains of depression and anxiety, was not adversely affected while on AS [287].

7.1.4.3 *Ablative therapies*

7.1.4.3.1 *Cryoablation*

Cryoablation is performed using either a percutaneous or a laparoscopic-assisted approach. In comparative studies, there was no significant difference in the overall complication rates between laparoscopic and percutaneous cryoablation [288-290]. One comparative study reported similar OS, CSS, and RFS in 172 laparoscopic patients with a longer follow up compared with 123 patients treated percutaneously with a shorter follow up [289]. A shorter average length of hospital stay was found with the percutaneous technique [289, 290]. No studies are available comparing surveillance strategies to cryoablation.

A recent SR including 82 articles reported complication rates ranging between 8 and 20% with most complications being minor [291]. Although a precise definition of tumour recurrence is lacking, the authors reported a lower RFS as compared to that of PN.

7.1.4.3.2 *Cryoablation versus partial nephrectomy*

Studies compared open, laparoscopic or robotic PN with percutaneous or laparoscopic cryoablation. Oncological outcomes were mixed, with some studies showing no difference in OS, CSS, RFS, DFS, local recurrence or progression to metastatic disease [292, 293], with some showing significant benefit for the PN techniques for some or all of these outcomes [294-297]. Not all studies reported all outcomes listed, and some were small and included benign tumours. No study showed an oncological benefit for cryoablation over PN.

Peri-operative outcomes, complication rates and other QoL measures were mixed. Some studies found the length of hospital stay was shorter and surgical blood loss was less with cryoablation [292-294], whilst also finding no differences in other peri-operative outcomes such as recovery times, complication rates

or post-operative serum creatinine levels. Two studies [296, 297] reported specific Clavien rates, with mostly non-significant differences, which were mixed for intra-operative vs. post-operative complications. Estimated GFRs were not significantly different in two of the studies, but in favour of cryoablation in a third [295-297]. Estimates of new CKD were also mixed, with one study in favour of cryoablation [295], another strongly in favour of PN [296], and the third showing no difference [297]. One study compared PN with ablation therapy, either cryoablation or RFA [223], and showed significantly improved DSS at both five and ten years for PN.

A recent study compared 1,057 patients treated by PN to 180 treated by RFA and 187 treated by cryoablation for a cT1 tumour and found no difference regarding RFS between the three techniques. Metastasis-free survival was superior after PN and cryoablation compared to RFA for cT1a patients. However, follow-up of patients treated by thermal ablations was shorter [198].

7.1.4.3.3 Radiofrequency ablation

Radiofrequency ablation is performed laparoscopically or percutaneously. Four studies compared patients with T1a tumours treated by laparoscopic or percutaneous RFA [298-301].

Complications occurred in up to 29% of patients but were mostly minor. Complication rates were similar in patients treated laparoscopically or percutaneously. One study with a limited number of patients [300] found a higher rate of incomplete ablation in patients treated by percutaneous RFA. However, no differences in recurrence or CSS were found in the three comparative studies.

7.1.4.3.4 Radiofrequency ablation versus partial nephrectomy

Most publications about RFA are retrospective cohort studies with a low number of patients and limited follow up. Three studies retrospectively compared RFA to surgery in patients with T1a tumours [302-304].

One study [303] compared T1a patients who underwent either RFA (percutaneous or laparoscopic) or PN and found no difference in OS and CSS. Another study retrospectively reviewed 105 T1a patients treated by percutaneous RFA or RN. Cancer-specific survival was 100% in both groups. Overall survival was lower in the RFA group but patients treated with surgery were younger [302].

In a monocentric study that compared 34 RFA patients to sixteen open PN patients, a higher rate of complications and transfusions was shown in the PN group. Although the tumours were larger in PN patients, progression rates were similar (0%) [304].

A recent meta-analysis [305] reported comparable complication rates and post-operative eGFRs between RFA and PN. The local tumour recurrence rate was higher in the RFA group than in the PN group (OR = 1.81) but there was no difference regarding the occurrence of distant metastasis.

7.1.4.3.5 Cryoablation versus radiofrequency ablation

Two studies compared RFA and cryoablation [306, 307]. No significant differences were reported for OS, CSS, or RFS in either study. For local RFS at five years, one study [306] reported improvement with RFA, while the other [307] reported a benefit with cryoablation. One study [306] reported no differences in Clavien complication rates between the techniques.

7.1.4.3.6 Other ablative techniques

Some studies have shown the feasibility of other ablative techniques, such as microwave ablation, laser ablation, and high-intensity focused US ablation. However, these techniques are considered experimental.

7.1.4.3.7 Summary of evidence and recommendation for therapeutic approaches as alternative to surgery

Summary of evidence	LE
Most population-based analyses show a significantly lower cancer-specific mortality for patients treated with surgery compared to non-surgical management.	3
In active surveillance cohorts, the growth of small renal masses is low in most cases and progression to metastatic disease is rare (1-2%).	3
Quality of the available data does not allow definitive conclusions regarding morbidity and oncological outcomes of cryoablation and radiofrequency ablation.	3
Low quality studies suggest a higher local recurrence rate for thermal ablation therapies compared to partial nephrectomy.	3

Recommendation	grade	
Offer active surveillance, radiofrequency ablation and cryoablation to elderly and/or comorbid patients with small renal masses.	weak	↑

7.2 Treatment of locally advanced RCC

7.2.1 Introduction

In addition to the summary of evidence and recommendations outlined in Section 7.1 for localised RCC, certain therapeutic strategies arise in specific situations for locally advanced disease.

7.2.2 Management of clinically positive lymph nodes (cN+)

In the presence of clinically positive LNs (cN+), LND is always justified [38]. However, the extent of LND remains controversial [214].

7.2.3 Management of locally advanced unresectable RCC

In patients with non-resectable disease, embolisation can control symptoms, including visible haematuria or flank pain [231-233]. The use of neoadjuvant targeted therapy to downsize tumours is experimental and cannot be recommended outside clinical trials.

7.2.4 Management of RCC with venous tumour thrombus

Tumour thrombus formation in the IVC in RCC patients is a significant adverse prognostic factor. Traditionally, patients with venous tumour thrombus undergo surgery to remove the kidney and tumour thrombus. Aggressive surgical resection is widely accepted as the default management option for patients with venous tumour thrombus [308-316]. However, uncertainties remain over the best approach for surgical treatment of these patients.

7.2.4.1 The evidence base for surgery in patients with venous tumour thrombus

The data on whether patients with venous tumour thrombus should undergo surgery is derived from case series. In one of the largest published studies [313] a higher level of thrombus was not associated with increased tumour dissemination to LNs, perinephric fat or distant metastasis. Thus, all patients with non-metastatic disease and venous tumour thrombus, and an acceptable PS, should be considered for surgical intervention, irrespective of the extent of tumour thrombus at presentation (LE: 3). The surgical technique and approach for each case should be selected based on the extent of tumour thrombus (LE: 3).

7.2.4.2 The evidence base for different surgical strategies

A SR was undertaken which included comparison-only studies on the management of venous tumour thrombus, in non-metastatic RCC [317, 318]. Only five studies were eligible for final inclusion, with high risks of bias across all studies.

Minimal access techniques resulted in significantly shorter operating time compared with traditional median sternotomy [319, 320]. Pre-operative embolisation [321] was associated with increased operating time, blood loss, hospital stay and peri-operative mortality in patients with T3 RCC.

No significant differences in oncological and process outcomes were observed between cardiopulmonary bypass with deep hypothermic circulatory arrest or partial bypass under normothermia or single caval clamp without circulatory support [322].

No surgical method was shown to be superior for the excision of venous tumour thrombus. The surgical method was dependent on the level of tumour thrombus, and the grade of occlusion of the IVC [317, 319, 320, 322]. The relative benefits and harms of other strategies and approaches regarding access to the IVC and the role of IVC filters and bypass procedures remain uncertain.

7.2.4.3 Summary of evidence and recommendations for the management of RCC with venous tumour thrombus

Summary of evidence	LE
In patients with locally advanced disease due to clinically enlarged lymph nodes, the survival benefit of lymph node dissection is unclear but lymph node dissection can add staging information.	3
Low quality data suggest that tumour thrombus excision in non-metastatic disease may be beneficial.	3
Tumour embolisation or inferior vena cava filter do not appear to offer any benefits.	3

Recommendations	grade	
In patients with clinically enlarged lymph nodes, perform lymph node dissection for staging purposes or local control.	weak	↑
In patients with non-metastatic RCC, excise the kidney tumour and the vena cava thrombus.	strong	↑↑

7.2.5 Adjuvant therapy

There is currently no evidence from randomised phase III trials that adjuvant therapy offers a survival benefit. The impact on OS of adjuvant tumour vaccination in selected patients undergoing nephrectomy for T3 renal carcinomas remains unconfirmed [323-327] (LE: 1b). Results from prior adjuvant trials studying interferon-alpha (IFN- α) and interleukin-2 (IL-2) did not show a survival benefit [328]. Heat shock protein-peptide complex-96 (vitespen) [329], may have a benefit in a subgroup of patients but the overall data from phase III trials were negative. A similar observation was made in an adjuvant trial of girentuximab, a monoclonal antibody against carboanhydrase IX (CAIX) (ARISER) [330]. No difference in DFS was observed in the overall trial analysis, but a subgroup evaluation of patients with high CAIX expression suggests a potential benefit of girentuximab in this population. Several RCTs investigating adjuvant sunitinib, sorafenib, pazopanib, axitinib and everolimus are ongoing. At present, there is no evidence for the use of adjuvant VEGF-R or mTOR inhibitors. One of the largest adjuvant trials of sunitinib vs. sorafenib vs. placebo reported in 2015 (ASSURE) after an interim analysis performed with 62% of the data available. Results demonstrated no significant differences in DFS or OS between the experimental arms and placebo and it was concluded that adjuvant therapy with sunitinib or sorafenib should not be given [162]. The S-TRAC study included 615 patients in a 1:1 randomisation (HR: 0.76; 95% CI: 0.59-0.98; $p = 0.03$ for DFS and an immature OS). Grade 3/4 toxicity in the study was 60.5% for patients receiving sunitinib, which translated into significant differences in QoL for loss of appetite and diarrhoea. Based on the conflicting results in the two available studies, the Panel rated the quality of the evidence, harms-benefits ratio, patient preferences and costs. Finally, the panel, including representatives from a patient advocacy group (IKCC), voted and reached a consensus decision to not recommend adjuvant therapy with sunitinib for patients with high-risk RCC after nephrectomy [331].

7.2.5.1 Summary of evidence and recommendations for adjuvant therapy

Summary of evidence	LE
Adjuvant cytokines do not improve survival after nephrectomy.	1b
Adjuvant sunitinib improved disease-free survival in one of the two available studies, but not overall survival, after nephrectomy in selected high-risk patients.	1b

Recommendations	grade	
Do not offer adjuvant therapy with sorafenib.	strong	↓↓
Do not offer adjuvant sunitinib following surgically resected high-risk clear-cell renal cell cancer.	weak	↓

7.3 Advanced/metastatic RCC

7.3.1 Local therapy of advanced/metastatic RCC

7.3.1.1 Cytoreductive nephrectomy

Tumour resection is curative only if all tumour deposits are excised. This includes patients with the primary tumour in place and single- or oligo-metastatic resectable disease. For most patients with metastatic disease, cytoreductive nephrectomy (CN) is palliative and systemic treatments are necessary. In a meta-analysis comparing CN+ immunotherapy vs. immunotherapy only, increased long-term survival was found in patients treated with CN [332]. Only retrospective non-comparative data for CN combined with targeting agents, such as sunitinib, sorafenib and others, are available. Cytoreductive nephrectomy is currently recommended in mRCC patients with a good PS, large primary tumours and low metastatic volume. In patients with poor PS or Metastatic Renal Cancer Database Consortium (IMDC) risk, small primaries and high metastatic volume and/or a sarcomatoid tumour, CN is not recommended.

7.3.1.1.1 Embolisation of the primary tumour

In patients unfit for surgery, or with non-resectable disease, embolisation can control symptoms, including visible haematuria or flank pain [231-233] (see recommendation Section 7.1.2.2.4).

7.3.1.1.2 Summary of evidence and recommendation for local therapy of advanced/metastatic RCC

Summary of evidence	LE
Cytoreductive nephrectomy combined with interferon-alpha improves survival in patients with metastatic RCC and good performance status.	1a
Cytoreductive nephrectomy for patients with simultaneous complete resection of a single metastasis or oligometastases may improve survival and delay systemic therapy.	3

Recommendation	grade	
Offer cytoreductive nephrectomy to favourable- and intermediate-risk patients with metastatic RCC.	weak	↑

7.3.2 **Local therapy of metastases in mRCC**

A systematic review of the local treatment of metastases from RCC in any organ was undertaken [333]. Interventions included metastasectomy, various radiotherapy modalities, and no local treatment. The outcomes assessed were OS, CSS and PFS, local symptom control and adverse events. A risk-of-bias assessment was conducted [334]. Of the 2,235 studies identified only sixteen non-randomised comparative studies were included.

Eight studies reported on local therapies of RCC-metastases in various organs [335-342]. This included metastases to any single organ or multiple organs. Three studies reported on local therapies of RCC metastases in bone, including the spine [343-345], two in the brain [346, 347] and one each in the liver [348] lung [349] and pancreas [350]. Three studies [339, 341, 349] were abstracts. Data were too heterogeneous for meta-analysis. There was considerable variation in the type and distribution of systemic therapies (cytokines and VEGF-inhibitors) and in reporting the results.

7.3.2.1 *Complete versus no/incomplete metastasectomy*

All eight studies [335-342] on RCC metastases in various organs compared complete vs. no and/or incomplete metastasectomy. However, in one study [338], complete resections were achieved in only 45% of the metastasectomy cohort, which was compared with no metastasectomy. Non-surgical modalities were not applied. Six studies [335, 337-339, 341, 342] reported a significantly longer median OS or CSS following complete metastasectomy (the median value for OS or CSS was 40.75 months, range 23-122 months) compared with incomplete and/or no metastasectomy (the median value for OS or CSS was 14.8 months, range 8.4-55.5 months). Of the two remaining studies, one [336] showed no significant difference in CSS between complete and no metastasectomy, and one [340] reported a longer median OS for metastasectomy albeit no p-value was provided.

Three studies reported on treatment of RCC metastases to the lung [349], liver [348], and pancreas [350], respectively. The lung study reported a significantly higher median OS for metastasectomy vs. medical therapy only for both target therapy and immunotherapy. Similarly, the liver and pancreas study reported a significantly higher median OS and five-year OS for metastasectomy vs. no metastasectomy.

7.3.2.2 *Local therapies for RCC bone metastases*

Of the three studies identified, one compared single-dose image-guided radiotherapy (IGRT) with hypofractionated IGRT in patients with RCC bone metastases [345]. Single-dose IGRT (≥ 24 Gray) had a significantly better three-year actuarial local PFS rate, also shown by Cox regression analysis. Another study [343] compared metastasectomy/curettage and local stabilisation with no surgery of solitary RCC bone metastases in various locations. A significantly higher five-year CSS rate was observed in the intervention group.

After adjusting for prior nephrectomy, gender and age, multi-variate analysis still favoured metastasectomy/curettage and stabilisation. A third study compared the efficacy and durability of pain relief between single-dose stereotactic body radiotherapy (SBRT) and conventional radiotherapy (CRT) in patients with RCC bone metastases to the spine [344]. Pain, objective response rate (ORR), time-to-pain relief and duration of pain relief were similar.

7.3.2.3 *Local therapies for RCC brain metastases*

Two studies on RCC brain metastases were included. A three-armed study [346] compared stereotactic radiosurgery (SRS) vs. whole brain radiotherapy (WBRT) vs. SRS + WBRT. Each group was further subdivided into recursive partitioning analysis (RPA) classes I to III (I favourable, II moderate and III poor patient status). Two-year OS and intracerebral control were equivalent in patients treated with SRS alone and SRS + WBRT.

Both treatments were superior to WBRT alone in the general study population and in the RPA subgroup analyses. A comparison of SRS vs. SRS + WBRT in a subgroup analysis of RPA class I showed significantly better two-year OS and intracerebral control for SRS + WBRT based on only three participants. The other study compared fractionated stereotactic radiotherapy (FSRT) with metastasectomy (MTS) + CRT or CRT alone [347]. Several patients in all groups underwent alternative surgical and non-surgical treatments after initial treatment. One-, two- and three-year survival rates were higher but not significantly so for FSRT as for metastasectomy + CRT, or CRT alone. Fractionated stereotactic radiotherapy did not result in a significantly better two-year local control rate compared with MTS + CRT.

7.3.2.4 Embolisation of metastases

Embolisation prior to resection of hypervascular bone or spinal metastases can reduce intra-operative blood loss [351]. In selected patients with painful bone or paravertebral metastases, embolisation can relieve symptoms [352] (see recommendation Section 7.1.2.2.4).

7.3.2.5 Summary of evidence and recommendations for local therapy of metastases in metastatic RCC

Summary of evidence	LE
All included studies were retrospective non-randomised comparative studies, resulting in a high risk of bias associated with non-randomisation, attrition, and selective reporting.	3
With the exception of brain and possibly bone metastases, metastasectomy remains by default the only local treatment for most sites.	3
Retrospective comparative studies consistently point towards a benefit of complete metastasectomy in mRCC patients in terms of overall survival, cancer-specific survival and delay of systemic therapy.	3
Radiotherapy to bone and brain metastases from RCC can induce significant relief from local symptoms (e.g. pain).	3

Recommendations	grade	
Consider local therapy for metastatic disease (including metastasectomy) in patients with a favourable risk profile in whom complete resection is achievable or when local symptoms need to be controlled.	weak	↑
Stereotactic radiotherapy for clinically relevant bone or brain metastases can be considered for local control and symptom relief.	weak	↑

7.4 Systemic therapy for advanced/metastatic RCC

7.4.1 Chemotherapy

Chemotherapy is moderately effective only if 5-fluorouracil (5-FU) is combined with immunotherapeutic agents [353]. However, in one study, interferon-alpha (IFN- α) showed equivalent efficacy to IFN- α + interleukin-2 (IL-2) + 5-FU [354].

A combination of gemcitabine and doxorubicin could be an option in sarcomatoid and rapidly progressive RCC [69, 355].

7.4.1.1 Summary of evidence and recommendation for systemic therapy for advanced/metastatic renal cell cancer

Summary of evidence	LE
In metastatic RCC, 5-FU combined with immunotherapy has equivalent efficacy to INF- α .	1b
In metastatic RCC, chemotherapy is otherwise not effective with the exception of gemcitabine and doxorubicine in sarcomatoid and rapidly progressive disease.	3

Recommendations	grade	
Do not offer chemotherapy as first-line therapy in patients with metastatic clear-cell renal cell cancer (RCC).	strong	↓↓
Consider offering a combination of gemcitabine and doxorubicin to patients with sarcomatoid or rapidly progressive RCC.	weak	↑

7.4.2 Immunotherapy

7.4.2.1 IFN- α monotherapy and combined with bevacizumab

Conflicting results exist for IFN- α in clear-cell (cc) mRCC. Several studies showed that IFN- α in mRCC has a survival advantage similar to that of hormonal therapy [356]. Interferon- α resulted in a response rate of 6-15%, a 25% decrease in tumour progression risk and a modest survival benefit compared to placebo [357, 358]. However, patients with intermediate-risk disease, failed to confirm this benefit [359].

Interferon- α may only be effective in some patient subgroups, including patients with ccRCC, favourable-risk criteria, as defined by the Memorial Sloan-Kettering Cancer Center (MSKCC) and lung metastases only [356]. The moderate efficacy of immunotherapy was confirmed in a Cochrane meta-analysis [358]. Bevacizumab + IFN- α increased response rates and PFS in first-line therapy compared with IFN- α monotherapy [360]. All studies comparing targeted drugs to IFN- α monotherapy therapy showed superiority for sunitinib, bevacizumab + IFN- α , and temsirolimus [360-363]. Interferon- α has been superseded by targeted therapy in cc-mRCC.

Table 7.1: The Metastatic Renal Cancer Database Consortium (IMDC) risk model [364]

Risk factors**	Cut-off point used
Karnofsky performance status	< 80%
Time from diagnosis to treatment	< 12 months
Haemoglobin	< Lower limit of laboratory reference range
Corrected serum calcium	> 10.0 mg/dL (2.4 mmol/L)
Absolute neutrophil count (neutrophilia)	> upper limit of normal
Platelets (thrombocytosis)	> upper limit of normal

* The MSKCC (Motzer) criteria are also widely used in this setting [357].

** Favourable (low) risk, no risk factors; intermediate risk, one or two risk factors; poor (high) risk, three to six risk factors.

7.4.2.2 Interleukin-2

Interleukin-2 has been used to treat mRCC since 1985, with response rates ranging from 7% to 27% [363, 365, 366]. Complete and durable responses have been achieved with high-dose bolus IL-2, however IL-2 remains the only drug to date that can cure a small percentage of RCC patients. [367]. The toxicity of IL-2 is substantially greater than that of IFN- α [358].

7.4.2.3 Vaccines and targeted immunotherapy

A vaccine trial with tumour antigen 5T4 + first-line standard therapy (i.e. sunitinib, IL-2 or IFN- α) showed no survival benefit compared with placebo and first-line standard therapy [368]. Several vaccination studies are ongoing. Monoclonal antibodies against programmed death-1 (PD-1) or its ligand (PD-1L), which have efficacy and acceptable toxicity in patients with RCC [369], are currently being investigated in phase III trials.

7.4.2.4 Immune checkpoint blockade

Immune checkpoint blockade with monoclonal antibodies target and block the inhibitory T-cell receptor PD-1 or cytotoxic T-lymphocyte associated antigen 4 (CTLA-4) signalling to restore tumour specific T-cell immunity [370]. A randomised dose-ranging phase II trial of nivolumab in metastatic RCC patients revealed a high objective response rate with rapid and durable responses in heavily pre-treated patients [371]. A phase III trial of nivolumab vs. everolimus after one or two lines of VEGF-targeted therapy (CheckMate 025, NCT01668784) reported a longer OS, better QoL and fewer Grade 3 or 4 adverse events with nivolumab than with everolimus [172, 372, 373]. Nivolumab has superior OS to everolimus ([HR]: 0.73, 95% CI: 0.57-0.93, $p < 0.002$) in VEGF-refractory RCC with a median OS of 25 months for nivolumab and 19.6 months for everolimus (LE: 1b). Patients who had failed multiple lines of VEGF-targeted therapy were included in this trial making the results broadly applicable. The trial included 15% MSKCC poor-risk patients. There was no PFS advantage with nivolumab despite the OS advantage. A phase III trial is currently investigating the combination of nivolumab and ipilimumab vs. sunitinib in first-line treatment (CheckMate 214, NCT 02231749) [167]. Combinations of VEGF-targeted therapy and immune therapy are also being investigated and include:

- Javelin Renal 101 - NCT02684006;
- IMmotion151 - NCT02420821;
- pembrolizumab + axitinib - NCT02133742;
- lenvatinib + everolimus or pembrolizumab - NCT02811861.

7.4.2.5 Summary of evidence and recommendations for immunotherapy in mRCC

Summary of evidence	LE
Interferon- α monotherapy is inferior to VEG-targeted therapy or mTOR inhibition in mRCC.	1b
Interleukin-2 monotherapy may have an effect in selected cases (good PS, ccRCC, lung metastases only).	2
IL-2 has more side-effects than IFN- α .	2
High dose (HD)-IL-2 is associated with durable complete responses in a limited number of patients. However, no clinical factors or biomarkers exist to accurately predict a durable response in patients treated with HD-IL-2.	1b
Bevacizumab plus IFN- α is more effective than IFN- α treatment-naïve, low-risk and intermediate-risk ccRCC.	1b
Vaccination therapy with tumour antigen 5T4 showed no survival benefit over first-line standard therapy.	1b
Cytokine combinations, with or without additional chemotherapy, do not improve OS compared with monotherapy.	1b
Nivolumab leads to superior OS compared to everolimus in patients failing one or two lines of VEGF-targeted therapy.	1b

Recommendations	grade	
Offer nivolumab after one or two lines of vascular endothelial growth factor-targeted therapy in metastatic RCC.	strong	↑↑
Do not offer monotherapy with interferon- α or high-dose bolus interleukin-2 as first-line therapy in metastatic RCC.	weak	↓

7.4.3 Targeted therapies

In sporadic ccRCC, hypoxia-inducible factor (HIF) accumulation due to VHL-inactivation results in over-expression of VEGF and platelet-derived growth factor (PDGF), which promote neo-angiogenesis [374-376]. This process substantially contributes to the development and progression of RCC. There are several targeting drugs approved for treating mRCC in both the USA and Europe.

Most published trials have selected for clear-cell carcinoma subtypes, thus no robust evidence-based recommendations can be given for non-ccRCC subtypes.

In major trials leading to registration of the approved targeted agents, patients were stratified according to the MSKCC risk model [356] (Table 7.1). Since the MSKCC (Motzer) criteria were developed during the cytokine era, the IMDC risk model has been established and validated to aid accurate prognosis of patients treated in the era of targeted therapy. Neutrophilia and thrombocytosis have been added to the list of MSKCC risk factors, while LDH has been removed [364].

The IMDC published data on conditional survival which may be used in patient counselling [377]. The IMDC risk model has been validated and compared with the Cleveland Clinic Foundation (CCF) model, the French model, MSKCC model, and the International Kidney Cancer Working Group (IKCWG) model. The IMDC model did not differ from the other models, indicating that a ceiling has been reached in predicting prognosis based solely on clinical factors [378]. Both the MSKCC and IMDC developed models for second-line treatment in the era of targeted therapy based, in part, on their risk models for treatment-naïve patients [379].

Table 7.2: Median OS and percentage of patients surviving two years treated in the era of targeted therapy per IMDC risk group (based on references [364, 378])

IMDC Model	Patients**		Median OS* (months)	2-y OS (95% CI)**
	n	%		
Favourable	157	18	43.2	75% (65-82%)
Intermediate	440	52	22.5	53% (46-59%)
Poor	252	30	7.8	7% (2-16%)

* Based on [378]; ** based on [364]

CI = confidence interval; IMDC = Metastatic Renal Cancer Database Consortium; OS = overall survival.

7.4.3.1 Tyrosine kinase inhibitors

7.4.3.1.1 Sorafenib

Sorafenib is an oral multi-kinase inhibitor. A trial compared sorafenib and placebo after failure of prior systemic immunotherapy or in patients unfit for immunotherapy. Sorafenib improved PFS [380] (HR: 0.44; 95% CI: 0.35-0.55; $p < 0.01$). Overall survival improved in patients initially assigned to placebo who were censored at crossover [381]. In patients with previously untreated mRCC sorafenib was not superior to IFN- α (phase II study). A number of studies have used sorafenib as the control arm in sunitinib-refractory disease vs. axitinib, dovitinib and temsirolimus. None showed superior survival for the study drug compared to sorafenib.

7.4.3.1.2 Sunitinib

Sunitinib is an oral tyrosine kinase (TK) inhibitor and has anti-tumour and anti-angiogenic activity. Sunitinib as second-line monotherapy (after cytokines) in patients with mRCC demonstrated a partial response in 34-40% and stable disease at > 3 months in 27-29% of patients [382]. First-line monotherapy with sunitinib demonstrated significantly longer PFS compared with IFN- α . Overall survival was greater in patients treated with sunitinib (26.4) vs. INF- α (21.8 months) despite crossover [383].

In the EFFECT trial, sunitinib 50 mg/day (four weeks on/two weeks off) was compared with continuous uninterrupted sunitinib 37.5 mg/day in patients with cc-mRCC [384]. Median time to progression (TTP) with sunitinib 50 mg was numerically longer than the 37.5 mg arm (9.9 months vs. 7.1 months). No significant differences in OS were seen (23.1 vs. 23.5 months; $p = 0.615$). Toxicity was comparable in both arms. Because of the non-significant, but numerically longer TTP with the standard 50 mg dosage, the authors recommended using this regimen. Alternate scheduling of sunitinib (two weeks on/one week off) is being used to manage toxicity, but robust data to support its use is lacking [385].

7.4.3.1.3 Pazopanib

Pazopanib is an oral angiogenesis inhibitor. In a trial of pazopanib vs. placebo in treatment-naïve mRCC patients and cytokine-treated patients, a significant improvement in PFS and tumour response was observed [386]. Median PFS with pazopanib compared with placebo was:

- 9.2 vs. 4.2 months in the overall study population;
- 11.1 vs. 2.8 months for the treatment-naïve subpopulation;
- 7.4 vs. 4.2 months for the cytokine-pre-treated subpopulation.

A trial comparing pazopanib with sunitinib (COMPARZ) established pazopanib as another first-line option. It showed that pazopanib was not associated with significantly worse PFS or OS compared to sunitinib. The two drugs had different toxicity profiles [387], and QoL was better with pazopanib. In another patient-preference study (PISCES), patients preferred pazopanib to sunitinib (70% vs. 22%; $p < 0.05$) due to symptomatic toxicity [388]. Both studies were limited in that intermittent therapy (sunitinib) was compared with continuous therapy (pazopanib).

7.4.3.1.4 Axitinib

Axitinib is an oral selective second-generation inhibitor of VEGFR-1, -2, and -3. Axitinib was first evaluated as second-line treatment. In the AXIS trial, axitinib was compared to sorafenib in patients with previously failed cytokine treatment or targeted agents (mainly sunitinib) [389].

The overall median PFS was greater for axitinib than sorafenib. The difference in PFS was greatest in patients in whom cytokine treatment had failed. For those in whom sunitinib had failed, axitinib was associated with a greater PFS than sorafenib (4.8 vs. 3.4 months). Axitinib showed $>$ Grade 3 diarrhoea in 11%, hypertension in 16%, and fatigue in 11%. Across all grades, nausea was recorded in 32%, vomiting in 24%, and asthenia in 21%. Overall survival was a secondary end-point of the trial in which crossover was not permitted. Final analysis of OS showed no significant differences between axitinib or sorafenib [390, 391].

In a randomised phase III trial of axitinib vs. sorafenib in first-line treatment-naïve cc-mRCC, a significant difference in median PFS between the treatment groups was not demonstrated [392]. As a result of this study, axitinib is not approved for first-line therapy.

7.4.3.1.5 Cabozantinib

Cabozantinib is an oral inhibitor of TK, including MET, VEGF and AXL. Cabozantinib was investigated in a phase I study in patients resistant to VEGFR and mTOR inhibitors demonstrating objective responses and disease control [171]. Based on these results a randomised phase III trial investigated cabozantinib vs. everolimus in patients with ccRCC failing one or more VEGF-targeted therapies (METEOR) [64]. Cabozantinib delayed PFS compared to everolimus in VEGF-targeted therapy refractory disease by 42% (HR: 0.58 95% CI: 0.45-0.75) [64] (LE: 1b). The median PFS for cabozantinib was 7.4 months (95% CI: 5.6-9.1) vs. 3.8 months (95% CI: 3.7-5.4) for everolimus. The trial recruited 658 patients although PFS was assessed on the first 375 patients. The median OS was 21.4 months (95% CI: 18.7 to not estimable) with cabozantinib and 16.5 months (95% CI 14.7-18.8) with everolimus in VEGF-resistant RCC. The HR for death was 0.66 (95% CI: 0.53-0.83; $p = 0.0003$) [393]. Grade 3 or 4 adverse events were reported in 74% with cabozantinib and 65% with everolimus. Adverse events were managed with dose reductions; doses were reduced in 60% of the patients who received cabozantinib. Discontinuation due to toxicity was not significantly different for the two drugs. The trial included 16% MSKCC poor-risk patients.

7.4.3.1.6 Lenvatinib

Lenvatinib is an oral multi-target TKI of VEGFR1, VEGFR2, and VEGFR3, with inhibitory activity against fibroblast growth factor receptors (FGFR1, FGFR2, FGFR3, and FGFR4), platelet growth factor receptor α (PDGFR α), re-arranged during transfection (RET), and receptor for stem cell factor (KIT). It has recently been investigated in randomised phase II study in combination with everolimus vs. lenvatinib or everolimus alone (see Section 7.4.6.1.1.5 for discussion of results).

7.4.4 **Monoclonal antibody against circulating VEGF**

7.4.4.1 *Bevacizumab monotherapy and bevacizumab + IFN- α*

Bevacizumab is a humanised monoclonal antibody. The double-blind AVOREN study compared bevacizumab + IFN- α with IFN- α monotherapy in mRCC [360]. Overall response was higher in the bevacizumab + IFN- α group. Median PFS increased from 5.4 months with IFN- α to 10.2 months with bevacizumab + IFN- α . No benefit was seen in MSKCC poor-risk patients. Median OS in this trial, which allowed crossover after progression, was not greater in the bevacizumab/IFN- α group (23.3 vs. 21.3) [394].

An open-label trial (CALGB 90206) [395, 396], of bevacizumab + IFN- α vs. IFN- α showed a higher median PFS for the combination group. Objective response rate was also higher in the combination group. Overall toxicity was greater for bevacizumab + IFN- α , with significantly more Grade 3 hypertension, anorexia, fatigue, and proteinuria.

7.4.5 **mTOR inhibitors**

7.4.5.1 *Temsirolimus*

Temsirolimus is a specific inhibitor of mTOR [397]. Patients with modified high-risk mRCC in the NCT00065468 trial received first-line temsirolimus or IFN- α monotherapy, or a combination of both [362]. Median OS was higher in the temsirolimus group. However, OS in the temsirolimus + IFN- α group was not significantly superior to IFN- α alone [362]. Interferon- α toxicity was marked, partly due to the high doses used. The INTORSECT trial investigated temsirolimus vs. sorafenib in patients who had previously failed sunitinib. Although no benefit in PFS was observed, a significant OS benefit for sorafenib was noted [398]. Based on these results, temsirolimus is not recommended in patients with VEGF TKI-refractory disease.

7.4.5.2 *Everolimus*

Everolimus is an oral mTOR inhibitor, which is established in the treatment of VEGF-refractory disease. The RECORD-1 study compared everolimus + best supportive care (BSC) vs. placebo + BSC in patients with previously failed anti-VEGFR treatment (or previously intolerant of VEGF-targeted therapy) [399]. The initial data showed a median PFS of four months vs. 1.9 months for everolimus and placebo, respectively [399]. This was extended to 4.9 months in the final analysis (HR: 0.33) [400]. Subset analysis of PFS for patients receiving only one previous VEGF TKI was 5.4 months [401]. This included some patients who were intolerant rather than progressed on therapy (PFS was also 5.4 months) [402]. RECORD-1 included patients who failed multiple lines of VEGF-targeted therapy, and received everolimus in a third- and fourth-line setting [399].

The RECORD-3 randomised phase II study of sequential first-line sunitinib and second-line everolimus vs. sequential first-line everolimus and second-line sunitinib in treatment-naïve mRCC reported a higher median

PFS for first-line treatment in the sunitinib group [403]. Primary endpoint was to assess PFS non-inferiority of first-line everolimus to first-line sunitinib. A large number of the crossover patients did not receive the planned subsequent therapy making further analysis complex and underpowered.

7.4.6 **Therapeutic strategies**

7.4.6.1 *Therapy for treatment-naïve patients with clear-cell mRCC*

Key trials have established sunitinib, pazopanib and bevacizumab plus IFN- α as first-line treatment options in treatment-naïve patients with cc-mRCC and a favourable-to-intermediate risk score. The evidence for subsequent therapies after temsirolimus in poor-risk patients is unclear. It is therefore more appealing to treat poor-risk patients with sunitinib or pazopanib, both of which were tested in pivotal trials in this population.

7.4.6.1.1 Sequencing targeted therapy

7.4.6.1.1.1 Following progression of disease with one or more lines of VEGF-targeted therapy

Several trials investigated therapeutic options for patients who progressed on first-line VEGF-targeted therapy, including studies which investigated options after one or more lines of VEGF-targeted therapy. RECORD-1 established VEGF TKI therapy until disease progression, followed by everolimus as one of the treatment options for patients with mRCC [399]. However, both nivolumab and cabozantinib were superior to everolimus following a similar trial design as RECORD-1 [172]. Both of these agents should be considered a new standard of care in patients of all risk categories who have failed one or more VEGF-targeted therapies (Figure 7.1).

Nivolumab should be considered for all patients in whom it is not contraindicated in the VEGF-refractory setting owing to a significant OS advantage compared to everolimus, as well as its attractive tolerability profile. Cabozantinib is the first TKI to have both a superior PFS and OS compared to everolimus. Both nivolumab and cabozantinib have different toxicity profiles.

Axitinib is superior to sorafenib in terms of PFS in sunitinib-refractory ccRCC [388]. Neither nivolumab nor cabozantinib has been tested directly against axitinib in the second-line setting. However, the OS advantage of both drugs and tolerability of nivolumab over everolimus in this setting makes them preferable to axitinib.

Tolerability is an important consideration when recommendations cannot be made for efficacy alone. Both everolimus and sorafenib have been outperformed by other agents in VEGF-refractory disease and should not be the standard of care in pure VEGF-refractory disease where superior alternatives are available. It is not currently possible to determine therapy based on baseline characteristics or biomarker expression for any of the above drugs.

Direct comparison of RECORD-1, Checkmate-25 and METEOR data with AXIS data is not advised due to differences in patient populations [389-391, 399].

INTORSECT compared temsirolimus vs. sorafenib after disease progression on sunitinib [398]. Median PFS was higher, but not significant, in the temsirolimus group. However, there was a significant difference in OS in favour of sorafenib. Neither of these agents are recommended or widely used in this setting. These data are not necessarily relevant to other mTOR inhibitors such as everolimus.

Based on difference in OS, recommendations can currently be made as to the best sequence of targeted therapy (Figure 7.1). Two major trials, testing nivolumab and cabozantinib, have changed treatment paradigms in VEGF-refractory RCC (LE: 1a). There is a strong rationale for using both drugs in sequence in the second and third line following VEGF-targeted therapy. This creates a new a standard for the majority of patients.

7.4.6.1.1.2 Treatment after progression of disease with mTOR inhibition

There are limited data addressing this issue. In view of the efficacy of VEGF-targeted therapy in renal cancer, a switch to VEGF-targeted therapy is advised (Panel consensus in conjunction with Motzer *et al.* [404]).

7.4.6.1.1.3 Treatment after progression of disease with cytokines

Trials have established sorafenib, axitinib and pazopanib as therapeutic options in this setting with a median PFS of 5.5, 12.1 and 7.4 months, respectively. Based on trial data, axitinib is superior to sorafenib in patients previously treated with cytokine therapy [389-391].

7.4.6.1.1.4 Treatment after second-line targeted therapy

7.4.6.1.1.4.1 Treatment after two VEGF-targeted therapies

Based on the results of the nivolumab and cabozantinib trials, a strong rationale exists for preferring both drugs as third-line treatment upon failure of two VEGF-targeted therapies [64, 172] (Figure 7.1).

7.4.6.1.1.4.2 Treatment after VEGFR- and mTOR inhibition

Although the GOLD trial failed to demonstrate superior efficacy of dovitinib over sorafenib in patients with mRCC who experienced disease progression after receiving prior VEGF- and mTOR-targeted therapies, the results suggest efficacy and safety of sorafenib in the third-line setting [404]. This sequence is not recommended when alternative superior drugs are available.

7.4.6.1.1.4.3 Combination of targeted agents

No combinations of targeted agents are currently recommended, however, there have been a number of trials with VEGF-targeted therapy and mTOR inhibitors [405-409]. A small randomised phase II trial in which 153 patients received either lenvatinib plus everolimus (n = 51), single-agent lenvatinib (n = 52), or single-agent everolimus (n = 50) demonstrated a PFS benefit for the combination [410]. Lenvatinib plus everolimus significantly prolonged PFS compared with everolimus alone (median 14.6 months [95% CI: 5.9-20.1] vs. 5.5 months [3.5-7.1]; HR: 0.40; 95% CI: 0.24-0.68; p = 0.0005), but not compared with lenvatinib alone (7.4 months [95% CI: 5.6-10.2]; HR: 0.66; 95% CI: 0.30-1.10; p = 0.12). In a post-hoc updated analysis (data cut-off Dec 10, 2014), the difference in OS between lenvatinib plus everolimus vs. single-agent everolimus was significantly increased, median OS 25.5 months [95% CI: 16.4-NE] vs. 15.4 months [11.8-19.6]; HR: 0.51; 95% CI: 0.30-0.88; p = 0.024. Grade 3 or worse serious adverse events occurred in 23 (45%) patients allocated to lenvatinib plus everolimus, 23 (44%) allocated to single-agent lenvatinib, and 19 (38%) allocated to single-agent everolimus.

7.4.6.2 *Non-clear-cell renal cancer*

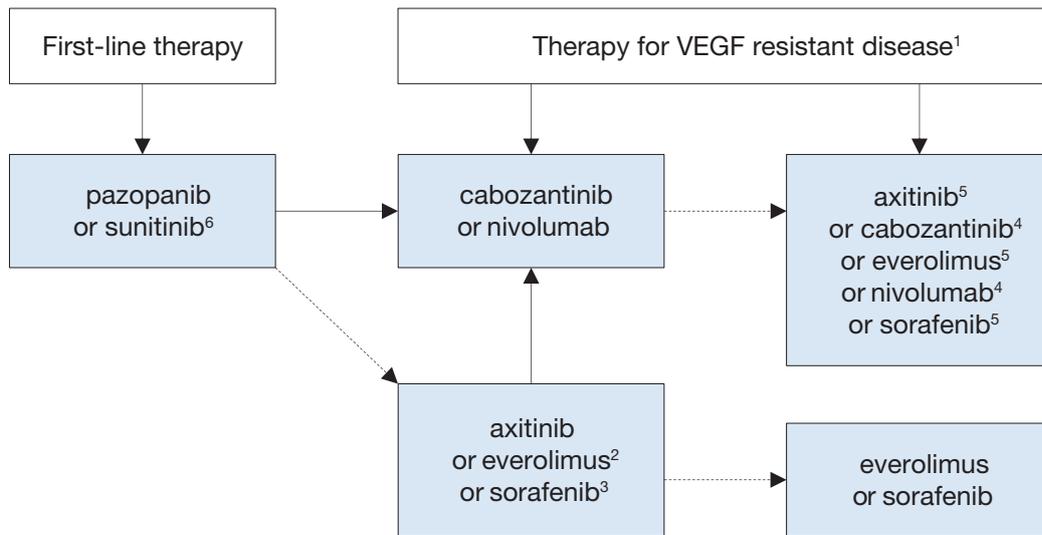

No phase III trials of patients with non-ccRCC have been reported. Expanded access programmes and subset analysis from RCC studies suggest the outcome of these patients with targeted therapy is poorer than for ccRCC. Targeted treatment in non-ccRCC has focused on temsirolimus, everolimus, sorafenib and sunitinib [362, 411-413].

The most common non-clear-cell subtypes are papillary type 1 and non-type 1 papillary RCCs. There are small single-arm trials for sunitinib and everolimus [413-416]. A trial of both types of pRCC treated with everolimus (RAPTOR) [416], showed a median PFS of 3.7 months per central review in the intention-to-treat population with a median OS of 21.0 months.

Another trial investigated foretinib (a dual MET/VEGFR2 inhibitor) in patients with pRCC. Toxicity was acceptable with a high relative risk in patients with germline MET mutations [417]. However, a randomised phase II trial of everolimus vs. sunitinib (ESPN) with crossover design in non-cc-mRCC including 73 patients (27 with pRCC) was stopped after a futility analysis for PFS and OS [418]. The final results presented at the 2014 annual meeting of the American Society of Clinical Oncology showed a non-significant trend favouring sunitinib (6.1 vs. 4.1 months). Based on a SR including subgroup analysis of the ESPN, RECORD-3 and another phase II trial (ASPEN) sunitinib and everolimus remain options in this population, with a preference for sunitinib [136, 419, 420]. Patients with non-cc-mRCC should be referred to a clinical trial where appropriate.

Collecting-duct cancers are resistant to systemic therapy. There is a lack of data to support specific therapy in these patients. There is limited data supporting the use of targeted therapy in other histological subtypes such as chromophobe tumours [362, 411].

Figure 7.1: Recommendations for patients with metastatic ccRCC who have failed one or more lines of VEGF targeted therapy

¹ Switch to therapies not given previously.
² Nivolumab and cabozantinib have not been given after everolimus and therefore cannot be recommended above other agents.
³ Sorafenib has an inferior progression-free survival to axitinib.
⁴ These drugs have shown a survival advantage in VEGF-resistant disease but not in this specific setting.
⁵ These drugs were given after progression in the pivotal cabozantinib or nivolumab trials [64, 172].
⁶ Sunitinib and pazopanib can be recommended in all MSKCC risk groups. Bevacizumab/interferon (favourable- and intermediate-risk disease) and temsirolimus (poor-risk disease) have not been widely used as first-line therapy in the pivotal VEGF-resistant trials and therefore recommendations are not possible.

Table 7.3: EAU 2017 evidence-based recommendations for systemic therapy in patients with mRCC

RCC type	MSKCC risk group [356]	First-line	LE [^]	Second-Line after VEGF therapy*	LE [^]	Third-line*	LE [^]	Later lines	LE
Clear cell*	Favourable, intermediate and poor	sunitinib pazopanib bevacizumab + IFN- α (favourable-intermediate only)	1b 1b 1b	based on OS: nivolumab cabozantinib based on PFS: axitinib sorafenib [#] everolimus ^{&}	2b 2b 2b 2b 2b	after VEGF therapy: nivolumab cabozantinib everolimus ^{&} after VEGF and mTOR therapy: sorafenib after VEGF and nivolumab: cabozantinib axitinib everolimus	2b 2b 2b 1b 4 4 4	any targeted agent	4
Clear cell*	poor	temsirolimus sunitinib pazopanib	1b 2b 2b	any targeted agent	4

7.4.6.3 Summary of evidence and recommendations for systemic therapy in metastatic renal cell cancer

Summary of evidence	LE
VEGF and TKIs increase PFS and/or OS as both first-line and second-line treatments for clear-cell mRCC.	1b
Axitinib has proven efficacy and superiority in PFS as a second-line treatment after failure of cytokines and VEGF-targeted therapy in comparison with sorafenib.	1b
Sunitinib is more effective than IFN-α in treatment-naïve patients.	1b
Bevacizumab plus IFN-α is more effective than IFN-α in treatment-naïve low-risk and intermediate-risk patients.	1b
pazopanib is superior to placebo in both naïve mRCC patients and post-cytokine patients.	1b
First line pazopanib is not inferior to sunitinib in clear-cell mRCC patients.	1b
Temsirolimus monotherapy prolongs OS compared to IFN-α in poor-risk mRCC.	1b
Nivolumab is superior to everolimus in terms of OS and adverse events in patients failing one or two lines of VEGF-targeted therapy.	1b
Cabozantinib is superior to everolimus in terms of PFS and OS in patients failing one or more lines of VEGF-targeted therapy.	1b
Everolimus prolongs PFS in patients who have previously failed or are intolerant of VEGF-targeted therapy when compared to placebo.	1b
Sorafenib has broad activity in a spectrum of settings in ccRCC patients previously treated with cytokine or targeted therapies. It is inferior to axitinib in both sunitinib or cytokine pre-treated patients.	4
Both mTOR inhibitors (everolimus and temsirolimus) and VEGF-targeted therapies (sunitinib or sorafenib) can be used in non-clear cell RCC.	3
No combination has proven to be better than single-agent therapy, with the exception of the combination of lenvatinib plus everolimus.	1a

Recommendations	grade	
Offer sunitinib or pazopanib as first-line therapy for metastatic clear-cell renal cell cancer (ccRCC).	strong	↑↑
Consider offering bevacizumab + Interferon (IFN)- α as first-line therapy for metastatic RCC in favourable and intermediate-risk ccRCC.	weak	↑
Consider offering temsirolimus as first-line treatment in poor-risk RCC patients.	weak	↑
Offer cabozantinib for ccRCC after one or two lines of vascular endothelial growth factor (VEGF)-targeted therapy in metastatic RCC.	strong	↑↑
Offer nivolumab after one or two lines of VEGF-targeted therapy in metastatic RCC.	strong	↑↑
Offer axitinib or everolimus to ccRCC patients who failed VEGF-targeted therapy, and when nivolumab or cabozantinib are not safe, tolerable or available.	strong	↑↑
Sequence targeted agents in treating metastatic RCC.	strong	↑↑
Sunitinib can be offered as first-line therapy for non-clear cell mRCC.	weak	↑

7.5 Recurrent RCC

7.5.1 Introduction

Locally recurrent disease can occur after RN, PN and thermal ablation. After nephron-sparing treatment the recurrence may be intrarenal and/or regional, e.g. venous tumour thrombi or retroperitoneal LN metastases. Both are often summarised as loco-regional recurrences. Recurrence for pT1 tumours after PN are observed in 2.2% and are generally managed surgically depending on the extent of the loco-regional recurrence [421]. After thermal ablation loco-regional recurrences (intrarenal and regional) have been described in up to 12% [422]. Repeated ablation has often been recommended for intrarenal recurrences following thermal ablation. For loco-regional recurrences surgical resection is mandatory and has been described for isolated local recurrences following nephrectomy.

After nephrectomy locally recurrent disease is defined as disease recurring in the renal fossa or remnant kidney. However, metastasis in the non-removed ipsilateral adrenal or non-resected LNs makes interpretation of the true incidence of isolated recurrence in the renal fossa difficult. Treatment of adrenal metastases or LN metastases are often described in series of metastasectomy (see Section 7.3). Isolated local recurrence, however, is rare.

The largest series on the treatment of isolated recurrence was published in 2009 [423]. In 2,945 patients who underwent nephrectomy the authors identified 54 isolated local recurrences in the renal fossa. These, however, included recurrences to the ipsilateral adrenal and LNs. Exclusively retrospective non-comparative data exist which suggest that aggressive local resection offers durable local tumour control and improves survival. Adverse prognostic factors were, a positive surgical margin after resection, the size of the recurrence and sarcomatoid histologic features [423]. In cases where complete surgical removal is not feasible due to advanced tumour growth and pain, palliative treatments including radiation treatment can be considered.

7.5.2 Summary of evidence and recommendation for advanced/metastatic RCC

Summary of evidence	LE
Isolated recurrence in the local renal fossa is rare.	3
Patients who undergo resection of local recurrences in the absence of sarcomatoid features may benefit from durable local control and improved survival.	3

Recommendation	grade	
Offer surgical resection of local recurrent disease, when feasible.	weak	↑

8. FOLLOW-UP IN RCC

8.1 Introduction

Surveillance after treatment for RCC allows the urologist to monitor or identify:

- post-operative complications;
- renal function;
- local recurrence;
- recurrence in the contralateral kidney;
- development of metastases.

There is no consensus on surveillance after RCC treatment, and there is no evidence that early vs. later diagnosis of recurrences improves survival. However, follow-up is important to increase the available information on RCC, and should be performed by a urologist, who should record the time to recurrence or the development of metastases. Patients undergoing follow-up seem to have a longer OS when compared to patients not undergoing routine follow-up [424].

An individualised, risk-based, approach to RCC surveillance was recently proposed. The authors use competing risk models, incorporating patient age, pathologic stage, relapse location and comorbidities, to calculate when the risk of non-RCC death exceeds the risk of RCC recurrence [425]. For patients with low-stage disease but with a Charlson comorbidity index ≥ 2 , the risk of non-RCC death exceeded that of abdominal recurrence risk already one month after surgery, regardless of patient age.

Renal function is assessed by the measurement of serum creatinine and eGFR. Repeated long-term monitoring of eGFR is indicated in case of impaired renal function before, or after, surgery. Renal function [426, 427] and non-cancer survival [196, 428, 429] can be optimised by performing NSS, whenever possible, for T1 and T2 tumours [430] (LE: 3). Recurrence after PN is rare, but early diagnosis is useful, as the most effective treatment is redux surgery [431, 432]. Recurrence in the contralateral kidney is also rare and might be related to positive margins, multifocality, and grade [433] (LE: 3). Surveillance can identify local recurrences or metastases at an early stage. In metastatic disease, extended tumour growth can limit the opportunity for surgical resection, which is considered the standard therapy in cases of resectable and preferably solitary lesions. In addition, early diagnosis of tumour recurrence may enhance the efficacy of systemic treatment if the tumour burden is low.

8.2 Which investigations for which patients, and when?

There is no high level evidence to support any surveillance scheme. However, intensive radiological surveillance for all patients is not necessary. The outcome after surgery for T1a low-grade tumours is almost always excellent. It is therefore reasonable to stratify the follow up, taking into account the risk of developing recurrence or metastases. Although there is no randomised evidence, large studies have examined prognostic factors with long follow-up periods [35, 434, 435] (LE: 4). One study has shown a survival benefit for patients who were followed within a structured surveillance protocol vs. patients who were not [424]:

- The sensitivity of chest radiography and US for small metastases is poor. Surveillance with these imaging modalities should not be done [436].
- In low-risk tumours, surveillance intervals should be adapted taking into account radiation exposure and benefit. To reduce radiation exposure, MRI can be used outside the thorax.
- When the risk of relapse is intermediate or high, CT of the chest and abdomen should be performed.
- Surveillance should also include evaluation of renal function and cardiovascular risk factors.
- Positron-emission tomography and PET-CT as well as bone scintigraphy should not be used in RCC surveillance, due to their limited specificity and sensitivity.
- The risk of acute renal failure seems to be negligible in patients with a GFR > 20 mL/min and chronic renal impairment [437].

Controversy exists on the optimal duration of follow-up. Some argue that follow-up with imaging is not cost-effective after five years; however, late metastases are more likely to be solitary and justify more aggressive therapy with curative intent. In addition, patients with tumours that develop in the contralateral kidney can be treated with NSS if the tumours are detected early. For tumours < 4 cm, there is no difference between PN and RN with regard to recurrences during follow up [438] (LE: 3).

Several authors [182, 184, 439, 440], have designed scoring systems and nomograms to quantify the likelihood of patients developing tumour recurrences, metastases, and subsequent death. These systems have been compared and validated [441] (LE: 2). Using prognostic variables, several stage-based surveillance

regimens have been proposed [442, 443], but none include ablative therapies. A post-operative nomogram is available to estimate the likelihood of freedom from recurrence at five years [179]. Recently, a pre-operative prognostic model based on age, symptoms, and TNM staging has been published and validated [188] (LE: 3). A surveillance algorithm for monitoring patients after treatment for RCC is needed, recognising not only the patient's risk profile, but also efficacy of the treatment given (Table 8.1). These prognostic systems can be used to adapt the surveillance schedule according to suspected risk of recurrence.

Data from adjuvant trials are generally based on the University of California Los Angeles integrated staging system (UISS) risk stratification, which makes it the most widely used, and validated system [162, 444].

Table 8.1: Proposed surveillance schedule following treatment for RCC, taking into account patient risk profile and treatment efficacy

Risk profile	Surveillance						
	6 mo	1 y	2 y	3 y	4 y	5 y	> 5 y
Low	US	CT	US	CT	US	CT	Discharge
Intermediate	CT	CT	CT	US	CT	CT	CT once every 2 years
High	CT	CT	CT	CT	CT	CT	CT once every 2 years

CT = computed tomography of chest and abdomen, alternatively use MRI;

US = ultrasound of abdomen, kidneys and renal bed.

8.3 Summary of evidence and recommendations for surveillance following RN or PN or ablative therapies in RCC

Summary of evidence	LE
Surveillance can detect local recurrence or metastatic disease while the patient is still surgically curable.	4
After NSS, there is an increased risk of recurrence for larger (> 7 cm) tumours, or when there is a positive surgical margin.	3
Patients undergoing surveillance have a better overall survival than patients not undergoing surveillance.	3

Recommendations	grade	
Base follow-up after RCC on the risk of recurrence.	strong	↑↑
For low-risk disease, computed tomography (CT)/magnetic resonance imaging (MRI) can be used infrequently.	weak	↑
In intermediate-risk patients, offer intensified follow-up, including chest and abdominal CT/MRI scans at regular intervals in accordance with a risk-stratified nomogram.	weak	↑
In high-risk patients, include chest and abdominal CT/MRI scans in follow-up examinations.	weak	↑
Intensify follow-up in patients after NSS for tumours > 7 cm or in patients with a positive surgical margin.	weak	↑
Base risk stratification on pre-existing classification systems such as the University of California Los Angeles integrated staging system integrated risk assessment score (http://urology.ucla.edu/body.cfm?id=443).	strong	↑↑

UISS = University of California Los Angeles integrated staging system.

8.4 Research priorities

There is a clear need for future research to determine whether follow-up can optimise patient survival. Further information should be sought at what time point restaging has the highest chance to detect recurrence. Prognostic markers at surgery should be investigated to determine the risk of relapse over time.

10. CONFLICT OF INTEREST

All members of the Renal Cell Cancer working group have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website: <https://uroweb.org/guideline/renal-cell-carcinoma/?type=panel/>.

This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

1. INTRODUCTION

1.1 Aim and objectives

The aim of these guidelines is to present the current evidence for the diagnosis and treatment of patients with cancer of the testis. Testicular cancer represents 5% of urological tumours affecting mostly younger males. This document addresses germ-cell tumours and sex cord/gonadal stromal tumours.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The European Association of Urology (EAU) Guidelines Panel on Testicular Cancer consists of a multidisciplinary group of clinicians including, urologists, oncologists, radiotherapists and a pathologist. Members of this panel have been selected, based on their expertise, to represent the professionals treating patients suspected of having testis cancer. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: <http://www.uroweb.org/guideline/testicular-cancer/>.

1.3 Available publications

A quick reference document (Pocket guidelines) is available, both in print and in a number of versions for mobile devices. These are abridged versions which may require consultation together with the full text version. Several scientific publications are available as are a number of translations of all versions of the EAU Testicular Cancer Guidelines. All documents can be viewed on the EAU website: <http://www.uroweb.org/guideline/testicular-cancer/>.

1.4 Publication history and summary of changes

1.4.1 Publication history

The European Association of Urology (EAU) published the first guidelines on Testicular Cancer in 2001. Since 2008, the Testicular Cancer Guidelines contain a separate chapter on testicular stromal tumours. This document presents a limited update of the 2016 publication. Review papers have been published in the society's scientific journal European Urology, the latest version dating to 2015 [1].

1.4.2 Summary of changes

For the 2017 Testicular Cancer Guidelines, new references have been added throughout the 2017 Testicular Cancer Guidelines document. Key changes in this publication include:

- Section 5.7 - Germ cell tumours histological markers. This is a new table.
- Table 7.2 - An alternative schedule for salvage chemotherapy has been included.
- Chapter 8 - Section 8.1 Rationale for follow up, has been completely replaced, including three new tables, based on the findings of an ESMO Testis Cancer Consensus Committee.

Recommendations were changed in the following sections:

5.9 Guidelines for the diagnosis and staging of testicular cancer

Recommendations	GR
Advise patients with a familiar history of testis cancer, as well as their family members, to perform regular testicular self-examination.	A

7.2.2.6 Risk-adapted treatment for clinical stage 1 based on vascular invasion

Stage 1B (pT2-pT4): high risk	GR
Offer surveillance to patients not willing to undergo adjuvant chemotherapy.	A*
Offer nerve-sparing RPLND to highly selected patients only; those with contraindication to adjuvant chemotherapy and unwilling to accept surveillance.	A*

*Upgraded following panel consensus.

7.4.6 Guidelines for the treatment of metastatic germ cell tumours

Recommendations	LE	GR
Initially offer radiotherapy for seminoma CS IIA. When necessary, use chemotherapy as a salvage treatment with the same schedule as for the corresponding prognostic groups of NSGCT.	1a	A
Initially offer chemotherapy in seminoma stage CS IIB (BEP x 3 or etoposide, cisplatin (EP) x 4, in good prognosis) as an alternative to radiotherapy.	1a	A

Table 8.1: Recommended minimal follow-up for seminoma stage I on active surveillance or after adjuvant treatment (carboplatin or radiotherapy)

Modality	Year 1	Year 2	Year 3	Years 4 & 5	After 5 years
Tumour markers ± doctor visit	2 times	2 times	2 times	once	Further management according to survivorship care plan
Chest X-ray	-	-	-	-	
Abdominopelvic computed tomography/ magnetic resonance imaging	2 times	2 times	Once at 36 months	Once at 60 months	

Table 8.2: Recommended minimal follow-up for non-seminoma stage I on active surveillance

Modality	Year 1	Year 2	Year 3	Years 4 & 5	After 5 years
Tumour markers ± doctor visit	4 times**	4 times	2 times	1-2 times	Further management according to survivorship care plan
Chest X-ray	2 times	2 times	Once, in case of LVI+	At 60 months if LVI+	
Abdominopelvic computed tomography/ magnetic resonance imaging	2 times	At 24 months***	Once at 36 months*	Once at 60 months*	

* Recommended by 50% of consensus group members.

**In case of high risk (LVI+) a minority of consensus group members recommended six times.

***In case of high risk (LVI+) a majority of consensus group members recommended an additional CT at eighteen months.

Table 8.3: Recommended minimal follow up after adjuvant treatment or complete remission for advanced disease (excluded: poor prognosis and no remission)

Modality	Year 1	Year 2	Year 3	Years 4 & 5	After 5 years
Tumour markers ± doctor visit	4 times	4 times	2 times	2 times	Further management according to survivorship care plan**
Chest X-ray	1-2 times	Once	Once	Once	
Abdominopelvic computed tomography/ magnetic resonance imaging	1-2 times	At 24 months	Once at 36 months	Once at 60 months	
Thorax CT	*	*	*	*	

*Same time points as abdomino-pelvic CT/MRI in case of pulmonary metastases at diagnosis.

**In case of teratoma in resected residual disease: patient should remain with uro-oncologist.

2. METHODS

For the Germ Cell Tumour section, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature. The search was limited to studies representing high levels of evidence only (i.e. systematic reviews with meta-analysis, randomised controlled trials (RCTs), and prospective non-randomised comparative studies) published in the English language. The search was restricted to articles published between Jan 1st 2010 and September 28th, 2016. Databases covered by the search included Pubmed, Ovid, EMBASE and the Cochrane Central Register of Controlled Trials and the Cochrane Database of Systematic Reviews. After deduplication, a total of 1,735 unique records were identified, retrieved and screened for relevance. A detailed search strategy is available on line:

<https://uroweb.org/guideline/non-muscle-invasive-bladder-cancer/?type=appendices-publications>.

For Testicular Stromal tumours additional literature has been added. A formal scoping search covering the time frame between Jan 1st, 2009 and October 13th, 2014 was performed, without restrictions applied on data level.

Recommendations in this text are assessed according to their level of evidence (LE) and Guidelines are given a grade of recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [2]. Additional information can be found in the general Methodology section of this print, and online at the EAU website: <http://uroweb.org/guidelines/>.

A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.1 Review

This document was subjected to peer review prior to publication in 2015.

2.2 Future goals

The results of an ongoing systematic review, performed using standard Cochrane systematic review methodology, will be included in 2018 update of the Testicular Cancer Guidelines: <http://www.cochranelibrary.com/about/about-cochrane-systematic-reviews.html>.

Ongoing systematic review:

- Tumour size and rete testis invasion in the radical orchiectomy specimens of patients with clinical stage I seminoma testis undergoing active surveillance risk factors for developing disease recurrence [3].

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Testicular cancer represents 1% of male neoplasms and 5% of urological tumours, with 3-10 new cases occurring per 100,000 males/per year in Western societies [4, 5]. Its incidence has been increasing during the last decades especially in industrialised countries [5-7]. Data from the Surveillance Epidemiology and End Results programme (1992 to 2011) show a continuing increased risk among Caucasian men in the USA for seminoma [8].

At diagnosis, 1-2% of cases are bilateral and the predominant histology is germ cell tumour (90-95% of cases) [4]. Peak incidence is in the third decade of life for non-seminoma, and in the fourth decade for pure seminoma.

Testicular cancers (TC) show excellent cure rates based on, their chemosensitivity especially to cisplatin-based chemotherapy [9], careful staging at diagnosis, adequate early treatment based on a multidisciplinary approach and strict follow-up and salvage therapies. A decrease in the meantime of delay to diagnosis and treatment has been observed. Although early stages can be successfully treated in a non-reference centre, the relapse rate is higher [10, 11]. In poor prognosis non-seminomatous germ cell tumours (NSGCT), overall survival (OS) within a clinical trial depends on the number of patients treated at the participating centre (worse if < 5 patients enrolled) [12]. In the same context, the frequency of post-chemotherapy residual tumour resection is associated with peri-operative mortality and OS [13, 14]. Establishment of second-opinion clinics for testicular cancer patients may prevent over- and under-treatment [15].

Genetic changes have been described in patients with TC. A specific genetic marker, an isochromosome of the short arm of chromosome 12 - i(12p) - has been described in all histological types of germ cell tumours [16] and in germ cell neoplasia *in situ* (GCNIS). Alterations in the p53 locus have been identified in 66% of cases of GCNIS [17] and association between genetic polymorphism in the PTEN tumours suppressor gene and risk of testicular germ cell tumours (TGCT) has been recently described [18]. A deregulation in the pluripotent programme of foetal germ cells (identified by specific markers, M2A, C-KIT and OCT4/NANOG) is likely responsible for the development of GCNIS and germ cell neoplasia. In line with this, significant association between markers at loci 4q22.2, 7p22.3, 16q22.3 and 17q22, all of which encoding proteins for male cell germ development and susceptibility for TGCT has been described [19]. There is overlap in the development to seminoma and embryonal carcinoma as shown by genome-wide expression analysis and detection of alpha-fetoprotein (AFP) mRNA in some atypical seminoma [20, 21].

Epidemiological risk factors for the development of testicular tumours are components of the testicular dysgenesis syndrome (i.e. cryptorchidism, hypospadias, decreased spermatogenesis evidenced by sub- or infertility) [22, 23], familial history of testicular tumours among first-grade relatives and the presence of a contralateral tumour or GCNIS [16, 22, 24-28]. A recent systematic review confirmed the association between height and TGCT with an odds ratio (OR) of 1.13 per 5 cm increase in height [29].

3.2 Pathological classification

The recommended pathological classification shown below is based on the 2016 update of the World Health Organization (WHO) pathological classification [30].

1. Germ cell tumours

- Derived from germ cell neoplasia *in situ* (GCNIS)
- Germ cell neoplasia *in situ*

Seminoma

- Embryonal carcinoma
- Yolk sac tumour, post-pubertal type
- Trophoblastic tumours
- Teratoma, post-pubertal type
- Teratoma with somatic-type malignancies
- Mixed germ cell tumours

2. Germ cell tumours unrelated to GCNIS

- Spermatocytic tumour
- Yolk sac tumour, pre-pubertal type
- Mixed germ cell tumour, pre-pubertal type

3. Sex cord/stromal tumours

- Leydig cell tumour
 - Malignant Leydig cell tumour
- Sertoli cell tumour
 - Malignant Sertoli cell tumour
 - Large cell calcifying Sertoli cell tumour
 - Intratubular large cell hyalinising Sertoli cell neoplasia
- Granulosa cell tumour
 - Adult type
 - Juvenile type
- Thecoma/fibroma group of tumours
- Other sex cord/gonadal stromal tumours
 - Mixed
 - Unclassified
- Tumours containing both germ cell and sex cord/gonadal stromal
 - Gonadoblastoma

4. Miscellaneous non-specific stromal tumours

- Ovarian epithelial tumours
- Tumours of the collecting ducts and rete testis
 - Adenoma
 - Carcinoma

- Tumours of paratesticular structures
 - Adenomatoid tumour
 - Mesothelioma (epithelioid, biphasic)
 - Epididymal tumours
- Cystadenoma of the epididymis
- Papillary cystadenoma
- Adenocarcinoma of the epididymis
- Mesenchymal tumours of the spermatic cord and testicular adnexae.

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Diagnostic tools

To determine the presence of macroscopic or occult metastatic disease, the half-life kinetics of serum tumour markers as well as the presence of nodal or visceral metastases need to be assessed. Consequently, it is mandatory to assess:

- the pre- and post-orchietomy half-life kinetics of serum tumour markers;
- the status of retroperitoneal and supraclavicular lymph nodes, bone and liver;
- the presence or absence of mediastinal nodal involvement and lung metastases;
- the status of brain and bone in cases of suspicious symptoms or high-risk disease, e.g. poor International Germ Cell Cancer Collaborative Group (IGCCCG) risk group, high human chorionic gonadotropin (hCG) and/or multiple pulmonary metastases.

The minimum mandatory tests are:

- serial blood sampling;
- abdominopelvic and chest computed tomography (CT).

4.2 Serum tumour markers: post-orchietomy half-life kinetics

The mean serum half-life of AFP and hCG is five to seven days and two to three days, respectively [31]. Tumour markers need to be re-evaluated after orchietomy to determine half-life kinetics. Marker decline in patients with clinical stage (CS) I disease should be assessed until normalisation has occurred. Markers before the start of chemotherapy are important to classify the patient according to the IGCCCG risk classification [32]. The persistence of elevated serum tumour markers after orchietomy might indicate the presence of metastatic disease (macro- or microscopically), while the normalisation of marker levels after orchietomy does not rule out the presence of tumour metastases. During chemotherapy, the markers should decline; persistence has an adverse prognostic value [33, 34]. Slow marker decline in patients with poor prognosis during the first cycle of standard bleomycin, etoposide and cisplatin (BEP) chemotherapy can be used as an indication for early chemotherapy dose intensification [35].

4.3 Retroperitoneal, mediastinal and supraclavicular lymph nodes and viscera

Retroperitoneal and mediastinal lymph nodes are best assessed by CT. The supraclavicular nodes are best assessed by physical examination followed by CT in cases of suspicion.

Abdominopelvic CT offers a sensitivity of 70-80% in determining the state of the retroperitoneal nodes. Its accuracy depends on the size and shape of the nodes; sensitivity and the negative predictive value increase using a 3 mm threshold to define metastatic nodes in the landing zones [36]. Those figures decrease slightly in stages I and II [37, 38], with a rate of understaging of 25-30% [39].

Magnetic resonance imaging (MRI) produces similar results to CT in the detection of retroperitoneal nodal enlargement [40, 41]. Again, the main objections to its routine use are its high cost and limited availability. Nevertheless, MRI can be helpful when abdominopelvic CT or ultrasound (US) are inconclusive [40], when CT is contraindicated because of allergy to contrast media containing iodine, or when the physician or the patient are concerned about radiation dose. MRI is an optional test, and there are currently no indications for its systematic use in the staging of TC.

A chest CT is the most sensitive way to evaluate the thorax and mediastinal nodes. This exploration is recommended in all patients with TC as up to 10% of cases can present with small subpleural nodes that are not visible on an X-ray [42]. A CT has high sensitivity, but low specificity.

There is no evidence to support the use of fluorodeoxyglucose-positron emission tomography (PET) (FDG-PET) in the staging of testis cancer [43, 44]. It is recommended in the follow up of patients with seminoma with a residual mass larger than 3 cm and should not be performed before eight weeks after

completing the last cycle of chemotherapy in order to decide on watchful waiting or active treatment [45, 46]. Fluorodeoxyglucose-PET is not recommended in the re-staging of patients with NSGCT after chemotherapy [47].

Other examinations, such as brain or spinal CT, bone scan or liver US, should be performed if there is suspicion of metastases to these organs. A CT or MRI of the brain is advisable in patients with NSGCT, multiple lung metastases and poor prognosis IGCCG risk group (e.g. high beta-hCG values). Table 4.1 shows the recommended tests at staging.

Table 4.1: Recommended tests for staging at diagnosis

Test	Recommendation	GR
Serum tumour markers	Alpha-fetoprotein human chorionic gonadotrophin (hCG) Lactate dehydrogenase	A
Abdominopelvic computed tomography (CT)	All patients	A
Chest CT	All patients	A
Testis ultrasound (bilateral)	All patients	A
Bone scan or magnetic resonance imaging (MRI) columna	In case of symptoms	
Brain scan (CT/MRI)	In case of symptoms and patients with metastatic disease with multiple lung metastases and/or high beta-hCG values.	
Further investigations		
Fertility investigations: Total testosterone Luteinising hormone Follicle-stimulating hormone Semen analysis		B
Discuss sperm banking with all men prior to starting treatment for testicular cancer.		A

4.4 Staging and prognostic classifications

The staging system recommended in these guidelines is the 2017 Tumour, Node, Metastasis (TNM) of the International Union Against Cancer (UICC) (Table 4.2) [30]. This includes:

- determination of the anatomical extent of disease;
- assessment of serum tumour markers, including nadir values of hCG, AFP and LDH after orchiectomy (S category);
- definition of regional nodes;
- N-category modifications related to node size.

Table 4.2: TNM classification for testicular cancer (UICC, 2017, 8th edn. [30])

pT -	Primary Tumour ¹
pTX	Primary tumour cannot be assessed (see note 1)
pT0	No evidence of primary tumour (e.g. histological scar in testis)
pTis	Intratubular germ cell neoplasia (carcinoma <i>in situ</i>)
pT1	Tumour limited to testis and epididymis without vascular/lymphatic invasion; tumour may invade tunica albuginea but not tunica vaginalis*
pT2	Tumour limited to testis and epididymis with vascular/lymphatic invasion, or tumour extending through tunica albuginea with involvement of tunica vaginalis
pT3	Tumour invades spermatic cord with or without vascular/lymphatic invasion
pT4	Tumour invades scrotum with or without vascular/lymphatic invasion
N -	Regional Lymph Nodes - Clinical
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis with a lymph node mass 2 cm or less in greatest dimension or multiple lymph nodes, none more than 2 cm in greatest dimension
N2	Metastasis with a lymph node mass more than 2 cm but not more than 5 cm in greatest dimension, or multiple lymph nodes, any one mass more than 2 cm but not more than 5 cm in greatest dimension.

N3	Metastasis with a lymph node mass more than 5 cm in greatest dimension		
Pn - Regional Lymph Nodes - Pathological			
pNX	Regional lymph nodes cannot be assessed		
pN0	No regional lymph node metastasis		
pN1	Metastasis with a lymph node mass 2 cm or less in greatest dimension and 5 or fewer positive nodes, none more than 2 cm in greatest dimension		
pN2	Metastasis with a lymph node mass more than 2 cm but not more than 5 cm in greatest dimension; or more than 5 nodes positive, none more than 5 cm; or evidence of extranodal extension of tumour		
pN3	Metastasis with a lymph node mass more than 5 cm in greatest dimension		
M - Distant Metastasis			
MX	Distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis		
	M1a Non-regional lymph node(s) or lung metastasis		
	M1b Distant metastasis other than non-regional lymph nodes and lung		
S - Serum Tumour Markers			
SX	Serum marker studies not available or not performed		
S0	Serum marker study levels within normal limits		
	LDH (U/l)	hCG (mIU/mL)	AFP (ng/mL)
S1	< 1.5 x N and	< 5,000 and	< 1,000
S2	1.5-10 x N or	5,000-50,000 or	1,000-10,000
S3	> 10 x N or	> 50,000 or	> 10,000

N indicates the upper limit of normal for the LDH assay.

LDH = lactate dehydrogenase; hCG = human chorionic gonadotrophin; AFP = alpha-fetoprotein.

*AJCC subdivides T1 by T1a and T1b depending on size no greater than 3 cm or greater than 3 cm in greatest dimension.

¹ Except for pTis and pT4, where radical orchidectomy is not always necessary for classification purposes, the extent of the primary tumour is classified after radical orchidectomy; see pT. In other circumstances, TX is used if no radical orchidectomy has been performed.

According to the 2009 TNM classification, stage I testicular cancer includes the following substages:

Stage grouping				
Stage 0	pTis	N0	M0	S0
Stage I	pT1-T4	N0	M0	SX
Stage IA	pT1	N0	M0	S0
Stage IB	pT2 - pT4	N0	M0	S0
Stage IS	Any patient/TX	N0	M0	S1-3
Stage II	Any patient/TX	N1-N3	M0	SX
Stage IIA	Any patient/TX	N1	M0	S0
	Any patient/TX	N1	M0	S1
Stage IIB	Any patient/TX	N2	M0	S0
	Any patient/TX	N2	M0	S1
Stage II	Any patient/TX	N3	M0	S0
	Any patient/TX	N3	M0	S1
Stage III	Any patient/TX	Any N	M1a	SX
Stage IIIA	Any patient/TX	Any N	M1a	S0
	Any patient/TX	Any N	M1a	S1
Stage IIIB	Any patient/TX	N1-N3	M0	S2
	Any patient/TX	Any N	M1a	S2
Stage IIIC	Any patient/TX	N1-N3	M0	S3
	Any patient/TX	Any N	M1a	S3
	Any patient/TX	Any N	M1b	Any S

Stage IA	patients have primary tumours limited to the testis and epididymis, with no evidence of microscopic vascular or lymphatic invasion by tumour cells on microscopy, no sign of metastases on clinical examination or imaging, and post-orchietomy serum tumour marker levels within normal limits. Marker decline in patients with CS I disease should be assessed until normalisation.
Stage IB	patients have a more locally invasive primary tumour, but no sign of metastatic disease.
Stage IS	patients have persistently elevated (and usually increasing) serum tumour marker levels after orchietomy, indicating subclinical metastatic disease (or possibly a second germ cell tumour in the remaining testis).

In large population-based patient series, 75-80% of seminoma patients, and about 55% of patients with NSGCT cancer have stage I disease at diagnosis [48, 49]. True stage IS (persistently elevated or increasing serum marker levels after orchietomy) is found in about 5% of non-seminoma patients.

In 1997, the IGCCCG defined a prognostic factor-based staging system for metastatic testis tumours based on identification of clinically independent adverse factors. This staging system has been incorporated into the TNM Classification and uses histology, location of the primary tumour, location of metastases and pre-chemotherapy marker levels in serum as prognostic factors to categorise patients into 'good', 'intermediate' or 'poor' prognosis (Table 4.3) [33].

Table 4.3: Prognostic-based staging system for metastatic germ cell cancer
(International Germ Cell Cancer Collaborative Group [50])*

Good-prognosis group	
<i>Non-seminoma (56% of cases)</i> 5-year PFS 89% 5-year survival 92%	<i>All of the following criteria:</i> <ul style="list-style-type: none"> • Testis/retro-peritoneal primary • No non-pulmonary visceral metastases • AFP < 1,000 ng/mL • hCG < 5,000 IU/L (1,000 ng/mL) • LDH < 1.5 x ULN
<i>Seminoma (90% of cases)</i> 5-year PFS 82% 5-year survival 86%	<i>All of the following criteria:</i> <ul style="list-style-type: none"> • Any primary site • No non-pulmonary visceral metastases • Normal AFP • Any hCG • Any LDH

<i>Seminoma</i>	No patients classified as poor prognosis

*Pre-chemotherapy serum tumour markers should be assessed immediately prior to the administration of chemotherapy (same day). PFS = progression-free survival; AFP = alpha-fetoprotein; hCG = human chorionic gonadotrophin; LDH = lactate dehydrogenase.

5. DIAGNOSTIC EVALUATION

5.1 Clinical examination

Testicular cancer usually presents as a painless, unilateral testicular scrotal mass, as a casual US finding or is revealed by a scrotal trauma [51]. Scrotal pain may be the first symptom in 20% of cases and it is present in up to 27% of patients with TC [51, 52]. Gynaecomastia appears in 7% of cases (more common in non-seminomatous tumours). Back and flank pain due to metastasis is present in about 11% of cases [52].

Diagnosis is delayed in around 10% of cases of testicular tumour that mimic orchioepididymitis [52], physical examination reveals the features of the mass and must always be carried out together with a general examination to find possible (supraclavicular) distant metastases, a palpable abdominal mass or gynaecomastia. Ultrasound must be performed in any doubtful case. A correct diagnosis must be established in all patients with an intrascrotal mass [53].

5.2 Imaging of the testis

Currently, US is used to confirm the presence of a testicular mass and explore the contralateral testis. Ultrasound sensitivity is almost 100%, and US has an important role in determining whether a mass is intra- or extra-testicular [54]. Ultrasound is an inexpensive test and should be performed even in the presence of clinically evident testicular tumour [55].

Ultrasound of the testis should be performed in young men with retroperitoneal or visceral masses and/or elevated serum hCG or AFP and/or consulting for fertility problems and without a palpable testicular mass [56, 57].

Magnetic resonance imaging of the scrotum offers higher sensitivity and specificity than US in the diagnosis of TC, but its high cost does not justify its routine use for diagnosis [54, 58].

5.3 Serum tumour markers at diagnosis

Serum tumour markers are prognostic factors and contribute to diagnosis and staging [59]. The following markers should be determined before, and 5-7 days after, orchiectomy:

- alpha-fetoprotein (produced by yolk sac cells);
- human chorionic gonadotrophin (expression of trophoblasts);
- lactate dehydrogenase.

Tumour markers are of value for diagnosis (before orchiectomy) as well as for prognosis (after orchiectomy). They are increased in approximately every second patient with TC [51, 60]. Alpha-fetoprotein and hCG are increased in 50-70% and in 40-60% of patients with NSGCT, respectively. About 90% of NSGCT present with a rise in one or both of the markers. Up to 30% of seminomas can present or develop an elevated hCG level during the course of the disease [31].

Lactate dehydrogenase is a less specific marker, its concentration being proportional to tumour volume. Its level may be elevated in 80% of patients with advanced TC [31]. Of note, negative marker levels do not exclude the diagnosis of a germ cell tumour. Placental alkaline phosphatase (PLAP), is an optional marker in monitoring patients with pure seminoma, but not recommended in smokers [61].

Cytogenetic and molecular markers are available in specific centres, but at present only contribute to research. There is preliminary evidence that some micro-RNAs (miRNA 371-373) may be of diagnostic value in the future [62].

5.4 Inguinal exploration and orchiectomy

Every patient with a suspected testicular mass must undergo inguinal exploration with exteriorisation of the testis within its tunics. Orchiectomy with division of the spermatic cord at the internal inguinal ring must be performed if a malignant tumour is found. If the diagnosis is not clear, a testicular biopsy (and enucleation of the intraparenchymal tumour) is taken for frozen (fresh tissue) section histological examination. Even though only limited data are available, it has been shown that during orchiectomy, a testicular prosthesis can be inserted without increased infectious complications or rejection rates [63].

In cases of life-threatening disseminated disease, lifesaving chemotherapy should be given up-front, especially when the clinical picture is very likely TC and/or tumour markers are increased. Orchiectomy may be delayed until clinical stabilisation occurs or in combination with resection of residual lesions.

5.5 Organ-sparing surgery

Although organ-sparing surgery is not indicated in the presence of non-tumoural contralateral testis, it can be attempted in special cases with all the necessary precautions. In synchronous bilateral testicular tumours, metachronous contralateral tumours, or in a tumour in a solitary testis with normal pre-operative testosterone levels, organ preserving surgery can be performed when tumour volume is less than approximately 30% of

the testicular volume and surgical rules are respected. In those cases, the rate of associated GCNIS is high (at least up to 82%) (see Section 5.7.)

5.6 Pathological examination of the testis

Mandatory pathological requirements:

- macroscopic features: side, testis size, maximum tumour size, and macroscopic features of the epididymis, spermatic cord, and tunica vaginalis;
- sampling: a 1 cm² section for every centimetre of maximum tumour diameter, including normal macroscopic parenchyma (if present), albuginea and epididymis, with selection of suspected areas;
- at least one proximal and one distal section of spermatic cord plus any suspected area;
- microscopic features and diagnosis: histological type (specify individual components and estimate amount as percentage) according to WHO 2004 [64];
 - presence or absence of peri-tumoural venous and/or lymphatic invasion;
 - presence or absence of albuginea, tunica vaginalis, rete testis, epididymis or spermatic cord invasion;
 - presence or absence of GCNIS in non-tumour parenchyma.
- pT category according to TNM 2016 [30];
- immunohistochemical studies: in seminoma and mixed germ cell tumour, AFP and hCG.

Advisable immunohistochemical markers, in cases of doubt, are:

- in seminoma: cytokeratins (CAM 5.2), PLAP, c-kit;
- in ITGCN: PLAP, c-kit;
- other advisable markers: chromogranin A (Cg A), Ki-67 (MIB-1).

5.7 Germ cell tumours histological markers

OCT3/4 = homeodomain transcription factor of the POU family; SALL 4 = transcription factor encoded by a member of the Spalt-like (SALL) gene family; Glypican 3 (GPC3) = a membrane-bound heparin sulphate proteoglycan; CD30 = immunohistochemical marker; AFP = alpha-fetoprotein; hCG = human chorionic gonadotrophin; CD117(c-KIT) = immunohistochemical marker; PLAP = placental alkaline phosphatase; α -inhibin = peptide hormone; Calretinin = 29 kD calcium-binding protein; AE1/AE3 = cytokeratins; EMA = epithelial membrane antigen; CEA = carcinoembryonic antigen; GATA 3 = transcription factor; hPL = human placental lactogen; CgA = Chromogranin A; Synapto = neuroendocrine markers; p63 = transformation-related protein 63.

5.8 Diagnosis and treatment of germ cell neoplasia *in situ* (GCNIS)

Contralateral biopsy has been advocated to rule out the presence of GCNIS [65]. Although routine policy in some countries [66], the low incidence of GCNIS and contralateral metachronous testicular tumours (up to 9% and approximately 2.5%, respectively) [67, 68] the morbidity of GCNIS treatment, and the fact that most of metachronous tumours are at a low stage at presentation make it controversial to recommend a systematic contralateral biopsy in all patients [69, 70].

It is still difficult to reach a consensus on whether the existence of contralateral GCNIS must be identified in all cases. However, biopsy of the contralateral testis should be offered to patients at high risk for contralateral GCNIS, i.e. testicular volume < 12 mL, a history of cryptorchidism or poor spermatogenesis (Johnson Score 1-3). A contralateral biopsy is not necessary in patients older than 40 years without risk factors [36, 49, 71-73]. A double biopsy increases sensitivity [72]. Patients should be informed that a testicular tumour may arise in spite of a negative biopsy [74].

Once GCNIS is diagnosed, local radiotherapy (16-20 Gy in fractions of 2 Gy) is the treatment of choice in the case of a solitary testis. Testicular radiotherapy in a solitary testis will result in infertility and increased long-term risk of Leydig cell insufficiency [37, 69, 75, 76]. Fertile patients who wish to father children may delay radiation therapy and be followed by regular testicular US [72]. Chemotherapy is significantly less effective and the cure rates are dose-dependent [77].

If GCNIS is diagnosed and the contralateral testis is healthy, the options for management are orchiectomy or close observation (with a 5-year risk of developing TC of 50%) [78].

5.9 Screening

There are no high level evidence studies proving the advantages of screening programmes [79], but it has been demonstrated that stage and prognosis are directly related to early diagnosis. In the presence of clinical risk factors, and especially in patients with a family history of testis cancer, family members and the patient should be informed about the importance of physical self-examination [80].

5.10 Guidelines for the diagnosis and staging of testicular cancer

Recommendations	GR
Perform testicular ultrasound in all patients with suspicion of testicular cancer.	A
Offer biopsy of the contralateral testis and discuss its consequences with patients at high risk for contralateral germ cell neoplasia <i>in situ</i> .	A
Perform orchiectomy and pathological examination of the testis to confirm the diagnosis and to define the local extension (pT category). In a life-threatening situation due to extensive metastasis, start chemotherapy before orchiectomy.	A
Perform serum determination of tumour markers (alpha-fetoprotein, human chorionic gonadotrophin, and lactate dehydrogenase), both before and five-seven days after orchiectomy for staging and prognostic reasons.	A
Assess the state of the retroperitoneal, mediastinal and supraclavicular nodes and viscera in testicular cancer.	A
Advise patients with a familiar history of testis cancer, as well as their family members, to perform regular testicular self-examination.	A

6. PROGNOSIS

6.1 Risk factors for metastatic relapse in clinical stage I

Retrospectively, for seminoma stage I, tumour size (> 4 cm) and invasion of the rete testis have been identified as predictors for relapse in a pooled analysis [81]. The absence of both factors indicated a low recurrence rate (6%) [82]. Although the original model was not found to apply in a further retrospective report [83], other prospective series [84, 85, 96] confirm the prognostic importance of tumour size and stromal invasion of the rete testis.

With modern imaging, CS I patients with seminoma face a risk of occult metastasis, independent of risk factors, of < 15% in all recently published series.

For non-seminoma stage I, vascular invasion of the primary tumour in blood or lymphatic vessels is the most important predictor of occult metastatic disease. The proliferation rate, as well as the percentage of embryonal carcinoma, are additional predictors that improve upon the positive and negative predictive value of vascular invasion [86]. Whether the absence of teratoma (as qualitative data, as opposed to the more subjective assessment of percentage of embryonal carcinoma) can independently complement vascular invasion as a predictive factor of relapse requires validation [87].

The significant prognostic pathological risk factors for stage I TC are listed in Table 6.1.

Table 6.1: Risk factors for occult metastatic disease in stage I testicular cancer

	For seminoma	For non-seminoma
Pathological (for stage I)		
Histopathological type	<ul style="list-style-type: none"> • Tumour size (> 4 cm) • Invasion of the rete testis 	<ul style="list-style-type: none"> • Vascular/lymphatic in or peritumoural invasion • Proliferation rate > 70% • Percentage of embryonal carcinoma > 50%

7. DISEASE MANAGEMENT

7.1 Impact on fertility and fertility-associated issues

Sperm abnormalities are frequently found in patients with testis tumours. Furthermore, chemotherapy and radiation treatment can additionally impair fertility, however long-term infertility is rare after radiotherapy and dose-cumulative-dependant after chemotherapy [88, 89]. In patients in the reproductive age group, pre-treatment fertility assessment (testosterone, luteinising hormone [LH] and follicle stimulating hormone [FSH] levels) should be performed, and semen analysis and cryopreservation should be offered. If cryopreservation is desired, it should preferably be performed before orchiectomy, but in any case prior to chemotherapy [75, 88-91]. In cases of bilateral orchiectomy or low testosterone levels after treatment of GCNIS, life-long testosterone supplementation is necessary [92]. Patients with unilateral or bilateral orchiectomy should be offered a testicular prosthesis [93]. For more detailed information, the reader is referred to the EAU Male Infertility Guidelines [94].

7.2 Stage I Germ cell tumours

7.2.1 Stage I seminoma

After modern staging procedures, less than 15% of stage I seminoma patients have subclinical metastatic disease, usually in the retroperitoneum, and will relapse after orchiectomy alone [83, 95-97].

The decision regarding adjuvant treatment should always be based on a thorough discussion with the patient, taking into account the described advantages and disadvantages, as well as the individual situation of the patient.

7.2.1.1 Surveillance

Several prospective non-randomised surveillance studies have been conducted during the past decade, the largest study from Canada with > 1,500 patients [98]. Previous analyses from four studies showed an actuarial five-year relapse-free rate of 82.3%. The Princess Margaret Hospital series (n = 1,559) showed an overall relapse rate in unselected patients of 16.8%. The actuarial relapse rate is in the order of 15-20% at five years,

and most of the relapses are first detected in infra-diaphragmatic lymph nodes [99].

In patients with low risk (tumour size < 4 cm and no rete testis invasion), the recurrence under surveillance is as low as 6% [85]. Chemotherapy, according to the IGCCCG classification, is a possible treatment for seminoma relapse under surveillance. However, 70% of patients with relapse are suitable for treatment with radiotherapy alone because of small volume disease at the time of recurrence. Patients who relapse after salvage radiotherapy can be effectively treated with chemotherapy [100]. The combination of carboplatin chemotherapy and modern radiotherapy for treatment of low stage seminoma relapse (IIA/IIB) is under investigation.

The overall cancer-specific survival (CSS) rate reported under surveillance performed by experienced centres is 97-100% for seminoma stage I [99, 100]. The main drawback of surveillance is the need for more intensive follow-up, especially with repeated imaging examinations of the retroperitoneal lymph nodes.

7.2.1.2 Adjuvant chemotherapy

A joint trial by the Medical Research Council (MRC) and the European Organisation for Research and Treatment of Cancer (EORTC), which compared one cycle of carboplatin area under curve (AUC) 7 with adjuvant radiotherapy, did not show a significant difference with regard to recurrence rate, time to recurrence and survival after a median follow up of four years [101-103]. Therefore, adjuvant carboplatin therapy using a dosage of one course of AUC 7 is an alternative to radiotherapy or surveillance in stage I seminoma [99, 101-103]. Two courses of adjuvant carboplatin seem to further reduce the relapse rate to the order of 1-3% [82, 104]. Long-term data report the recurrence rate after three years after adjuvant carboplatin as 15%. Not all of these patients were cured [105].

7.2.1.3 Adjuvant radiotherapy and risk-adapted treatment

Seminoma cells are extremely radiosensitive. Adjuvant radiotherapy to a para-aortic (PA) field or to a PA and ipsilateral field (PA and ipsilateral iliac nodes), with moderate doses (total 20-24 Gy), will reduce the relapse rate to 1-3% [106-108]. Adjuvant irradiation of supra-diaphragmatic lymph nodes is not indicated.

With regard to the irradiation dose, a large Medical Research Council (MRC) randomised trial of 20 Gy vs. 30 Gy PA radiation in stage I seminoma showed non-inferiority in terms of recurrence rates [107]. The rate of severe radiation induced long-term toxicity is less than 2%. Moderate chronic gastrointestinal (GI) side-effects are seen in about 5% of patients, and moderate acute GI toxicity in about 60% [106]. The main concern surrounding adjuvant radiotherapy is the increased risk of radiation-induced second non-germ cell malignancies [109-111].

A scrotal shield should be considered during adjuvant radiotherapy in order to prevent scattered radiation toxicity in the contralateral testis [109].

7.2.1.4 Risk-adapted treatment

Using tumour size > 4 cm and rete testis invasion, patients with seminoma stage I may be subdivided into a low- and high-risk groups for occult metastatic disease. Patients with and without both risk factors have a 32% and 12% risk of occult disease respectively. These risk factors were introduced through an analysis of retrospective trials [81], and then confirmed in prospective studies [85, 96, 112]. A prospective trial based on one or no risk factors, showed the feasibility of a risk-adapted approach; the group without risk factors were managed with surveillance, whilst the group with both risk factors received two courses of carboplatin, AUC 7. Early data with limited follow up indicated that patients without either risk factor have a very low risk, 6.0% - 15%, of relapse at five years. Patients in the high-risk group treated with two courses of carboplatin experienced a 1.4% - 3.2% relapse rate at mean follow up of 34 months [85, 112].

7.2.1.5 Guidelines for the treatment of stage I seminoma

Recommendations	GR
Offer surveillance as a management option if facilities are available and the patient is compliant.	A*
Offer one course at area under curve (AUC) 7, if carboplatin chemotherapy is considered.	A
Do not perform adjuvant treatment in patients at very low risk (no risk factors).	A
Do not perform radiotherapy as adjuvant treatment.	A

*Upgraded following panel consensus.

7.2.2 NSGCT clinical stage I

Up to 30% of NSGCT patients with CS1 disease have subclinical metastases and will relapse during surveillance. The decision regarding adjuvant treatment should always be based on a thorough discussion with

the patient, taking into account the described advantages and disadvantages, as well as the individual situation of the patient.

7.2.2.1 Surveillance

Improvements in clinical staging and follow-up methods, and the availability of effective salvage treatment with cisplatin-based chemotherapy and post-chemotherapy surgery, have led to studies of only close surveillance after orchiectomy in CS1 NSGCT patients. The largest reports of the surveillance strategy indicate a cumulative relapse rate of about 30%, with 80% of relapses occurring during the first twelve months of follow up, 12% during the second year and 6% during the third year, decreasing to 1% during the fourth and fifth years, and occasionally even later [114, 115]. Approximately 35% of relapsing patients have normal levels of serum tumour markers at relapse, with 60% of relapses occurring in the retroperitoneum. Despite very close follow-up, 11% of relapsing patients presented with large-volume recurrent disease.

The somewhat lower relapse rates reported from surveillance studies compared with some series of patients staged by RPLND [116] can be explained by the fact that some patients (presumably at higher risk) are excluded once surveillance is advised. Based on the overall CSS data, surveillance within an experienced surveillance programme can safely be offered to patients with non-risk stratified CSI non-seminoma as long as they are compliant and informed about the expected recurrence rate as well as the salvage treatment [117, 118].

7.2.2.2 Adjuvant chemotherapy

Patients with CS1 NSGCT have a 14-48% risk of recurrence within two years after orchiectomy. Adjuvant chemotherapy with two courses of BEP was introduced in 1996 by a prospective MRC trial [119]. Subsequently, adjuvant chemotherapy was mainly given in high-risk patients (vascular invasion present) [119-121]. In these series, including 200 patients, some with a median follow-up of nearly 7.9 years [119], a relapse rate of only 2.7% was reported, with very little long-term toxicity. Two cycles of cisplatin-based adjuvant chemotherapy do not seem to adversely affect fertility or sexual activity [122]. However, the very-long term (> 20 years) side effects of adjuvant chemotherapy in this setting are currently unknown, especially the long-term cardio-vascular effects of chemotherapy [123]. This should be taken into consideration during decision-making.

In 2008, a randomised trial of nerve-sparing RPLND or one course of BEP as adjuvant treatment in CS1 NSGCT without risk-adaptation reported [124]. Adjuvant chemotherapy significantly increased the two-year recurrence-free survival rate to 99.41% (CI: 95.87%, 99.92%) as opposed to surgery, which had a two-year recurrence-free survival rate of 92.37% (CI: 87.21%, 95.50%). The difference was 7.04%, (CI: 2.52%, 11.56%) and, therefore, the main endpoint of the trial was reached. The hazard ratio to experience a tumour recurrence with surgery as opposed to chemotherapy was 7.937, (CI: 1.808, 34.48). Of the 174 patients having received one course of BEP, 43% had high-risk features (> pT1) [124].

A community-based prospective study recommended one course of BEP in LVI+ patients, while LVI- patients chose between surveillance and BEP x 1 [125]. The relapse-rate of the 490 patients who received BEP x 1 at five years was 3.2% for LVI+ patients and 1.6% for LVI- patients. After a median follow up of 8.1 years the relapse rate was 2.3%, 3.4% and 1.3% for all, LVI+, and LVI-, respectively [126]. These numbers imply that > 90% of relapses were prevented by adjuvant chemotherapy and, importantly, no relapses were observed later than 3.3 years. Reduction from two to one cycle of BEP improves the risk-benefit ratio of adjuvant chemotherapy considerably.

In addition, it is important to be aware of slow-growing retroperitoneal teratomas after primary chemotherapy [109]. Until now, only a limited number of patients with long-term follow-up and toxicity data have been reported on [127].

The results of cost analyses comparing surveillance, RPLND and primary chemotherapy show different results among the reported studies, possibly because of differences in intensity and costs related to follow-up procedures [128]. With low frequency follow-up CTs (a surveillance strategy which has been proven to be effective in non-seminoma CS1), the costs of follow up can be considerably reduced [129].

7.2.2.3 Risk-adapted treatment

Risk-adapted treatment is an alternative to surveillance for all patients with CS1 NSGCT. Risk-adapted treatment is based on the risk factor of vascular invasion. Stratifying patients with CS1 NSGCT according to their presumed risk of relapse is a rational option, as several studies have reported similar survival rates and a final cure rate close to 100% with all available treatment options using the risk-stratifying approach [119-121, 125, 126, 130-132].

If the risk-adapted policy is applied, patients with vascular invasion are recommended to undergo adjuvant chemotherapy and patients with absent vascular invasion are recommended a surveillance strategy. In the past, two cycles of BEP have been recommended for adjuvant treatment. In view of the low rates of recurrence (2-3%) and equivalent CSS rates including salvage strategies in large prospective trials with sufficient follow-up, one cycle of BEP is now recommended as adjuvant chemotherapy in patients with vascular invasion.

In cases of relapse after BEP x 1, three courses of BEP are recommended. However, there is not a large body of evidence to support any one specific salvage regimen.

7.2.2.4 Retroperitoneal lymph node dissection

In view of the high CSS rates of surveillance with salvage treatment in cases of relapse and the low relapse rates if adjuvant chemotherapy is chosen, the role of primary diagnostic RPLND has diminished. A randomised phase III trial compared RPLND to BEP x 1 as adjuvant treatment, with a 7% difference in favour of chemotherapy. One course of BEP showed a significantly lower recurrence rate as compared to surgery [124].

When RPLND is performed in a multicentre setting, higher rates of in-field recurrences and complications were reported [124, 133]. Therefore, nerve-sparing RPLND - if indicated - should be performed by an experienced surgeon in specialised centres.

About 18-30% of patients are found to have retroperitoneal lymph node metastases on RPLND, corresponding to pathological stage II (PS2) disease [133, 134]. If no retroperitoneal metastases are found at RPLND (PS1), approximately 10% of the PS1 patients relapse at distant sites [86, 134]. If metastases are present and not treated with adjuvant chemotherapy, recurrence will occur in 31% of patients [134].

The presence of vascular invasion, predominant embryonal carcinoma, pT category as well as a high number of extranodal extension in metastatic nodes may be associated with an increased risk of recurrence in PS2 cases without adjuvant chemotherapy. As yet, the clinical significance of these further parameters remains limited and not applicable in clinical practice [134, 135].

The follow-up after RPLND is simpler and less costly than that carried out during post-orchietomy surveillance because of the reduced need for abdominal CT scans [136]. If there is an indication to perform a staging RPLND, a laparoscopic or robot-assisted RPLND is feasible in expert hands. This minimal-invasive approach cannot be recommended as the standard approach outside of a specialised laparoscopic centre [137].

7.2.2.5 Guidelines for the treatment of stage 1 non-seminomatous germ cell tumour

Recommendations	LE	GR
Inform patients with stage 1 non-seminomatous germ cell tumour (NSGCT) about all adjuvant treatment options after orchiectomy (surveillance, adjuvant chemotherapy, and retroperitoneal lymph node dissection [RPLND]) including treatment-specific recurrence rates as well as acute and long-term side effects.	2a	A*
In patients with stage 1 NSGCT, offer surveillance or risk-adapted treatment based on vascular invasion (see below).	2a	A*
If patients are not willing to undergo surveillance, offer one course of cisplatin, etoposide, bleomycin (BEP) as an adjuvant treatment alternative since it has proven to be superior to RPLND in terms of recurrence rates.	1b	A*
In patients with marker-positive recurrent and/or progressing lesion during surveillance, perform salvage treatment consisting of three or four courses of BEP chemotherapy according to the International Germ Cell Cancer Collaborative Group classification, followed by post-chemotherapy retroperitoneal lymph node dissection if necessary.	2a	A

*Upgraded following panel consensus.

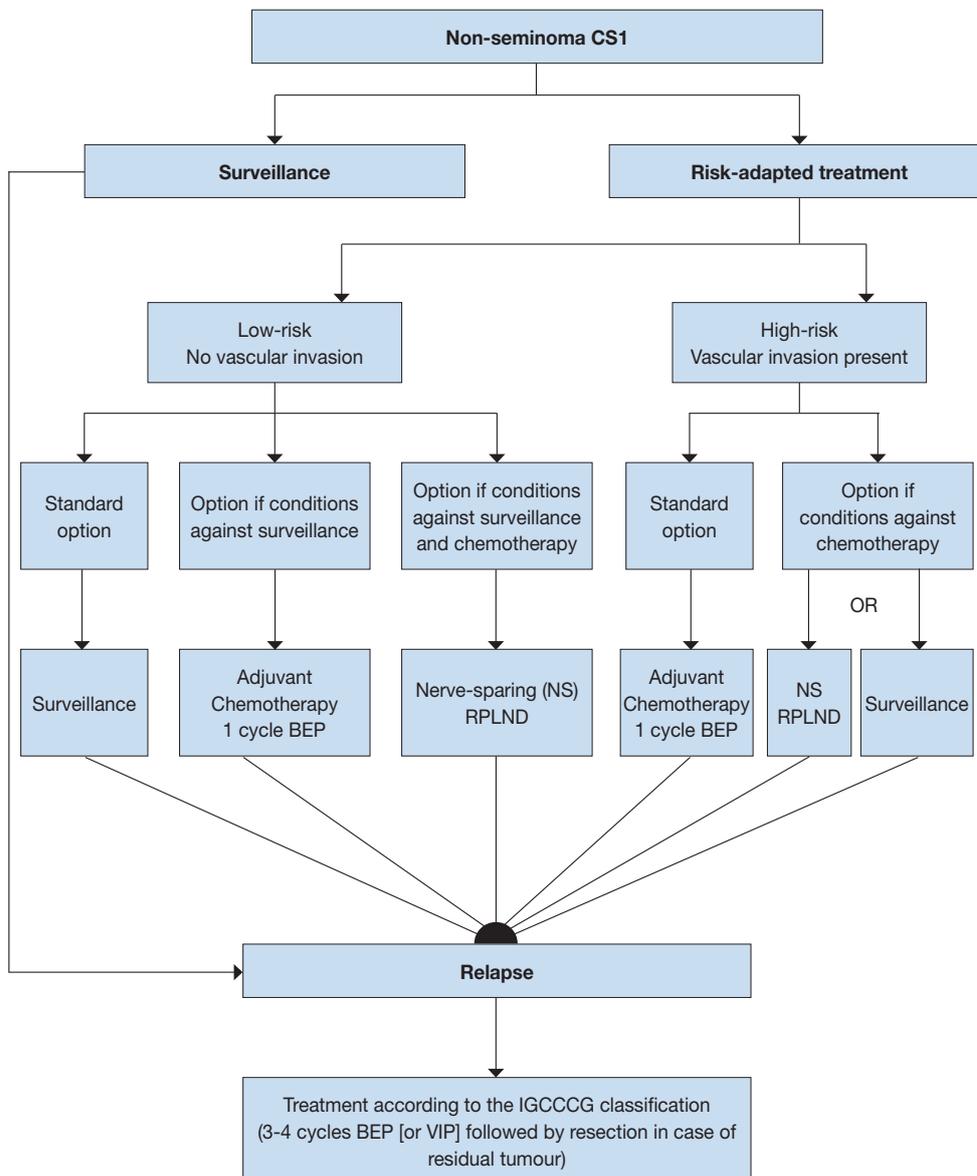

7.2.2.6 Risk-adapted treatment for clinical stage 1 based on vascular invasion

Recommendations	LE	GR
Stage IA (pT1, no vascular invasion): low risk		
Offer surveillance if the patient is willing and able to comply.	2a	A
In low-risk patients not willing (or unsuitable) to undergo surveillance, offer adjuvant chemotherapy with one course of cisplatin, etoposide, bleomycin (BEP).	2a	A*
Stage IB (pT2-pT4): high risk		
Offer primary chemotherapy with one course of BEP.	2a	A*
Inform patients having adjuvant chemotherapy about the advantages and disadvantages of one vs. two cycles of BEP.	2a	A*
Offer surveillance to patients not willing to undergo adjuvant chemotherapy.		A*
Offer nerve-sparing retroperitoneal lymph node dissection to highly selected patients only; those with contraindication to adjuvant chemotherapy and unwilling to accept surveillance.		A*

*Upgraded following panel consensus.

Figure 1 provides a treatment algorithm for patients with NSGCT stage I.

Figure 1: Risk-adapted treatment in patients with clinical stage 1 non-seminoma NSGCT CS1 [138]*

*All treatment options will need discussing with individual patients, to allow for them to make an informed decision as to their further care.

BEP = cisplatin, etoposide, bleomycin; CS = clinical stage; IGCCCG = International Germ Cell Cancer Collaborative Group; RLNPD = retroperitoneal lymph node dissection; VIP = etoposide, cisplatin, ifosfamide.

7.3 Metastatic germ cell tumours

The first-line treatment of metastatic germ cell tumours depends on:

- the histology of the primary tumour;
- prognostic groups as defined by the IGCCCG based on 5,202 non-seminoma and 660 seminoma cases (Table 4.3) [139];
- Marker decline during the first cycle of chemotherapy in “poor prognosis” patients

In relapsed patients a new prognostic score has been developed including response to first-line therapy which can be used to estimate patient outcome following salvage chemotherapy (see below).

7.3.1 CS1S with (persistently) elevated serum tumour markers

Serum tumour markers should be followed closely until levels fall into the reference values according to the expected half-life values for AFP and hCG. The clinical significance of persistently elevated LDH after orchiectomy in stage I disease is unclear. If the marker level for AFP or HCG increases after orchiectomy, the patient has residual disease. An US examination of the contralateral testicle must be performed. In case of NSGCT, if RPLND is performed, up to 87% of these patients have pathologically documented nodes in the retroperitoneum [140]. The treatment of true CS1S NSGT patients is still controversial. They may be treated with chemotherapy and with follow-up as for CS1B patients (high risk, see below) after primary chemotherapy [141], or by RPLND [129].

A population-based study reported on persistently elevated LDH or β -hCG in 19 and 15% of stage I seminoma patients, respectively. These patients frequently had more advanced T stage, but both CSS and OS did not differ from stage I A/B patients independent of treatment [142].

In all patients with germ cell tumours and rising markers, only after orchidectomy, a repeated imaging to detect metastasis is justified in order to individually tailor treatment.

7.3.2 Metastatic disease (stage IIA/B)

7.3.2.1 Stage IIA/B seminoma

Slightly enlarged retroperitoneal lymph nodes < 2 cm in patients without elevated tumour markers offer a diagnostic problem. These lymph nodes may be benign or represent metastases. An observation period of eight weeks with a second staging is recommended unless a biopsy verifies metastatic disease. Treatment should not be initiated unless metastatic disease is unequivocal, (e.g. growth or positive biopsy).

Specific trials (e. g. including RPLND or involved field radiation combined with a single course of carboplatin chemotherapy) are addressing the role of treatment options with potentially lower toxicity as compared to either radiotherapy or chemotherapy with three cycles of BEP.

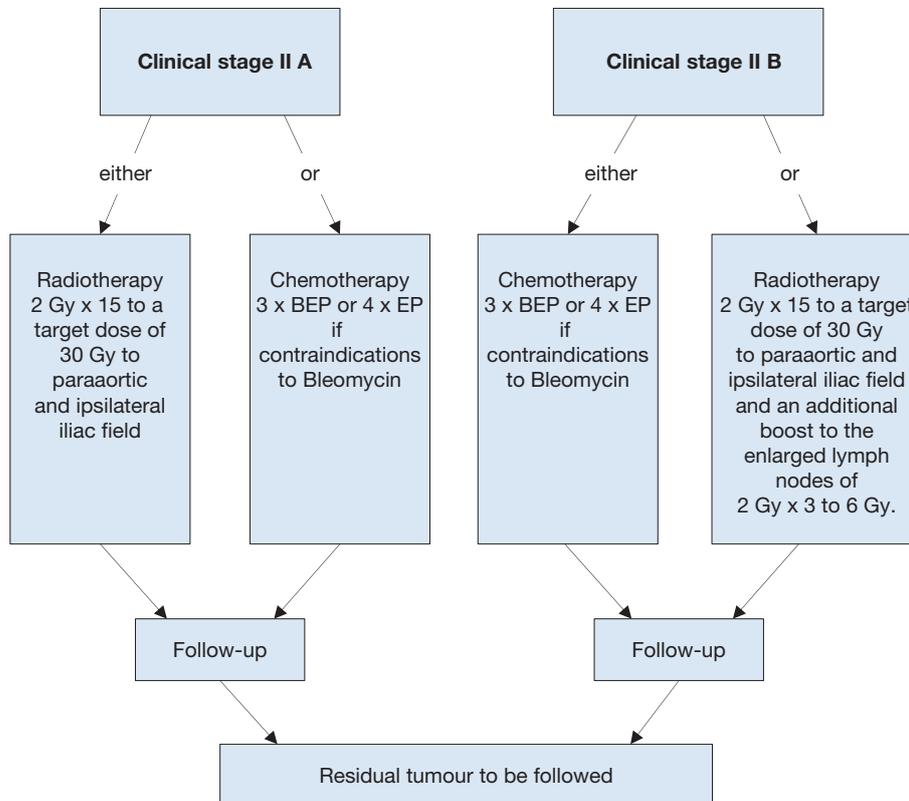

Until recently, the standard treatment for stage IIA/B seminoma has been radiotherapy with reported relapse rates of 9-24% [143, 144]. Accumulating data on long-term morbidity, such as increased risk of cardiovascular events and increased risk of second malignancies following radiotherapy has led to concern. One study displaying a long-term follow-up of 19 years, reports a mortality not due to seminoma seven-fold greater than mortality due to seminoma [145]. Most reports refer to patients irradiated with larger target volumes and higher doses but there are also more recent studies reporting on patients treated with more modern radiotherapy [146]. The radiation dose recommended in stage IIA and IIB is 30 Gy and 36 Gy, respectively. The standard radiation field compared with stage I will be extended from the PA region to the ipsilateral iliac field. In stage IIB, the lateral borders should include the metastatic lymph nodes with a safety margin of 1.0-1.5 cm. This technique yields a relapse-free survival in stage IIA and IIB of 92% and 90%, respectively [143, 144]. Conversely, dose reduction to 27 Gy has been associated with 11% of relapses in stage IIA patients [100, 146].

In patients with stage IIA/B seminoma, chemotherapy with three courses of BEP or four courses of etoposide and cisplatin (EP), in cases with contraindications to bleomycin, is an alternative to radiotherapy. There are no randomised studies comparing radiotherapy vs. chemotherapy. A recent meta-analysis of thirteen high quality studies compared efficacy and toxicity of radiotherapy and chemotherapy in stage IIA and IIB patients [147]. Radiotherapy and chemotherapy appeared to be similarly effective in both stages. Nonetheless a non-significant trend toward a greater efficacy of chemotherapy (HR: 2.17) was shown in stage IIB seminoma. Acute toxicity was almost exclusively reported following chemotherapy, while long-term toxicity was more frequent

following radiotherapy, mainly represented by bowel toxicity and by a higher occurrence of second cancers, almost all occurring in the irradiated field. This may favour the use of chemotherapy, BEP x 3, in stage IIB as standard treatment. In stage IIA, radiotherapy should present the initial treatment option.

Single-agent carboplatin is not an alternative to standard EP or BEP chemotherapy for metastatic disease [148].

Figure 2: Treatment options in patients with seminoma clinical stage IIA and B

BEP = cisplatin, etoposide, bleomycin; EP = etoposide, cisplatin.

7.3.2.2 Stage IIA/B non-seminoma

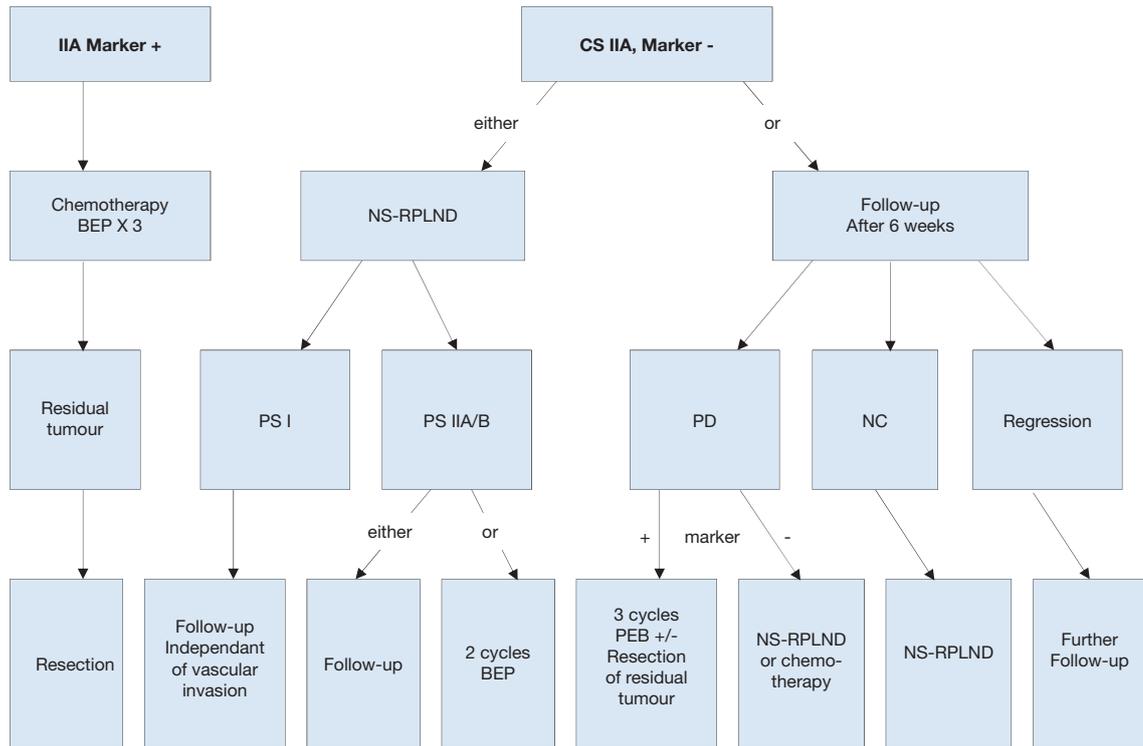

There is a general consensus that treatment should start with initial chemotherapy in all advanced cases of NSGCT except for stage IIA NSGCT disease and pure teratoma without elevated tumour markers, which can be managed by primary RPLND or surveillance to clarify stage [128, 149].

If surveillance is chosen, one follow-up evaluation after six weeks is indicated to document whether the lesion is growing, remaining stable or shrinking. A shrinking lesion is probably non-malignant in origin and should be observed further. A stable or growing lesion indicates either teratoma or an undifferentiated malignant tumour. If the lesion is growing without a corresponding increase in the tumour markers AFP or β -hCG, teratoma is suspected. In such cases “nerve-sparing” RPLND represents the first treatment option and should be performed by an experienced surgeon [149]. Patients with a growing lesion and a concomitant increase in the tumour markers AFP or β -hCG require primary chemotherapy according to the treatment algorithm for patients with metastatic disease and IGCCCG recommendations (Figure 2). A CT-or US-guided biopsy, if technically possible, may represent an alternative to surveillance strategy in stage IIA non-seminoma patients. When a marker negative stage IIA/B relapse is diagnosed two or more years following initial diagnosis, a CT-or US-guided biopsy should be advised to confirm the diagnosis of germ cell tumour (GCT) relapse. There is insufficient published data on PET scans in this situation to provide a recommendation on.

Primary chemotherapy and primary ‘nerve-sparing’ RPLND are comparable options in terms of outcome, but early and long-term side-effects and toxicity are different, allowing for involvement of the patient in selecting the treatment of choice [150]. The cure rate with either approach will be close to 98% [151-153].

Figure 3 presents the treatment options for patients with NSGCT CS IIA.

Figure 3: Treatment options in patients with non-seminoma clinical stage IIA

BEP = cisplatin, etoposide, bleomycin; NS = nerve-sparing; RPLND = retroperitoneal lymph node dissection; PS = pathological stage; PD = progressive disease; NC = no change.

7.3.3 Metastatic disease (stage IIC and III)

7.3.3.1 Primary chemotherapy

7.3.3.1.1 Good prognosis risk group - SGCT

For metastatic seminoma, only very limited data are available from randomised trials and they indicate that a cisplatin-based regimen should be preferred to carboplatin chemotherapy [154]. Recent data indicate that EP x 4 results in cure in almost all cases of good-prognosis seminomatous germ cell cancers [155]. Standard treatment in good-prognosis seminoma should therefore be, BEP x 3 or EP x 4. In the case of contraindications to bleomycin, EP x 4 should be given [156].

Post-chemotherapy masses should be managed as described in Section 7.5.2.

7.3.3.1.2 Intermediate prognosis risk group - seminomatous germ cell tumour

For patients with intermediate-risk seminoma, BEP x 4 or etoposide, cisplatin, ifosfamide (VIP) (in the case of contraindications to bleomycin) are recommended options, although no randomised trial has focused specifically on this group of rare patients [157]. A risk adapted approach with EP x 4 for patients with good prognosis and VIP x 4 for patients with intermediate prognosis metastatic seminoma yielded an OS of 99% and 87% for good and intermediate prognosis patients, respectively [155].

7.3.3.1.3 Good prognosis risk group – non-seminomatous germ cell tumour

For non-seminoma, the primary treatment of choice for metastatic disease in patients with good prognosis risk disease, according to the IGCCCG risk classification, is BEP x 3 (Table 7.1). This regimen was proven superior to cisplatin, vinblastine and bleomycin (PVB) in patients with advanced disease [158, 159]. While data support a three-day regimen of administering combination chemotherapy to be equally effective as a five-day regimen, this is associated with increased toxicity when four cycles are used [160], thus the five-day BEP regimen is recommended.

Table 7.1: cisplatin, etoposide, bleomycin (BEP) regimen (interval 21 days)

Drug	Dosage	Duration of cycles
Cisplatin	20 mg/m ²	Days 1-5*
Etoposide	100 mg/m ²	Days 1-5
Bleomycin	30 mg	Days 1, 8, 15

*Plus hydration.

In selected cases where bleomycin is contraindicated, EP x 4 can be given [139, 159]. A randomised trial from the French Groupe d'Etude des Tumeurs Genito-Urinaires (GETUG) suggested that when BEP is used in this setting the mortality rate was half that of EP, although the difference did not reach statistical significance [161]. Furthermore, the incidence of active cancer in the retroperitoneal specimen at post-chemotherapy retroperitoneal lymph node dissection was, however, to significantly higher in patients who received EP x 4 as compared to BEP x 3 (31.9% vs. 7.8%, $p < 0.001$) [162, 163]. The risk of requiring post-RPLND adjuvant chemotherapy could be higher after EP x 4 which could thereby offset a hoped-for less toxic treatment.

Higher age is an adverse factor for the efficacy of BEP x 3 [164].

Therapy should be given without reduction of the doses at 21-day intervals; delaying the following chemotherapy cycle is justified only in cases of fever with granulocytopenia $< 1,000/\text{mm}^3$ or thrombocytopenia $< 100,000/\text{IU}$. Neutropenia without fever is not by itself a reason to delay the next cycle. There is no indication for prophylactic application of haematopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF). However, if infectious complications have occurred during chemotherapy or the treatment interval was delayed due to myelotoxicity, prophylactic administration of G-CSF is recommended for the following cycles [165].

7.3.3.1.4 Intermediate prognosis risk group – non-seminomatous germ cell tumour

The 'intermediate prognosis' group in the IGCCCG has been defined as patients with a five-year survival rate of about 80%. The available data support BEP x 4 as standard treatment [139, 166]. A randomised trial compared BEP x 4 to BEP x 4 with the addition of paclitaxel (T-BEP) with no significant improvement in OS [167]. The overall toxicity with T-BEP was higher than with BEP, therefore it cannot be recommended as a standard approach.

7.3.3.1.5 Poor prognosis risk group - NSGCT

For patients with a 'poor prognosis' non-seminoma as defined by the IGCCCG, standard treatment consists of BEP x 4. Four cycles of cisplatin, etoposide and ifosfamide (PEI) have the same effect, but are more myelotoxic [168, 169]. The five-year PFS is between 45% and 50%. Four randomised trials have shown no advantage in OS for high-dose chemotherapy in the overall 'poor prognosis' patients group [33, 170-172]. However, patients with a slow tumour marker decline after the first or second cycle represent a prognostically inferior subgroup [33, 34]. An online calculator is available at www.igr.fr/calculation-tumor/NSGCT.xls. Recently, an international randomised phase III trial (GETUG 13) conducted in 263 patients with IGCCCG poor-risk NSGCT demonstrated that intensifying treatment with dose-dense chemotherapy improves PFS, but not OS in patients with an early unfavourable tumour marker decline [35]. Based on the results from this trial, patients with an unfavourable tumour marker decline after BEP x 1 should be switched to a more intensive chemotherapy regimen [173, 174]. Further prospective trials/registries are planned to validate this approach.

Additional patient groups that may benefit from up-front dose intensification are those with mediastinal primary non-seminoma and patients with brain metastases at initial diagnosis [175, 176].

Since a matched-pair analysis comparing high-dose to conventional treatment resulted in a better survival rate [34, 177], poor prognosis patients should still be treated in ongoing prospective trials or registries, whenever possible. Patients meeting 'poor-prognosis' criteria should be transferred to a reference centre as a better outcome was reported for intermediate and poor prognosis patients who had been treated within a clinical trial in a high volume centre [12, 155]. There are no general recommendations for treatment modifications for patients with a poor general condition (Karnofsky $< 50\%$) or extended liver infiltration ($> 50\%$), but two small reports indicate that a first cycle of dose-reduced therapy may reduce acute mortality without compromising long-term outcome. However, the number of subsequent cycles of full-dose therapy should not be reduced after a first low-dose induction cycle [178, 179].

Patients with extended pulmonary infiltration are at risk for acute respiratory distress syndrome: adapting the doses of the BEP regimen in the first cycle of chemotherapy (only three days of EP without bleomycin) was suggested to reduce the risk of early death in this setting [178].

7.4 Restaging and further treatment

7.4.1 Restaging

Restaging is performed by imaging investigations and re-evaluation of tumour markers. Upon marker decline and stable or regressive tumour manifestation, chemotherapy will be completed (three or four cycles, depending on the initial stage) [139, 180, 181]. In the case of marker decline, but growing metastases, resection of the tumour is obligatory after termination of induction therapy, other than in an emergency, according to local tumour growth [182].

Patients with clear upfront progression (primary cisplatin refractory) should be switched to experimental new drug trials [183]. Patients with slow marker decline after the first one-two cycles of chemotherapy are candidates for dose intensification (see Section 7.4.3.1.5.). Patients with a low-level hCG marker plateau post-treatment should be observed to see whether complete normalisation occurs. In patients with a low plateau serum AFP level after chemotherapy, surgery of residual masses should be performed, with post-surgery AFP monitoring. Salvage chemotherapy is indicated for documented marker rise only [184, 185].

7.4.2 Residual tumour resection

7.4.2.1 Seminoma

A residual mass of seminoma should not be primarily resected, irrespective of the size, but controlled by imaging investigations and tumour markers [186-189].

Fluorodeoxyglucose-positron emission tomography has a high negative predictive value in patients with residual masses after treatment of seminoma. False positive results are less frequent when scans are scheduled > 2 months after chemotherapy. In patients with residuals of > 3 cm, FDG-PET should be performed in order to gain more information on the viability of these residuals. In patients with residuals of < 3 cm, the use of FDG-PET is optional [45].

In the case of a post-chemotherapy mass that is still positive at reclassification FDG-PET with no volume increase, a second FDG-PET should be performed six weeks later. Alternatively, a biopsy should be taken to ascertain persistent disease. In these cases as well as in those with progressive disease (i.e. a growing mass which up-takes contrast medium at CT scans or radionuclide tracer at FDG-PET), salvage therapy is indicated (usually chemotherapy or radiotherapy) [190-192]. Patients with persistent and progressing hCG elevation after first line chemotherapy should immediately proceed with salvage chemotherapy. Progressing patients without hCG progression should undergo histological verification (e. g. by biopsy or mini-invasive or open surgery) before salvage chemotherapy is given.

When RPLND is indicated, this should be performed in referral centres, as residuals from seminoma may be difficult to remove due to intense fibrosis [191]. Ejaculation may be preserved in these cases [193].

7.4.2.2 Non-seminoma

Following first-line BEP chemotherapy, only 6-10% of residual masses contain viable cancer, 50% contain mature teratoma, and 40% contain necrotic-fibrotic tissue [194]. FDG-PET is not indicated to re-stage patients after chemotherapy [47]. In cases of complete remission after first line chemotherapy (no visible tumour), tumour resection is not indicated [195, 196]. Residual tumour resection is mandatory in all patients with a residual mass > 1 cm in the short axis at cross-sectional CT imaging [197-200].

The role of surgery is debated in patients with retroperitoneal residual lesions < 1 cm. There is still a risk of residual cancer or teratoma although the vast majority of patients (> 70%) harbour fibro-necrotic tissue [201]. Proponents of post-chemotherapy-RPLND for all patients refer to the fact that both teratoma and vital malignant germ cell tumours are still found after radiologic complete remission in lesions < 10 mm [202]. The alternative is to put patients with residual disease < 1 cm on an observation protocol based on recurrence data of 6-9% depending on the time of follow-up [195, 196]. In the series with a longer observation of 15.5 years, 12 of 141 patients (9%) relapsed after having achieved a complete response after primary treatment [196], but eight of the 12 relapsing patients were cured. Therefore, patients treated with first-line chemotherapy should be informed about this life-long risk of recurrence in the order of 10% before consenting to observe residual lesions < 1 cm. Patients after salvage chemotherapy or high-dose chemotherapy in first or subsequent salvage situations harbour vital tumour at a much higher rate [203]. Therefore, there is an indication to perform surgery in salvage patients even with residual disease < 1 cm [195, 196].

If residual surgery is indicated, all areas of primary metastatic sites must be completely resected within two-six weeks of completion of chemotherapy. If technically feasible, a bilateral nerve-sparing procedure should be performed. There is growing evidence that template resections with unilateral preservation of nerves in selected patients yield equivalent long-term results compared to bilateral systematic resections in all patients. The mere resection of the residual tumour (so called lumpectomy) should not be performed [196, 201, 204-207].

In persistent larger volume retroperitoneal disease, all areas of primary metastatic sites must be completely resected within two-six weeks of completion of chemotherapy. If technically feasible, a nerve-sparing procedure should be performed [196, 201, 204]. Laparoscopic RPLND may yield similar outcomes to the open procedure in very selected cases of very low residual disease and in very experienced hands, but it is not recommended outside a specialised laparoscopic centre [208-210].

7.4.3 **Timing of surgery in the case of multiple sites**

In general, residual surgery should start at the location with the highest volume of residual disease. The histology may diverge in different organ sites [197]. In cases of retroperitoneal and lung residual masses, the presence of fibro-necrotic tissue in the retroperitoneum is associated with a probability as high as 90% that lung masses contain the same histology [211].

Resection of contralateral pulmonary lesions is not mandatory in cases where pathologic examination of the lesions from the first lung show complete necrosis. However, discordant histology between both lungs may occur in up to 20% of patients [212, 213].

7.4.3.1 *Quality and intensity of surgery*

Post-chemotherapy surgery is always demanding. Most of the time, post-chemo RPLND does not require further interventions on abdominal or retroperitoneal organs. About a third of patients may require a planned intervention where removal of organs affected by the disease (for example kidney, psoas muscle or gross vessels) is performed and followed by *ad hoc* reconstructive surgery (e.g. vascular interventions such as vena cava or aortic prostheses) [214, 215]. In patients with intermediate- or poor-risk and residual disease > 5 cm the probability of vascular procedures is as high as 20% [216]. This surgery must therefore be referred to specialised centres capable of interdisciplinary surgery (hepatic resections, vessel replacement, spinal neurosurgery, thoracic surgery). Even with centralisation of treatment the median number of RPLNDs performed per surgeon/year in the U.K. is six [217]. Nevertheless, patients treated within such centres benefit from a significant reduction in peri-operative mortality from 6% to 0.8% [13]. In addition, specialised urologic surgeons are capable of reducing the local recurrence rate from 16% to 3% with a higher rate of complete resections [14].

7.4.3.2 *Salvage and desperation surgery.*

Surgery of resectable disease after salvage treatment remains a potentially curative option in all patients with any residual mass following salvage chemotherapy. Survival after surgery and first salvage chemotherapy was improved, 70% at 10 years, following taxane-containing regimens [218]. Also, in the case of extensive salvage chemotherapy, surgery remains a fundamental tool to achieve durable complete remissions in up to 20% of patients [219, 220].

Desperation surgery refers to resection of non-responsive or progressive (e.g. rising markers) disease following salvage chemotherapy. When the disease is resectable, a significant proportion of these patients can be rendered disease-free in the long term [221].

7.4.3.3 *Consolidation chemotherapy after secondary surgery*

After resection of necrosis or mature/immature teratoma, no further treatment is required. In cases of incomplete resection of viable cancer, two adjuvant cycles of conventionally dosed cisplatin-based chemotherapy may be given in certain subgroups (e.g. 'poor prognosis' patients) [205] (caution: cumulative doses of bleomycin). After complete resection of 'vital' tumour < 10% of the total volume, especially in patients in an initially good prognosis group according to IGCCCG, the relapse rate is very low and adjuvant chemotherapy is not beneficial for preventing further relapse [222]. The prognosis will definitely deteriorate if vital malignant neoplasm is found in resection specimens after second- and third-line chemotherapy. In this latter situation, post-operative chemotherapy is not indicated and is unable to improve the prognosis [223].

7.4.4 **Systemic salvage treatment for relapse or refractory disease**

Cisplatin-based combination salvage chemotherapy will result in long-term remissions in about 50% of the patients who relapse after first-line chemotherapy, but the results are highly dependent on several prognostic factors [224]. The regimens of choice are four cycles of a triplet regimen including cisplatin and ifosfamide plus a third agent: etoposide (PEI/VIP), paclitaxel (TIP), or potentially gemcitabine (GIP) (Table 7.2) [225]. No randomised trial has compared these regimens. Due to their potentially lethal risk of haematological toxicity, these regimens should be used with G-CSF support and by well-trained oncologists.

The only available randomised trial comparing standard-dose vs. high-dose chemotherapy plus transplant in the salvage setting showed no benefit in OS in patients treated with three cycles of vinblastine, ifosfamide, and cisplatin (VeIP) plus one cycle of consolidation high-dose chemotherapy, compared with VeIP x 4 [226]. Due to several methodological reasons this trial design can no longer be considered state of the art.

There is clear evidence from large retrospective analyses that there are different prognostic groups in the case of relapse after first-line chemotherapy [227, 228], and the Lorch-Beyer score has resulted in five prognostic subgroups (Table 7.3). Several recent trials have confirmed this score [229, 230]. As in first-line therapy, the prognostic impact of tumour marker decline has also been demonstrated in the salvage setting [231]. While progression to induction chemotherapy was negative for OS, prior use of paclitaxel was not significantly associated with a negative outcome [232].

A second large analysis in this cohort of 1,600 patients showed an improvement of about 10-15% in OS in patients from all prognostic subgroups when treated with high-dose salvage therapy compared to standard dose therapy. To prospectively confirm this finding, an international randomised trial of high-dose vs. conventional dose chemotherapy in patients with first-line relapse has started (Tiger trial). If high-dose chemotherapy is used as a salvage treatment, sequential treatment cycles of high-dose carboplatin and etoposide HD-CE should be preferred to a single high-dose regimen because the former is associated with less toxicity-related deaths [233].

It is clearly of the utmost importance that these rare patients with relapse are treated within clinical trials and at experienced centres.

Table 7.2: Standard PEI/VIP, TIP and GIP chemotherapy (interval 21 days)

Regimen	Chemotherapy agents	Dosage	Duration of cycles
PEI/VIP	Cisplatin*	20 mg/m ²	Days 1-5
	Etoposide	75-100 mg/m ²	Days 1-5
	Ifosfamide†	1.2 g/m ²	Days 1-5
TIP	Paclitaxel	250 mg/m ² xx	24 hour continuous infusion day 1
	Ifosfamide†	1.5 g/m ²	Days 2-5
	Cisplatin*	25 mg/m ²	Days 2-5
	Alternative schedule		
GIP	Paclitaxel	175 mg/m ²	Day 1, 3 hour infusion
	Ifosfamide†	1.2 g/m ²	Days 1-5
	Cisplatin*	20 mg/m ²	Days 1-5
GIP	Gemcitabine	1000 mg/m ²	Day 1 + 5
	Ifosfamide	1200 mg/m ²	Days 1-5
	Cisplatin	20 mg/m ²	Days 1-5

* Plus hydration.

† Plus mesna protection.

xx An MRC schedule uses paclitaxel at 175 mg/m² in a 3 hour infusion [234].

The International Prognostic Factors Study Group score, comprised of seven important factors, is listed in Table 7.3. Using these factors, 5 risk groups (very low risk = -1 points; low risk = 0 points; intermediate-risk = 1-2 points, high risk = 3-4 points; and very high risk > 5 points) were identified with significant differences in PFS and OS. Table 4.3 illustrates the five risk groups and the corresponding two-year PFS and three-year OS rates [235].

Table 7.3: The International Prognostic Factors Study Group Score Construction [228]

Points	-1	0	1	2	3
Variable					
Histology	Seminoma	Non-seminoma			
Primary site		Gonadal	Retroperitoneal		Mediastinal
Response		CR/PRm-	PRm+/SD	PD	
PFI		> 3 months	≤ 3 months		
AFP salvage		Normal	< 1000	1000	
hCG salvage		< 1000	1000		
LBB		No	Yes		

AFP = alpha-fetoprotein; hCG = human chorionic gonadotrophin; LBB = liver, bone, brain metastases; PD = progressive disease; PFI = progression-free interval.

Table 7.4: PFS and OS estimates for all patients according to IGCCCG-2 prognostic score [228]

	N	%	HR	2-years PFS	3-year OS
Score (n = 1,435)					
Very Low	76	5.30	1	75.1	77.0
Low	257	17.9	2.07	52.6	69.0
Intermediate	646	45.0	2.88	42.8	57.3
High	351	24.5	4.81	26.4	31.7
Very High	105	7.3	8.95	11.5	14.7
Missing	159				

7.4.5 **Second relapse**

There are no randomised trials for patients with second relapse; however, conventional therapy does not appear to be very effective. For patients having received two series of conventionally dosed therapy (first-line and first salvage), High-dose (HD) chemotherapy with autologous stem cell support should be used [228]. Even with HD-therapy the chance of cure is only 20-25%.

Refractory disease: Patients relapsing within four-eight weeks after platinum-based therapy or who are progressing despite platinum-based therapy as well as those relapsing shortly after HD chemotherapy are considered cisplatin refractory. For those patients, combinations of gemcitabine and oxaliplatin or the triple combination of gemcitabine, oxaliplatin and paclitaxel have resulted in response rates of 25-45%. Targeted agents have mostly failed [236-238]. Cisplatin re-challenge in association with gemcitabine and paclitaxel, could be considered in patients with good renal function [239].

Patients with a good response undergoing subsequent resection of residual tumour lesions may still have a 15-20% chance of long-term cure [219, 240]. Immunotherapy with PD1- checkpoint inhibitors is currently studied due a substantial expression of PDL1 in germ cell tumours, in most series about 50% of tumour cells or tumour infiltration cells express PDL1.

7.4.5.1 *Late relapse (> two years after end of first-line treatment)*

Late relapse is defined as recurrence more than two years following cure after chemotherapy for metastatic TC, with, or without, residual tumour surgery and occurs, according to a pooled analysis, in 1.4% and 3.2% in seminoma and non-seminoma patients, respectively [241, 242]. If feasible, all lesions of late relapsing non-seminoma patients should be removed by radical surgery.

Patients with rapidly rising hCG may benefit from induction salvage chemotherapy before complete resection, but in most patients surgery should be performed irrespective of the level of their tumour markers in order to completely resect all undifferentiated germ-cell tumour, mature teratoma with or without somatic transformation [204, 243, 244].

Survival strongly depends on the histology of the removed lesions rather than on the initial germ cell cancer. Interestingly, in a population-based study all late-relapsing seminoma patients had viable germ cell tumour, whereas teratoma or necrosis was found in half of the patients with initial non-seminoma [245].

If the lesions are not completely resectable, biopsies should be obtained for histological assessment, and salvage chemotherapy should be initiated according to the histological results. In these cases, consultation of an experienced pathologist is required to avoid misinterpretation of the therapeutic morphological changes in the germ cell neoplasms [246]. If the patient responds to salvage chemotherapy, secondary surgery should be conducted whenever possible. In the case of unresectable, but localised, refractory disease, stereotactic or conventional radiotherapy may be considered. To avoid excess mortality, late relapses should be treated only at centres experienced in managing such patients [247].

7.4.5.2 *Treatment of brain metastases*

Brain metastases occur in the frame of the initial diagnosis of metastatic disease or a systemic relapse and rarely as an isolated relapse. The long-term survival of patients presenting with brain metastases at initial diagnosis is poor (30-50%), but it is even poorer when brain metastasis develops as recurrent disease (the five-year survival-rate is 2-5%) [248, 249]. A large international database comprising 523 patients reported 48% three-year OS rates in patients with brain metastases at initial diagnoses and 27% three-year OS rates for patients with brain metastases at relapse [250]. Chemotherapy was the initial treatment in this case, which proved particularly effective in a first line setting (potentially even as dose-intensified therapy upfront) while data support the use of multimodal treatment particularly in relapsed patients [250]. Consolidation radiotherapy, even in the case of a total response after chemotherapy should thus be used in patient with brain metastases

at relapse, but this option must be carefully discussed in a first-line setting [251]. Surgery can be considered in the case of a persistent solitary metastasis, depending on the systemic state, the histology of the primary tumour and the location of the metastasis.

7.4.6 Guidelines for the treatment of metastatic germ cell tumours

Recommendations	LE	GR
Treat low volume non-seminomatous germ cell tumour (NSGCT) stage IIA/B with elevated markers like 'good or intermediate prognosis' advanced NSGCT, with three or four cycles of cisplatin, etoposide, bleomycin (BEP).	2	A
In stage IIA/B NSGCT without marker elevation, exclude marker negative embryonal carcinoma by obtaining histology by either retroperitoneal lymph node dissection (RPLND) or biopsy. If not possible, repeat staging after six weeks of surveillance before making a final decision on further treatment.	3	B
In metastatic NSGCT with an intermediate prognosis, treat with four courses of standard BEP.	1	A
In metastatic NSGCT with a poor prognosis, treat with one cycle of BEP, followed by tumour marker assessment after three weeks: in the case of an unfavourable decline, initiate chemotherapy intensification. In the case of a favourable decline, continue BEP up to a total of four cycles.	1	A
Perform surgical resection of residual masses after chemotherapy in NSGCT in the case of visible residual masses and when serum levels of tumour markers are normal or normalising.	2	A
Initially offer radiotherapy for seminoma CS IIA. When necessary, use chemotherapy as a salvage treatment with the same schedule as for the corresponding prognostic groups of NSGCT.	2	B
Initially offer chemotherapy in seminoma stage CS IIB (BEP x 3 or etoposide, cisplatin x 4, in good prognosis) as an alternative to radiotherapy.	1a	A
Treat seminoma stage IIC and higher, with primary chemotherapy according to the same principles used for NSGCT.	1	A

8. FOLLOW UP AFTER CURATIVE THERAPY

8.1 Rationale for follow-up

The primary aim of follow-up in the first five years is the timely diagnosis of recurrent disease in order to be able to treat the patient with curative intent with the least aggressive therapy [241]. An adequate follow-up relies on the profound knowledge about TC with regards to histology, stage, primary treatment and treatment success. Follow-up has to be tailored to each individual patient and the schedule has to be acceptable to the patient, the physician, as well as the health care system. The interval of follow-up visits and the clinical investigations to be performed at each visit should depend on the risk of relapse, in general, and on the likely site of relapse in an individual patient [252]. Only one RCT was published addressing the implication of different follow-up schedules and the use of imaging and tumour markers [129]. Several recent publications have added valuable information and recommendations [84, 96, 97, 101, 103, 126, 253-255], contributing to the development of consensus recommendations and by the European Society for Medical Oncology Testicular Cancer Consensus Committee [256].

In recognition of the ionizing radiation exposure risks associated with repeated CT scanning [257] a reduction in the number of follow up CT scans advised has been seen in these past years [1, 258].

Looking at the different risks of relapse depending on diagnosis and initial treatment three major follow-up groups can be defined:

1. patients with seminoma stage I;
2. patients with non-seminoma stage I on active surveillance;
3. all patients having received either adjuvant treatment or curative chemotherapy for good- and intermediate-prognosis metastatic disease (according to the IGCCCG) achieving a complete remission with, or without, surgery (for seminoma this includes residual lesions < 3 cm, or residual lesions > 3 cm that are PET-negative).

It is important to note that patients not achieving a complete remission or presenting with poor prognosis disease should be followed up individually in specialised centres.

Tables 8.1-8.3 show the minimal recommendations for follow up of the three different groups based on recommendations developed at a consensus conference [256].

Generally, MRI of the abdomen can be used instead of CT in experienced centres. Regarding the use of US of the contralateral testis, the majority of the consensus meeting participants voted against repeat US investigation, both in case of negative biopsy (21/31) and also if no contralateral biopsy has been performed (17/32).

Follow up for relapse beyond five years is generally not recommended. A very late relapse (VLR) after five years is a rare event occurring in approximately 0.5% of patients according to a population-based analysis [245]. The aim of follow up beyond five years therefore shifts to detection of late side effects of treatment.

Most patients with VLR are diagnosed due to symptoms, however in up to 50% elevated tumour markers can be found in both seminomatous and non-seminomatous germ cell tumours [245, 259]. Patient education about relapse symptoms and physician awareness is a very important part of survivorship management. The early use of imaging and tumour markers in case of suspicion of relapse is encouraged.

Table 8.1: Recommended minimal follow-up for seminoma stage I on active surveillance or after adjuvant treatment (carboplatin or radiotherapy)

Modality	Year 1	Year 2	Year 3	Years 4 & 5	After 5 years
Tumour markers ± doctor visit	2 times	2 times	2 times	once	Further management according to survivorship care plan
Chest X-ray	-	-	-	-	
Abdominopelvic computed tomography/magnetic resonance imaging	2 times	2 times	Once at 36 months	Once at 60 months	

Table 8.2: Recommended minimal follow-up for non-seminoma stage I on active surveillance

Modality	Year 1	Year 2	Year 3	Years 4 & 5	After 5 years
Tumour markers ± doctor visit	4 times	4 times**	2 times	1-2 times	Further management according to survivorship care plan
Chest X-ray	2 times	2 times	Once, in case of LVI+	At 60 months if LVI+	
Abdominopelvic computed tomography/magnetic resonance imaging	2 times	At 24 months***	Once at 36 months*	Once at 60 months*	

* Recommended by 50% of the consensus group members.

**In case of high risk (LVI+) a minority of the consensus group members recommended six times.

***In case of high risk (LVI+) a majority of the consensus group members recommended an additional CT at eighteen months.

Table 8.3: Recommended minimal follow up after adjuvant treatment or complete remission for advanced disease (excluded: poor prognosis and no remission)

Modality	Year 1	Year 2	Year 3	Years 4 & 5	After 5 years
Tumour markers ± doctor visit	4 times	4 times	2 times	2 times	Further management according to survivorship care plan**
Chest X-ray	1-2 times	Once	Once	Once	
Abdominopelvic computed tomography (CT)/magnetic resonance imaging	1-2 times	At 24 months	Once at 36 months	Once at 60 months	
Thorax CT	*	*	*	*	

*Same time points as abdominopelvic CT/MRI in case of pulmonary metastases at diagnosis.

**In case of teratoma in resected residual disease: the patient should remain with the uro-oncologist.

8.2 Quality of life and long-term toxicities after cure of testicular cancer

The vast majority of patients will be cured and five-year relative survival rates approximate 95% in Western Europe. Furthermore, TC patients are usually between 18 and 40 years at diagnosis such that life expectancy after cure extends over several decades [260]. Patients should be informed before treatment of common long-term toxicities, which are probably best avoided by adherence to international guidelines. Treatment of stage I TC is controversial with some experts advocating surveillance for all, thereby avoiding unnecessary adjuvant chemotherapy [118], whereas others highlight the importance of patient autonomy and consider the prospect of avoiding salvage treatment with its known long-term toxicities as quite appealing [261]. Unfortunately, it is not known which treatment spares most patients long-term toxicities, which so far seem to be absent or mild after adjuvant chemotherapy [120, 127, 262].

During follow-up, patients should be screened and treated for known risk factors such as high blood pressure, hyperlipidaemia and testosterone deficiency. When follow-up by the TC expert is discontinued, a written cancer survivorship plan addressing late toxic effects, lifestyle recommendations, recurrence risk, and cancer-specific follow-up might be helpful [241, 263]. The following overview is not complete and interested readers are referred to review articles on this topic [260, 263, 264].

8.2.1 Second malignant neoplasms (SMN)

Treatment-induced SMN usually occur after the first ten years [263]. The risk for solid SMN increases with younger age at radio- or chemotherapy and remains significantly elevated for at least 35 years [110, 265-267]. Radiotherapy-related SMN are primarily localised within or close to the RT field (colon, stomach, pancreas, bladder and the urinary tract) [110, 111, 266-269]. Hauptmann *et al.* could demonstrate a remarkably clear radiation-dose relationship to gastric- and pancreatic cancer [175, 250]. Fung *et al.* demonstrated that modern cisplatin-based chemotherapy was associated with a 40% increased risk of a solid SMN [270].

8.2.2 Leukaemia

In a series of 40,576 TC survivors, the observed/expected ratio for developing a leukaemia, mostly acute myeloid (AML) and lymphoblastic leukaemia was 2.6 [271]. The risk of AML seems to be both related to the dose of cisplatin and etoposide. Doses of etoposide exceeding 2 g/m² have been shown to increase the subsequent risk of AML [272]. It is important to keep in mind that the majority of TC patients do receive much lower doses of etoposide such that the absolute risk of AML after three to four courses of BEP is very low, and in patients requiring high-dose chemotherapy with cumulative etoposide doses exceeding this threshold, less than 1.5% have been reported to suffer from AML. There is a cumulative dose-disease relationship regarding cisplatin and AML. Chemotherapy-induced leukaemia is usually diagnosed within the first ten years after treatment for TC and has a very poor prognosis [273].

8.2.3 Infections

Chemotherapy-treated TC survivors (TCSs) have a higher risk of dying from infections than the normal population, (SMR 2.48, 95% CI: 1.70 to 3.50) [274]. This is possibly due to long-term depression of the bone-marrow, but also complications of subsequent salvage treatment (which was not reliably registered) or extensive or subsequent surgical treatment might lie behind these numbers. Furthermore, asymptomatic pulmonary fibrosis by mediastinal radiotherapy and/or bleomycin may render TCSs vulnerable to potentially deadly pneumonias many years after treatment.

8.2.4 **Pulmonary complications**

Chemotherapy exposed TCSs have a nearly three-fold increased risk of dying of pulmonary diseases than the normal population [274]. Bleomycin-induced lung toxicity may affect 7% to 21% of patients in the long term, resulting in death in 1%-3% [275]. TCSs treated with high cumulative cisplatin doses and/or pulmonary surgery, have a poorer pulmonary function than those cured by surgery only [276]. Intriguingly, long-term pulmonary complications were associated with the cumulative cisplatin dose and not to the dose of bleomycin [276]. Pulmonary function recovered during repeated assessments over five years in almost all other assessed 565 TCSs [277]. Of note, an association with risk factors such as reduced renal function, age, tobacco-smoking, and cumulative chemotherapy, were not associated with pulmonary function, but with pulmonary embolism, lung surgery, and poor IGCCCG risk group [277].

8.2.5 **Cardiovascular toxicity**

Thromboembolic events (mostly venous) occur more frequently in patients with GCT receiving chemotherapy than in other young male adults treated with chemotherapy for other cancers [278]. Low-dose heparins used during the course of chemotherapy may prevent the onset of thromboembolic events [279], though level 1 evidence is lacking. Mortality from cardiovascular disease (CVD) is higher in TCSs than in the general population [274, 280]. Furthermore, CVD is more common in chemotherapy-treated TCSs than in those who underwent surgery only [123, 281]. A recent report estimated even a 0.24% incidence of major vascular events during cisplatin-based chemotherapy [278]. The metabolic syndrome is a strong predictor for CVD and its components, hypertension, obesity and hypercholesterolemia, increase with treatment intensity [282, 283]. Circulating residual serum platinum might exert endothelial stress and thereby possibly lead to hypertension [284],[285]. Furthermore, exposure to circulating platinum has been shown to be associated with paraesthesia, hypogonadism, and hypercholesterolaemia [285].

8.2.6 **Raynaud-like phenomena**

Chemotherapy-related Raynaud-like phenomena were reported before the introduction of cisplatin and are usually ascribed to the application of bleomycin [286, 287]. Cisplatin is believed to contribute to cold-induced vasospasms. Vogelzang *et al.* reported that the incidence of Raynaud's phenomenon was higher after treatment with CVB than after vinblastine and bleomycin only, 41% vs. 21%, respectively [288].

8.2.7 **Neurotoxicity**

Cisplatin induces a symmetric dose-dependent sensory, distal, length-dependent glove and stocking paraesthesias, affecting 29% of TCSs who received cisplatin-based chemotherapy as opposed to 10% after orchiectomy alone [289]. Application of five or more cycles increases the frequency of this symptom to 46%. Paclitaxel-induced acute neuropathy consists of an acute pain syndrome, which usually develops within three days of paclitaxel administration, or within a week. Platinum is measurable in the serum of TCSs many years after its application and the intensity of paraesthesias is more strongly associated with platinum serum level than with the cumulative dose of applied cisplatin [284].

8.2.8 **Ototoxicity**

Cisplatin-induced ototoxicity comprises tinnitus and hearing impairment, particularly frequencies of 4,000 Hz and higher, and is caused by damage to the outer hair cells in the inner ear [290-292]. Both hearing impairment and tinnitus are considerably increased after application of 50 mg/m² cisplatin over two days as compared to 20 mg/m² over five days (odds ratio 5.1 and 7.3, respectively), indicating a higher impact of serum peak concentrations than cumulative doses [289]. A significant association between glutathione S-transferases (GST) genotypes and the risk of cisplatin-induced ototoxicity has been demonstrated [293, 294]. Hopefully, increasing insight into the pathogenesis of and vulnerability for this complication will lead to more individualised treatment in the future.

8.2.9 **Nephrotoxicity**

Cisplatin-based chemotherapy may lead to long-term renal function impairment in 20-30% of TCSs [289-292]. In TC patients, reduced renal elimination of cisplatin and bleomycin might increase the risk of other toxicities, e.g. bleomycin-related pneumonitis [295, 296]. However, a comprehensive assessment of 1,206 Danish TCSs did not reveal a significant association between chemotherapy-induced impaired renal function and other toxicities [279]. Renal recovery was poor after 5 or more cycles of BEP as compared to after BEP x3 [279].

8.2.10 **Hypogonadism**

Testicular endocrine dysfunction comprises insufficient testosterone production and/or compensatory increased Luteinizing hormone (LH) levels. Subnormal testosterone levels have been reported in TCSs treated with chemotherapy, when compared to those treated with surgery only or the general population [262, 297].

8.2.11 **Fatigue**

Chronic fatigue (CF) is described as a subjective feeling of emotional, physical and/or cognitive tiredness that is not relieved by rest, and persists for more than six months. Significantly higher levels of C-reactive protein and interleukin-1 receptor antagonist are measured in TCSs with CF [298]. Also, a significantly higher frequency of CF (16%) was reported in a cross-sectional Norwegian study of long-term TCSs at a median of twelve years after treatment for TC when compared with the age-matched Norwegian population (10%) [299]. Of note, the prevalence of CF increased from 15% to 27% during a 10 year period in long-term TCSs [300].

8.2.12 **Quality of life**

Quality of life (QoL) is transiently reduced by chemotherapy, during which patients experience a loss of appetite, increased fatigue, increased dyspnoea and reduced social and physical functions [299]. When comparing three or four cycles of BEP in good risk patients, all outcomes favour treatment with three courses [160]. After one and two years, one third of patients reported an improvement in global QoL after chemotherapy, while one fifth of patients reported deterioration, with no difference between treatment groups. In adjuvant treatment of non-seminoma stage I patients, there was no difference in short-term or long-term (5 year) QoL between RPLND or one course of BEP [301]

9. TESTICULAR STROMAL TUMOURS

9.1 **Classification**

Non-germ-cell tumours of the testicle include sex cord/gonadal stromal tumours and miscellaneous nonspecific stromal tumours. The different histological subtypes of testicular tumours are defined according to the WHO classification 2016 (adapted) [30].

9.1.1 **Epidemiology and prognosis**

Sex cord stromal tumours comprise less than 5% of testicular neoplasms. Data from the National Cancer Data Base, published in 2016, showed that 0.39% of patients (315/79,120) were diagnosed with primary malignant Leydig or Sertoli cell tumours [113]. Of these 315 patients 250 (79%) had malignant Leydig cell tumours and 65 (21%) had malignant Sertoli cell tumours. Overall survival at one and five years for CS Leydig cell tumours was 98% (95% CI: 96-100) and 91% (95% CI: 85-96), respectively, and for CSI Sertoli cell tumours OS was 93% (95% CI: 83-100) and 77% (95% CI: 62-95), respectively ($p = 0.015$).

Conclusion is that five-year survival estimates of stage I Leydig and Sertoli cell tumours are significantly lower compared to those of stage I germ cell tumours with Sertoli cell tumours significantly worse than Leydig cell tumours.

A recent systematic review [285] analysing the impact of previously identified pathologic risk factors on harbouring occult metastatic disease (OMD) in patients with CS I testicular stromal tumours showed an increased risk of occult metastatic disease for each additional risk factor ($P < .001$). Five-year occult metastatic disease-free survival was 98.1% for those with < 2 risk factors vs. 44.9% for those with ≥ 2 risk factors ($P < .001$). Whilst the existing literature does not support making firm recommendations, it seems to be of interest to risk-stratify patients for future research and initiate adjuvant therapy in higher-risk patients.

These data support the importance of large databases to evaluate the efficacy of treatment in rare neoplasms.

9.2 **Leydig cell tumours**

9.2.1 **Epidemiology**

Leydig cell tumours constitute about 1-3% of adult testicular tumours [302, 303] and 3% of testicular tumours in infants and children [303]. These tumours are most common in the third to sixth decade in adults, with a similar incidence observed in each decade. Another peak incidence is seen in children aged between three and nine years. Only 3% of Leydig cell tumours are bilateral [302]. These tumours occur in about 8% of patients with Klinefelter's syndrome [303].

9.2.2 **Pathology of Leydig cell tumours**

Leydig cell tumours are the most common type of sex cord/gonadal stromal tumours. Histopathologically, they are well delineated and usually up to 5 cm in diameter. They are solid, yellow to tan in colour, with haemorrhage and/or necrosis in 30% of cases. Microscopically, the cells are polygonal, with eosinophilic cytoplasm and occasional Reinke crystals, regular nucleus, solid arrangement and capillary stroma. The cells express vimentin, inhibin, protein S-100, steroid hormones, calretinin and cytokeratin (focally) [64].

Approximately 10% of Leydig cell tumours are malignant and present with the following parameters [304, 305]:

- large size (> 5 cm);
- older age;
- increased mitotic activity (> 3 per 10 high-power field [HPF]);
- vascular invasion;
- cytological atypia;
- increased MIB-1 expression;
- necrosis;
- infiltrative margins;
- extension beyond the testicular parenchyma;
- DNA aneuploidy.

9.2.3 **Diagnosis**

Patients either present with a painless enlarged testis or the tumour is found incidentally on US. In up to 80% of cases, hormonal disorders with high oestrogen and oestradiol levels, low testosterone, and increased levels of LH and FSH are reported [306, 307], while negative results are always obtained for the testicular germ cell tumour-markers AFP, hCG, LDH and PLAP. Up to 10% of adult patients present with gynaecomastia [307, 308].

Diagnostic work-up must include markers, hormones (at least testosterone, LH and FSH; if not conclusive, also oestrogen, oestradiol, progesterone and cortisol), US of both testes, and CT of chest and abdomen. On US, it may be possible to observe well-defined, small, hypoechoic lesions with hypervascularisation, however, the appearance is variable and is indistinguishable from germ-cell tumours [309]. Contrast-enhanced US [310] or contrast-enhanced MRI [311] may improve the diagnosis. The proportion of metastatic tumours in all published case reports is less than 10%. In three old series with long follow-up, eighteen metastatic tumours were found in a total of 83 cases (21.7%) [302, 304, 312], while 5 recently published studies with long follow-up reported only 2 metastatic tumours in 156 patients (1.3%) [113, 307, 308, 313, 314].

9.3 **Sertoli cell tumours**

9.3.1 **Epidemiology**

Sertoli cell tumours account for fewer than 1% of testicular tumours, and the mean age at diagnosis is around 45 years, with sporadic cases under 20 years of age [315, 316]. On rare occasions, these tumours may develop in patients with androgen insensitivity syndrome and Peutz-Jeghers syndrome.

9.3.2 **Pathology of Sertoli cell tumours**

These tumours are well circumscribed, yellow, tan or white in colour, with an average diameter of 3.5 cm [315]. Microscopically, the cells are eosinophilic to pale with vacuolated cytoplasm. The nuclei are regular with grooves and inclusions may be present. The arrangement of the cells is tubular or solid; a cord-like or retiform pattern is possible. The stroma is fine with capillaries, but in some cases a sclerosing aspect predominates. The cells express vimentin, cytokeratins, inhibin (40%) and protein S-100 (30%) [315]. The rate of malignancy ranges between 10% and 22%. Signs of a malignant Sertoli tumour are as follows [317, 318]:

- large size (> 5 cm);
- increased mitotic activity (> 5 per 10 HPF);
- pleomorphic nuclei with nucleoli;
- necrosis;
- vascular invasion.

9.3.2.1 **Classification**

Three subtypes have been described [316]:

- classic Sertoli cell tumour [315];
- large cell calcifying form with characteristic calcifications [319, 320];
- sclerosing form [321, 322].

9.3.3 **Diagnosis**

Patients present either with an enlarged testis or the tumour is found incidentally on US. Most classic Sertoli cell tumours are unilateral and unifocal. Hormonal disorders are infrequent, although gynaecomastia is sometimes seen [315]. The testicular tumour-markers AFP, hCG, LDH and PLAP are always negative. Diagnostic work-up must include tumour markers, hormones (at least testosterone, LH and FSH; if not conclusive, also oestrogen, oestradiol, progesterone and cortisol), US of both testes and CT of chest and

abdomen. Sertoli cell tumours are generally hypoechoic on US, but they can be of variant appearance and thus cannot be safely distinguished from germ-cell tumours [316]. Only the large cell calcifying form has a characteristic image with bright echogenic foci due to calcification [323]. Metastatic disease of 12% in classic Sertoli cell tumour has been reported. In general, affected patients are older, tumours are nearly always palpable, and show more than one sign of malignancy [315].

The large cell calcifying form is diagnosed in younger men and is associated with genetic dysplastic syndromes (Carney's complex [324] and Peutz-Jeghers syndrome [325]) or, in about 40% of cases, endocrine disorders. Forty-four percent of cases are bilateral, either synchronous or metachronous, and 28% show multifocality with good prognosis [320].

Up to 20% of the large cell calcifying forms are malignant. It has been suggested that discrimination between an early and late onset type may define a different risk for metastatic disease (5.5% compared to 23%) [316].

The sclerosing subtype is very rare, unilateral, with a mean age around 40 years and metastases are infrequent [322].

9.4 Treatment of Leydig- and Sertoli cell tumours

Asymptomatic, small volume testicular tumours are often misinterpreted as germ-cell tumours, and inguinal orchidectomy is performed. An organ-sparing procedure in every small US-detected, nonpalpable intraparenchymal lesion is highly recommended in order to obtain a histological diagnosis. The incidence of benign definitive histology is high at approximately 80% [326]. In patients with symptoms of gynaecomastia or hormonal disorders, a non-germ-cell tumour should be considered and immediate orchidectomy avoided. In cases with germ-cell tumour in either frozen section or paraffin histology, orchidectomy is recommended as long as a contralateral normal testicle is present.

When diagnosed and treated early, long-term favourable outcomes are seen at follow-up in Leydig cell tumours, even with its potential metastatic behaviour. In stromal tumours with histological signs of malignancy, especially in older patients, orchidectomy and early retroperitoneal lymphadenectomy may be an option to prevent metastases [113, 327] or to achieve long-term cure in stage IIA cases [328]. Prophylactic RPLND is unjustified for patients with CS I disease without high-risk features [329].

Tumours that have metastasised to lymph nodes, lung, liver or bone respond poorly to chemotherapy or radiation and survival is poor [113, 327]. No recommendations are available for the treatment of these patients.

9.5 Follow-up of Leydig- and Sertoli cell tumours

Without clinical signs of malignancy, an individualised surveillance strategy after orchidectomy is recommended in patients with one, or more, pathological features of malignancy. Follow-up is recommended in all high-risk patients; every three to six months with physical examination, hormone assays, scrotal and abdominal US, chest radiography, and CT [307].

9.6 Granulosa cell tumour

This is a rare tumour with two variants: juvenile and adult. Less than 100 cases are reported with a predominance of the juvenile type.

- The juvenile type is benign. It is the most frequent congenital testicular tumour and represents about 1-5% of all pre-pubertal testicular neoplasms. The cystic appearance is characteristic of this tumour type [330, 331].
- The average age of the adult type at presentation is 45 years. The typical morphology is a homogeneous, yellow-grey tumour, with elongated cells with grooves in microfollicular and Call-Exner body arrangements [332].

Malignant tumours represent around 20% of cases. Lymphovascular invasion, necrosis, infiltrative borders and size > 4 cm may help in identifying cases with aggressive behaviour. Mitotic counts vary and do not appear to be of prognostic significance [333].

9.7 Thecoma/fibroma group of tumours

These tumours are rare with variable histology such as minimal invasion into surrounding testis, high cellularity, and increased mitotic rate. Their immunoprofile is variable and typically not diagnostic. They seem to be uniformly benign [334].

9.8 Other sex cord/gonadal stromal tumours

Sex cord/gonadal stromal tumours may be incompletely differentiated or in mixed forms. There is limited experience with incompletely differentiated sex cord/gonadal stromal tumours and no reported cases of metastasis [37]. In mixed tumour forms, all the histological components should be reported. However, the clinical behaviour most likely reflects the predominant pattern or the most aggressive component of the tumour [335].

9.9 Tumours containing germ cell and sex cord/gonadal stroma (gonadoblastoma)

Some patients with disorders of sex development (DSDs) have abnormal gonadal development with ambiguous genitalia and an increased risk of germ-cell tumours. If the arrangement of the germ cells is in a nested pattern and the rest of the tumour is composed of sex cord/gonadal stroma, the term gonadoblastoma is used. Bilateral tumours are present in 40% of cases. The prognosis correlates with the invasive growth of the germinal component [336, 337].

In the case of a diffuse arrangement of the different components, there are some doubts about the neoplastic nature of the germinal cells and some authors consider them to be entrapped rather than neoplastic [338].

9.10 Miscellaneous tumours of the testis

9.10.1 Tumours of ovarian epithelial types

These tumours resemble epithelial tumours of the ovary. A cystic appearance with occasional mucinous material can be observed. Microscopically, the aspect is identical to their ovarian counterparts, and their evolution is similar to that of the different epithelial ovarian subtypes. Some Brenner types are malignant [64].

9.10.2 Tumours of the collecting ducts and rete testis

These tumours are very rare. Benign (adenoma) and malignant (adenocarcinoma) variants have been reported, with malignant tumours showing local growth with a mortality rate of 40% within one year [339].

9.10.3 Tumours (benign and malignant) of non-specific stroma

These are very uncommon and have similar criteria, prognosis and treatment to soft tissue sarcomas.

1. INTRODUCTION

1.1 Aim and objectives

The European Association of Urology (EAU) Guidelines on Penile Cancer provides up-to-date information on the diagnosis and management of penile squamous cell carcinoma (SCC).

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Penile Cancer Guidelines Panel consists of an international multi-disciplinary group of clinicians, including a pathologist and an oncologist. Members of this panel have been selected based on their expertise and to represent the professionals treating patients suspected of having penile cancer. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU website Uroweb: <http://uroweb.org/guideline/penile-cancer/>.

1.3 Available publications

A quick reference document (Pocket guidelines) is available, both in print and in a number of versions for mobile devices. These are abridged versions which may require consultation together with the full text version. Several scientific publications are available, the most recent dating back to 2014 [1], as are a number of translations of all versions of the Penile Cancer Guidelines. All documents are available through the EAU website Uroweb: <http://uroweb.org/guideline/penile-cancer/>.

1.4 Publication history

The EAU Penile Cancer Guidelines were first published in 2000 with the most recent full update undertaken in 2014.

2. METHODS

2.1 Data identification

A systematic literature search on penile cancer was performed between August 2008 and November 2013. All articles relating to penile cancer (n = 1,602) in the relevant literature databases were reviewed and 352 papers were considered suitable for addition to the research base of the Guidelines. Fully revised Guidelines were produced using the updated research base, together with several national and international guidelines on penile cancer (National Comprehensive Cancer Network [2], French Association of Urology [3] and the European Society of Medical Oncology [4]). Recommendations in this text are assessed according to their level of evidence (LE) and Guidelines are given a grade of recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [5]. Additional information can be found in the general Methodology section of this print, and online at the EAU website: <http://uroweb.org/guideline/>. A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review

This document was subjected to independent peer review prior to publication in 2014.

2.3 Future goals

The results of an ongoing systematic review will be included in the 2018 update of the Penile Cancer Guidelines. This review is performed using standard Cochrane systematic review methodology: <http://www.cochranelibrary.com/about/about-cochrane-systematic-reviews.html>.

Ongoing systematic review:

- What are the risks and benefits of adjuvant radiotherapy after inguinal lymphadenectomy for penile cancer? [6]

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Definition of penile cancer

Penile carcinoma is usually a SCC, although there are other types of penile cancer (see Table 3). Penile SCC usually arises from the epithelium of the inner prepuce or the glans. Penile SCC exists in several histological subtypes. Its pathology is similar to SCC of the oropharynx, female genitalia (cervix, vagina and vulva) and anus and shares some of their natural history.

3.2 Epidemiology

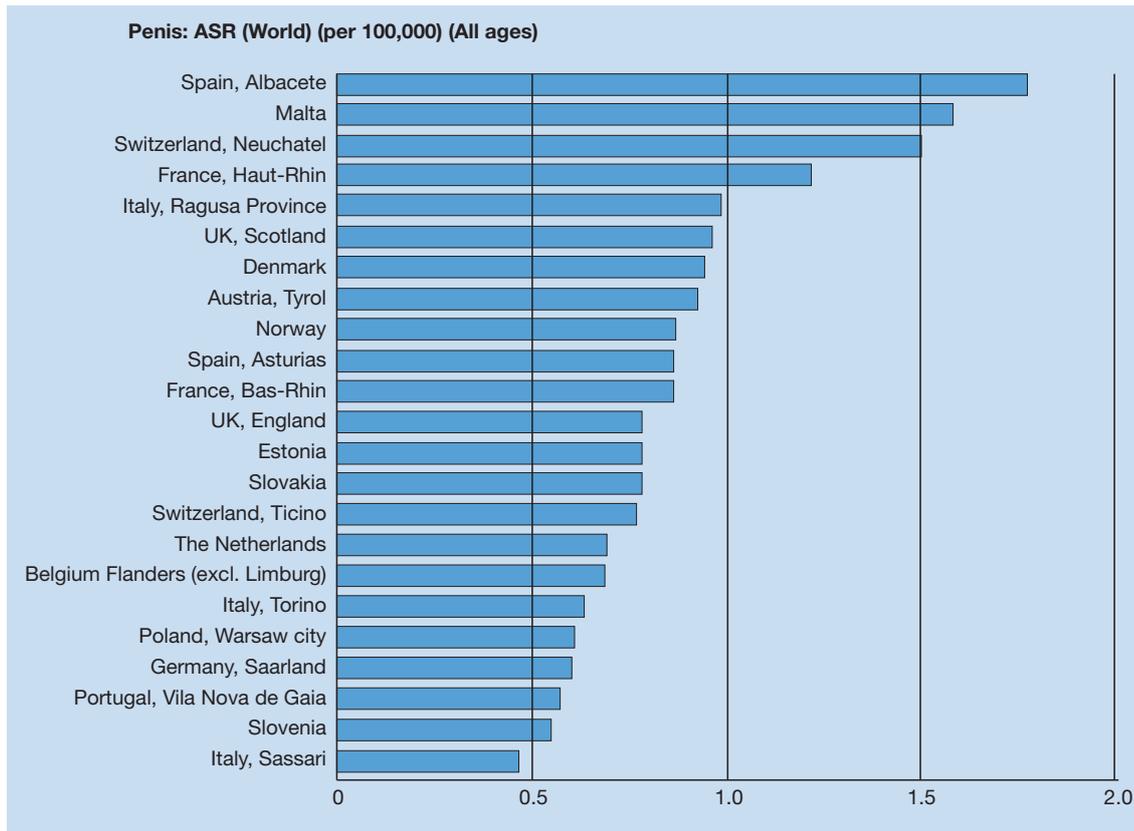

In the Western World, primary penile cancer is uncommon, with an overall incidence of < 1.00/100,000 males in Europe and the USA [7, 8] although there are several geographical areas in Europe with an incidence over 1.00/100,000 (Figure 1) [9]. In North America [7], the incidence of penile cancer is also affected by race and ethnicity, with the incidence highest in white Hispanics (1.01/100,000) compared to Alaskans, Native American Indians (0.77/100,000), African Americans (0.62/100,000) and white non-Hispanics (0.51/100,000), respectively. In contrast, other parts of the world, such as South America, South East Asia and parts of Africa, have a much higher incidence, with penile cancer accounting for 1-2% of malignant diseases in men [9].

Penile cancer is common in regions with a high prevalence of human papilloma virus (HPV), which may account for the variation in incidence, as the worldwide HPV prevalence varies considerably [7]. The annual age-adjusted incidence is 0.7-3.0/100,000 men in India, 8.3/100,000 men in Brazil and even higher in Uganda, where it is the most commonly diagnosed male cancer [9, 10]. The majority of knowledge about penile cancer comes from countries with a high incidence rate.

There is also a less noticeable variation in incidence between European regions (Figure 1). At least one third of cases can be attributed to HPV-related carcinogenesis. There is no data linking penile cancer to human immunodeficiency virus (HIV) or acquired immune deficiency syndrome (AIDS).

In the USA, the overall age-adjusted incidence rate decreased from 1973 to 2002 from 0.84/100,000 in 1973-1982 to 0.69/100,000 in 1983-1992, and to 0.58/100,000 in 1993-2002 [7]. In Europe, the overall incidence has been stable from the 1980s until 2013 [8], with an increased incidence reported in Denmark [11] and the UK. A UK longitudinal study confirmed a 21% increase in incidence from 1979-2009 [12].

The incidence of penile cancer increases with age [8]. The peak age is during the sixth decade of life, though the disease does occur in younger men [13].

Figure 1: Annual incidence rate (world standardised) by European region/country*

*Adapted from [9].

3.3 Risk factors and prevention

A review of the published literature from 1966-2000 identified several risk factors for penile cancer [14] (Table 1) (LE: 2a).

Table 1: Recognised aetiological and epidemiological risk factors for penile cancer

Risk factors	Relevance	Ref
Phimosis	Odds ratio 11-16 vs. no phimosis	[15, 16]
Chronic penile inflammation (balanoposthitis related to phimosis) Balinitis xerotica obliterans (lichen sclerosus)	Risk	[17]
Sporalene and ultraviolet A phototherapy for various dermatological conditions such as psoriasis	Incidence rate ratio 9.51 with > 250 treatments	[18]
Smoking	Five-fold increased risk (95% Confidence interval: 2.0-10.1) vs. nonsmokers	[15, 16, 19]
Human papilloma virus infection condylomata acuminata	22.4% in verrucous squamous cell carcinoma 36-66.3% in basaloid-warty	[7, 20]
Rural areas, low socio-economic status, unmarried		[21-24]
Multiple sexual partners, early age of first intercourse	Three to five-fold increased risk of penile cancer	[14, 16, 25]

Human papilloma virus infection (HPV) is an important risk factor; HPV DNA was found in 70-100% of intra-epithelial neoplasia and in 30-40% of invasive penile cancer tissue samples (LE: 2a). It is thought to be a cofactor in the carcinogenesis of some variants of penile SCC [20] through interaction with oncogenes and tumour suppressor genes (P53, Rb genes) [26]. The commonest HPV subtypes in penile cancer are types 16 and 18 [27] and the risk of penile cancer is increased in patients with condyloma acuminata [28] (LE: 2b).

It remains unclear whether HPV-associated penile cancer has a different prognosis to non-HPV-associated penile cancer. A significantly better five-year disease-specific survival (DSS) rate was reported for HPV-positive vs. HPV-negative cases (93% vs. 78%) [29], while others reported no difference in lymph node metastases and ten-year survival rates [30]. There is no direct association between the incidence of penile cancer and cervical cancer. However, both cancers are independently linked with the prevalence of HPV infections [31, 32]. Female sexual partners of patients with penile cancer do not have an increased incidence of cervical cancer.

There is no current recommendation for HPV vaccination in males because of the different HPV-associated risk patterns in penile and cervical cancer. The epidemiological effects of HPV vaccination in girls are also awaited [33, 34].

Phimosis is strongly associated with invasive penile cancer [16, 21, 35, 36], probably due to associated chronic infection since smegma is not a carcinogen [35]. A further risk factor suggested by epidemiological studies is cigarette smoking, 4.5-fold increased risk (95% CI: 2.0-10.1) [36]. The incidence of lichen sclerosus (balanitis xerotica obliterans) in patients with penile cancer is relatively high but is not associated with increased rates of adverse histopathological features, including carcinoma *in situ* (CIS). Other epidemiological risk factors are low levels of socio-economic status and education [21].

Countries and cultures practising routine neonatal circumcision have a lower incidence of penile cancer. Israeli Jews have the lowest incidence at 0.3/100,000/year. Neonatal circumcision removes approximately half the tissue that can develop into penile cancer. A USA study of a 100 matched case-control pairs found that the protective effect of neonatal circumcision against invasive penile cancer (OR 0.41) became much weaker when the comparative analysis was only against men without a history of phimosis (OR 0.79, 95% CI: 0.29-2 [16]). Neonatal circumcision does not reduce the risk of CIS [16].

3.4 Pathology

Squamous cell carcinoma accounts for > 95% of cases of penile malignancies (Tables 2 and 3). It is not known how often SCC is preceded by premalignant lesions (Table 3) [37-40]. Some variants of primary penile cancer have not yet been included in the World Health Organisation (WHO) classification, including pseudohyperplastic carcinoma, carcinoma cuniculatum, pseudoglandular carcinoma, and warty-basaloid carcinoma.

There are many mixed forms of SCC, including the warty-basaloid form (50-60% of mixed penile SCC), usual- verrucous (hybrid), usual-warty, usual-basaloid or usual-papillary and other rarer combinations.

Other penile malignant lesions include melanocytic lesions, mesenchymal tumours, lymphomas and metastases which are unrelated to penile cancer, and rarer. Aggressive penile sarcoma has been reported. Penile metastases from other neoplasias often have a prostatic or colorectal origin.

Table 2: Premalignant penile lesions (precursor lesions)

Lesions sporadically associated with squamous cell carcinoma (SCC) of the penis: <ul style="list-style-type: none"> • Cutaneous horn of the penis • Bowenoid papulosis of the penis • Lichen sclerosus (balanitis xerotica obliterans)
Premalignant lesions (up to one-third transform to invasive SCC): <ul style="list-style-type: none"> • Intra-epithelial neoplasia grade III • Giant condylomata (Buschke-Löwenstein) • Erythroplasia of Queyrat • Bowen's disease • Paget's disease (intra-dermal ADK)

Table 3: Histological subtypes of penile carcinomas, their frequency and outcome

Subtype	Frequency (% of cases)	Prognosis
Common squamous cell carcinoma (SCC)	48-65	Depends on location, stage and grade
Basaloid carcinoma	4-10	Poor prognosis, frequently early inguinal nodal metastasis [41]
Warty carcinoma	7-10	Good prognosis, metastasis rare
Verrucous carcinoma	3-8	Good prognosis, no metastasis
Papillary carcinoma	5-15	Good prognosis, metastasis rare
Sarcomatoid carcinoma	1-3	Very poor prognosis, early vascular metastasis
Mixed carcinoma	9-10	Heterogeneous group
Pseudohyperplastic carcinoma	< 1	Foreskin, related to lichen sclerosus, good prognosis, metastasis not reported
Carcinoma cuniculatum	< 1	Variant of verrucous carcinoma, good prognosis, metastasis not reported
Pseudoglandular carcinoma	< 1	High-grade carcinoma, early metastasis, poor prognosis
Warty-basaloid carcinoma	9-14	Poor prognosis, high metastatic potential [42] (higher than in warty, lower than in basaloid SCC)
Adenosquamous carcinoma	< 1	Central and peri-meatal glans, high-grade carcinoma, high metastatic potential but low mortality
Mucoepidermoid carcinoma	< 1	Highly aggressive, poor prognosis
Clear cell variant of penile carcinoma	1-2	Exceedingly rare, associated with human papilloma virus, aggressive, early metastasis, poor prognosis, outcome is lesion-dependent, frequent lymphatic metastasis [43]

3.4.1 **Gross handling of pathology specimens**

Tissue sections must include entire small lesions and at least three to four blocks of larger lesions. Lymph nodes must be included in their entirety to ensure the detection of micrometastases. Surgical margins must also be completely included.

3.4.2 **Pathology report**

The pathology report must include the anatomical site of the primary tumour, the histological type/subtypes, grade, perineural invasion, depth of invasion, vascular invasion (venous/lymphatic), irregular growth and front of invasion, urethral invasion, invasion of corpus spongiosum/cavernosum and surgical margins.

3.4.3 **Grading**

The Tumour, Node, Metastasis (TNM) classification for penile cancer includes tumour grade, due to its prognostic relevance (Table 4). Both Broder's classification and the WHO grading system for grading penile cancer are highly observer dependent and are no longer used [44].

3.4.4 **Pathological prognostic factors**

Carcinomas limited to the foreskin have a better prognosis and lower risk of regional metastasis [45]. Perineural invasion and histological grade are very strong predictors of poor prognosis and cancer-specific mortality [46]. Although tumour grade is a predictor of metastatic spread, it can be difficult to grade heterogeneous tumours. Lymphatic invasion is an independent predictor of metastasis. Venous embolism is often seen in advanced stages.

Types of penile SCC with an excellent prognosis include: verrucous, papillary, warty, pseudohyperplastic and carcinoma cuniculatum. These SCCs are locally destructive, rarely metastasise and have a very low cancer-related mortality.

High-risk SCC variants are the basaloid, sarcomatoid, adenosquamous and poorly differentiated types. They metastasise early and mortality rates are high. The intermediate-risk SCC group comprises the most common SCC, mixed forms and the pleomorphic form of warty carcinomas.

Stage pT3 tumours that invade the distal (glandular) urethra (25% of cases) do not have a worse outcome [47]. However, invasion of the more proximal urethra, also classified as stage pT3, is due to a highly aggressive SCC with a poor prognosis (see Table 3). The inclusion in the one pT2 group of cancers which invade the corpus spongiosum and the corpora cavernosa is confusing clinically as these conditions have very different prognoses. After a mean follow-up of three years, higher rates of local recurrence (35% vs. 17%)

and mortality (30% vs. 21%) were reported in pT2 tumours (n = 72) with tunica or cavernosal involvement vs. glans-only invasion, respectively [48] (LE: 2b). The Panel proposed defining T2a with spongiosum-only invasion and T2b with tunica and/or corpus cavernosum invasion. A similar prognostic difference was observed in a retrospective analysis of 513 patients treated between 1956 and 2006 [49].

Long-term survival is similar in patients with T2 and T3 tumours and in patients with N1 and N2 disease, using the 1987-2002 TNM classification [49] (LE: 2a).

Two nomograms, based only on small numbers, were developed to estimate prognosis in penile cancer. One study suggested that pT1G1 tumours are low-risk tumours, with 0% developing lymph node metastases, in contrast to high-risk pT2/3 G2/3 tumours, with 83% developing lymph node metastases [50]. Remaining tumours were intermediate-risk tumours with 33% developing metastases. Another study reported similar findings and recommended prophylactic lymphadenectomy for high-risk patients [51]. There is also a 'prognostic index', which ranks several pathological parameters (grade, deepest anatomical level, perineural invasion) to predict the likelihood of inguinal lymph node metastases and five-year survival [52]. The lower the score, the higher the probability of 95% survival at five years.

3.4.5 **Penile cancer and HPV**

A high prevalence of HPV infection is found in basaloid (76%), mixed warty-basaloid (82%) and warty penile (39%) SCCs. The commonest HPV-types in penile SCC are HPV 16 (72%), HPV 6 (9%) and HPV 18 (6%). Verrucous and papillary penile SCCs are HPV-negative. Overall, only one-third of penile SCCs show HPV infection, but those that do are usually infected by several HPV strains.

3.4.6 **Molecular biology**

Little is known about the role of chromosomal abnormalities in penile SCC in relation to biological behaviour and patient outcome [25]. Lower DNA copy and alteration numbers are linked to poorer survival. Alterations in the locus 8q24 may play a major role and are implicated in other neoplasms such as prostate cancer [53, 54]. Telomerase activity has been shown in invasive penile carcinoma [55], and some authors have shown that aneuploidy changed according to tumour grade [56].

Epigenetic alterations evaluating the methylation pattern of CpG islands in CDKN2A have been described. CDKN2A encodes for two tumour suppressor proteins (p16INK4A and p14ARF) which control cell growth through Rb and p53 pathways. Poetsch *et al.* showed that 62% of invasive SCC of the penis displayed allelic loss of p16 and 42% displayed promoter hypermethylation. Tumours immunohistochemically negative for p16 showed hypermethylation of and/or loss of heterozygosity (LOH) near the p16INK4A locus. In that study, p16 negativity was linked to lymph node metastasis, in another study to prognosis [57]. Allelic loss of the p53 gene is a frequent event in penile SCC (42%) [58] and p53 expression has been linked to poor prognosis [59]. Another element influencing lymph node metastasis is the metastasis suppressor protein KAI1/CD82; decreased expression of this protein favours lymph node metastasis [60].

3.4.7 **Penile biopsy**

The diagnosis of penile cancer must be confirmed by biopsy. Although penile cancer is usually obvious, very occasionally it may be confused with non-SCC penile carcinoma or inflammatory lesions. Histological confirmation is necessary to guide management when:

- there is doubt about the exact nature of the lesion (e.g. CIS, metastasis or melanoma);
- treatment is planned with topical agents, radiotherapy or laser surgery;
- lymph node treatment is based on pre-operative histological information (risk-adapted strategy).

Biopsy size is important; in biopsies with an average size of 0.1 cm, it is difficult to evaluate the depth of invasion in 91% of biopsies. The grade at biopsy and in the final specimen may differ in up to 30% of cases with failure to detect cancer in 3.5% of cases [37]. Furthermore, vascular and lymphatic tumour emboli were detected in only 9-11% of cases. Although a punch biopsy may be sufficient for superficial lesions, an excisional biopsy is preferred as it should be deep enough to properly assess the degree of invasion and stage.

3.4.8 **Intra-operative frozen sections and surgical margins**

The aim of surgical treatment is complete removal of the penile carcinoma and negative surgical margins. The width of negative surgical margins should follow a risk-adapted strategy based on tumour grade. Negative surgical margins may be confirmed intra-operatively by frozen section [61]. If surgical margins are studied following these criteria (including urethral and periurethral tissue), only 5 mm of tumour-free tissue is sufficient to consider the surgical margins to be negative [62].

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 TNM classification

The 2016 UICC TNM classification for penile cancer [63] introduced some changes as compared to prior editions. The T1 category is stratified into two prognostically different risk groups, depending on the presence or absence of lymphovascular invasion, and grading (Table 4). The classification T2 denotes invasion of the corpus spongiosum, while the T3 category is defined as invasion of the corpora cavernosa, recognising the fact that these two invasion patterns differ prognostically [48, 49]. The current pN1 group consists of one or two inguinal lymph node metastases, pN2 is more than two uni- or bilateral metastatic nodes, and pN3 any pelvic nodes, uni- or bilateral as well as any extranodal extension [63].

Retroperitoneal lymph node metastases are extra-regional nodal and therefore distant metastases.

Table 4: 2016 TNM clinical and pathological classification of penile cancer [63]

Clinical classification	
T - Primary Tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Tis	Carcinoma <i>in situ</i>
Ta	Non-invasive verrucous carcinoma*
T1	Tumour invades subepithelial connective tissue
T1a	Tumour invades subepithelial connective tissue without lymphovascular invasion and is not poorly differentiated (T1G1-2)
T1b	Tumour invades subepithelial connective tissue with lymphovascular invasion or is poorly differentiated (T1G3-4)
T2	Tumour invades corpus spongiosum with or without invasion of the urethra
T3	Tumour invades corpus cavernosum with or without invasion of the urethra
T4	Tumour invades other adjacent structures
N - Regional Lymph Nodes	
NX	Regional lymph nodes cannot be assessed
N0	No palpable or visibly enlarged inguinal lymph nodes
N1	Palpable mobile unilateral inguinal lymph node
N2	Palpable mobile multiple or bilateral inguinal lymph nodes
N3	Fixed inguinal nodal mass or pelvic lymphadenopathy, unilateral or bilateral
M - Distant Metastasis	
M0	No distant metastasis
M1	Distant metastasis
Pathological classification	
The pT categories correspond to the clinical T categories. The pN categories are based upon biopsy or surgical excision	
pN - Regional Lymph Nodes	
pNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis in one or two inguinal lymph nodes
pN2	Metastasis in more than two unilateral inguinal nodes or bilateral inguinal lymph nodes
pN3	Metastasis in pelvic lymph node(s), unilateral or bilateral extranodal extension of regional lymph node metastasis
pM - Distant Metastasis	
pM0	No distant metastasis
pM1	Distant metastasis
G - Histopathological Grading	
GX	Grade of differentiation cannot be assessed
G1	Well differentiated
G2	Moderately differentiated
G3-4	Poorly differentiated/undifferentiated

*Verrucous carcinoma not associated with destructive invasion.

5. DIAGNOSTIC EVALUATION AND STAGING

Penile cancer can be cured in over 80% of cases if diagnosed early. Local treatment, although potentially lifesaving, can be mutilating and devastating for the patient's psychological well-being.

5.1 Primary lesion

Penile carcinoma is usually a clinically obvious lesion; however, it may be hidden under a phimosis. Physical examination should include palpation of the penis to assess the extent of local invasion. Ultrasound (US) can give information about infiltration of the corpora [64, 65]. Magnetic resonance imaging (MRI) with an artificially induced erection can help to exclude tumour invasion of the corpora cavernosa if preservation of the penis is planned [66, 67].

5.2 Regional lymph nodes

Careful palpation of both groins for enlarged inguinal lymph nodes must be part of the initial physical examination of patients with penile cancer.

5.2.1 *Non-palpable inguinal nodes*

If there are no palpable lymph nodes, the likelihood of micrometastatic disease is about 25%. Imaging studies are not helpful in staging clinically normal inguinal regions, though imaging may be helpful in obese patients in whom palpation is unreliable or impossible:

- Inguinal US (7.5 MHz) can reveal abnormal nodes with some enlargement. The longitudinal/transverse diameter ratio and absence of the lymph node hilum are findings with relatively high specificity [68].
- Conventional computed tomography (CT) or MRI scans cannot detect micrometastases reliably [69].
- Imaging with ¹⁸F-DG-positron emission tomography (PET)/CT does not detect lymph node metastases < 10 mm [70, 71].

The further diagnostic management of patients with normal inguinal nodes should be guided by pathological risk factors. Lymphovascular invasion, local stage and grade are risk factors for the likelihood of lymphatic metastasis [72, 73]. Existing nomograms are not accurate enough. Invasive lymph node staging is required in patients at intermediate or high risk of lymphatic spread (see Section 6.2).

5.2.2 *Palpable inguinal nodes*

Palpable lymph nodes are highly indicative of lymph node metastases. Physical examination should note the number of palpable nodes on each side and whether these are fixed or mobile. Additional inguinal imaging does not alter management (see Section 6) and is usually not required.

A pelvic CT scan can be used to assess the pelvic lymph nodes. Imaging with ¹⁸F-DG-PET/CT has shown a high sensitivity of 88-100%, with a specificity of 98-100%, for confirming metastatic nodes in patients with palpable inguinal lymph nodes [71, 74].

5.3 Distant metastases

An assessment of distant metastases should be performed in patients with positive inguinal nodes [75-77] (LE: 2b). Computed tomography of the abdomen and pelvis and a chest X-ray are recommended. Thoracic CT is more sensitive than chest X-ray. Positron emission tomography/computed tomography is an option for identifying pelvic nodal and distant metastases in patients with positive inguinal nodes [78]. There is no established tumour marker for penile cancer. The SCC antigen (SCC Ag) is increased in < 25% of penile cancer patients. One study found that SCC Ag did not predict occult metastatic disease, but was an indicator of disease-free survival (DFS) in lymph-node-positive patients [79].

5.4 Summary of evidence and recommendations for the diagnosis and staging of penile cancer

5.4.1 *Summary of evidence for diagnosis*

Examination should include morphology, extent and invasion of penile structures.
Both groins should be examined and the number, laterality and characteristics of nodes recorded.
Computed tomography of chest, abdomen and pelvis is recommended for patients with inguinal lymph node metastasis.
Magnetic resonance imaging (MRI) with artificial erection improves local staging for men being considered for organ preserving surgery.

5.4.2 Recommendations for the diagnosis and staging of penile cancer

Recommendations	GR
Primary tumour	
Perform a physical examination, record morphology, extent and invasion of penile structures.	C
Obtain MRI with artificial erection in cases for which organ-preserving surgery is intended.	
Inguinal lymph nodes	
Perform a physical examination of both groins, record the number, laterality and characteristics of inguinal nodes and: <ul style="list-style-type: none"> if nodes are not palpable, offer invasive lymph node staging in high-risk patients; if nodes are palpable, stage with a pelvic computed tomography (CT) or positron emission tomography (PET)/CT. 	C
Distant metastases	
In N+ patients, obtain an abdominopelvic CT scan and chest X-ray for systemic staging. Alternatively, stage with a PET/CT scan.	C
In patients with systemic disease or with relevant symptoms, obtain a bone scan.	

6. DISEASE MANAGEMENT

6.1 Treatment of the primary tumour

Treatment of the primary penile cancer lesion aims to remove the tumour completely, while preserving as much of the penis as possible without compromising radicality. Local recurrence has little effect on long-term survival so that organ preservation strategies can be used [80].

The overall quality of the available research evidence is low. There are no randomised controlled trials or observational studies for surgical management of localised penile cancer nor studies comparing surgical and non-surgical modalities.

Penile preservation appears to be superior in functional and cosmetic outcomes. It is the primary treatment method for men with localised penile cancer. However, there are no randomised studies comparing organ-preserving and ablative treatment strategies, only retrospective studies with a LE: 3, or less.

Histological diagnosis with local staging must be obtained in all cases, especially if considering non-surgical treatment modalities. Treatment of the primary tumour and of the regional nodes can be staged. It is mandatory to remove all malignant tissue with negative surgical margins. Patients must be counselled about all relevant treatment modalities.

Local treatment modalities for small and localised penile cancer include excisional surgery, external beam radiotherapy (EBRT), brachytherapy and laser ablation.

6.1.1 Treatment of superficial non-invasive disease (CIS)

For penile CIS, topical chemotherapy with imiquimod or 5-fluorouracil (5-FU) can be an effective first-line treatment. Both agents have relatively low toxicity and adverse events, but efficacy is limited. Complete responses have been reported in up to 57% of CIS cases [81]. Due to the high rate of persistence and/or recurrence, close and long-term surveillance of such patients is required. If topical treatment fails, it should not be repeated.

Laser treatment can be used for CIS. Photodynamic control may be used in conjunction with carbon dioxide (CO₂) laser treatment [82].

Alternatively, total or partial glans resurfacing can be offered as a primary treatment modality for CIS and as a secondary treatment in case of treatment failure with topical chemotherapy or laser therapy. Glans resurfacing is a surgical technique which consists of complete abrasion of the glandular epithelium followed by covering with a split skin graft. With glans resurfacing for presumed non-invasive disease, up to 20% of patients are found to have superficial invasive disease [83].

6.1.2 Treatment of invasive disease confined to the glans (category Ta/T1a)

A penis-preserving strategy is recommended for small and localised invasive lesions (Ta/T1a). It is mandatory to do a biopsy to confirm diagnosis prior to using conservative treatments. All patients must be circumcised before considering conservative non-surgical treatments. For tumours confined to the prepuce, radical circumcision alone may be curative provided that negative surgical margins are confirmed by definitive histology.

For all surgical treatment options, the intra-operative assessment of surgical margins by frozen section is recommended as tumour-positive margins lead to local recurrence [84]. Total removal of the glans (glansectomy) and prepuce has the lowest recurrence rate for the treatment of small penile lesions (2%) [84]. Negative surgical margins are imperative when using penile-conserving treatments and a margin of 5 mm is considered oncologically safe [84, 85].

Treatment choice depends on tumour size, histology, including stage and grade, localisation (especially relative to the meatus) and patient preference as there are no documented differences in long-term local recurrence rates between surgery, laser and radiation therapy.

6.1.3 **Results of different surgical organ-preserving treatments**

There are only retrospective case series for these treatments. The results have been reported heterogeneously; therefore, the database for assessment is of limited quality.

6.1.3.1 *Laser therapy*

Laser ablation is carried out with a neodymium:yttrium-aluminum garnet (Nd:YAG) laser or a CO₂ laser [86-91]. Visualisation may be improved by photodynamic diagnosis.

The results of CO₂ laser treatment have been reported by three studies all from the same institution [86-88]. Laser treatment was given in combination with radiotherapy or chemotherapy to patients with CIS or T1 penile cancers. Follow-up was five years (median) in all three studies. There is some overlap between the cohorts reported, with a total of 195 patients included in these retrospective series.

No cancer-specific deaths were reported. One study reported an estimated cumulative risk of local recurrence at five years of 10% with CIS (n = 106) and 16% with T1 (n = 78) tumours [86]. Taking all three series together, local recurrence ranged from 14% for CIS [88] to 23% for T1 tumours [87]. The reported rate of inguinal nodal recurrence after local CO₂ laser treatment was 0% [88] and 4% [87]. Secondary partial penectomy at ten years was 3% and 10%, depending on the tumour (CIS vs. T1) and whether or not combination treatment had been given [86].

Four studies on the results of Nd:YAG laser treatment [89-92] reported on a total of 150 patients with a follow-up of at least four years. Local recurrence rates at last follow-up ranged across the four studies from 10% [89] to 48% [90]. In one study [91], recurrence-free survival rates were reported as 100%, 95% and 89% at one, two and five years, respectively. Inguinal nodal recurrence was reported in 21% of patients [89]. Cancer-related deaths were reported in 2% [92] and 9% of patients [90], respectively. Three studies from the same institution, probably including overlapping patient cohorts, reported overall survival (OS) rates by censored or uncensored data which ranged from 100% at four years [89] and 95% [91] to 85% [93] at seven years. The rate of secondary partial penectomy after initial Nd:YAG laser treatment was reported as 4% [91] and 45% [90], respectively. Complications, urinary and sexual function outcomes were assessed in only one study with 29 patients [89], none of which reported complications or a change in urinary and sexual function after successful Nd:YAG laser treatment.

Other studies have presented data on a variety of laser treatments with either a CO₂ laser, Nd:YAG laser, a combination of both, or a potassium titanyl phosphate (KTP) laser [94-97], with a mean follow-up of 32-60 months with stages CIS to T3 included. These studies reported on a total of 138 patients.

The cancer-specific survival (CSS) probability at five years was 95% in one study using the Kaplan-Meier method [95]. This was consistent with the finding from another study in which the cancer-specific mortality rate was relatively low at 2% at a mean follow-up of approximately five years [95]. Local recurrence rates were 11% [96], 19% [95] and 26% [97]. In one study recurrence-free survival at five years was estimated to be 88% [95].

6.1.3.2 *Moh's micrographic surgery*

Moh's micrographic surgery is a technique by which histological margins are taken in a geometrical fashion around a cone of excision. This technique has not been widely used. Only two studies reported a total of 66 patients [98, 99]. The original description [98] consisted of 33 consecutive patients treated between 1936 and 1986 and reported on 29 patients with at least five years follow-up. In each study there was one secondary penile amputation and one death from penile cancer. In Moh's series, 79% were cured at five years [98]. In the other series, 68% were recurrence-free after a median of 37 months and 8% had inguinal nodal recurrence and died of the disease [99]. The local recurrence rate was 32% in one series [99].

6.1.3.3 *Glans resurfacing*

Three studies have reported results with glans resurfacing [83, 100, 101] in a total of 71 patients with CIS or T1. The range of the median duration of follow-up in the three studies was 21-30 months. No cancer-specific deaths were reported and the rates of local recurrence were 0% [100] and 6% [101], without reports of nodal recurrence. There were no reported complications.

6.1.3.4 Glansectomy

Results of another relatively new technique, glansectomy, was reported in three studies [84, 102, 103], whilst a fourth study also reported on glans-preserving surgery [103]. A total of 68 patients with a follow-up of 114 months [102] and 63 months [103] were included. One patient (8%) had a local recurrence [102] and six patients (9%) had inguinal nodal metastases. No cancer-specific deaths were reported. Another group reported 87 patients with six local (6.9%), eleven regional (12.6%) and two systemic recurrences (2.3%), during a mean follow-up of 42 months [84].

6.1.3.5 Partial penectomy

Results of partial penectomy were reported in eight rather heterogeneous studies [88, 103-109] with 184 patients, with T1-T3 tumours, and follow-up between 40-194 months. Cancer-specific mortality ranged from 0-27%, with local recurrence rates ranging from 4-50%. The five-year OS rate was reported by three of the studies and ranged from 59-89% [106, 107, 109].

6.1.3.6 Summary of results of surgical techniques

There is insufficient evidence to suggest a difference regarding the outcomes of different penis-sparing strategies, all generally appear to show good oncological outcomes. Although conservative surgery may improve quality of life (QoL), local recurrence is more likely than after radical surgery, e.g. partial penectomy (5-12% vs. 5%). In a large cohort of patients undergoing conservative surgery, isolated local recurrence was 8.9%, with a five-year DSS rate of 91.7%. Tumour grade, stage and lymphovascular invasion appear to be predictors of local recurrence.

6.1.4 Results of radiotherapy for T1 and T2 disease

Radiation treatment of the primary tumour is an alternative organ-preserving approach with good results in selected patients with T1-2 lesions < 4 cm in diameter [110-115] (LE: 2b). External radiotherapy is given with a minimum dose of 60 Gy combined with a brachytherapy boost or brachytherapy on its own [111, 113]. Radiotherapy results are best with penile brachytherapy with local control rates ranging from 70-90% [111, 113]. The American Brachytherapy Society and the Groupe Européen de Curiethérapie-European Society of Therapeutic Radiation Oncology (ABS-GEC-ESTRO) consensus statement for penile brachytherapy reported good tumour control rates, acceptable morbidity and functional organ preservation for penile brachytherapy for T1 and T2 penile cancers [116]. The rates of local recurrence after radiotherapy are higher than after partial penectomy. With local failure after radiotherapy, salvage surgery can achieve local control [117]. Patients with lesions > 4 cm are not candidates for brachytherapy.

Common complications with radiotherapy include urethral stenosis (20-35%), glans necrosis (10-20%) and late fibrosis of the corpora cavernosa [118] (LE: 3). With brachytherapy, meatal stenosis occurs in > 40% of cases.

Table 5: Summary of reported complications and oncological outcomes of local treatments*

Treatment	Complications	Local recurrence	Nodal recurrence	Cancer-specific deaths	References
Neodymium: yttrium-aluminum garnet laser	None reported	10-48%	21%	2-9%	[89-92]
Carbon dioxide laser	Bleeding, meatal stenosis both < 1%	14-23%	2-4%	None reported	[86-88]
Lasers (unspecified)	Bleeding 8%, local infection 2%	11-26%	2%	2-3%	[94-97]
Moh's micrographic surgery	Local infection 3%, meatal stenosis 6%	32%	8%	3-4%	[98, 99]
Glans resurfacing	None reported	4-6%	Not reported	Not reported	[83, 100, 101]
Glansectomy	None reported	8%	9%	None reported	[102, 103]
Partial penectomy	Not reported	4-13%	14-19%	11-27%	[88, 106, 107, 109]
Brachytherapy	Meatal stenosis > 40%	10-30%	Not reported	Not reported	[110, 111, 113]
Radiotherapy	Urethral stenosis 20-35%, glans necrosis 10-20%	Not reported	Not reported	Not reported	[112, 115-118]

*The ranges are the lowest and highest number of occurrences reported in different series.

6.1.5 **Summary of treatment recommendations for non-invasive and localised superficially invasive penile cancer**

6.1.5.1 *Treatment of invasive disease confined to the corpus spongiosum/glans (T2)*

Total glansectomy, with or without resurfacing of the corporeal heads, is recommended [104] (LE: 3). Radiotherapy is an option (see Section 6.1.6). Partial amputation should be considered in patients unfit for reconstructive surgery [117].

6.1.5.2 *Treatment of disease invading the corpora cavernosa and/or urethra (T2/T3)*

Partial amputation with a tumour-free margin and reconstruction is standard [114]. A surgical margin of 5 mm is considered safe [84, 85]. Patients should remain under close follow-up. Radiotherapy is an option.

6.1.5.3 *Treatment of locally advanced disease invading adjacent structures (T3/T4)*

These are relatively rare (Europe 5%, Brazil 13%) [85]. Total penectomy with perineal urethrostomy is standard surgical treatment for T3 tumours [85]. In more advanced disease (T4), neoadjuvant chemotherapy may be advisable, followed by surgery in responders, as in the treatment of patients with fixed enlarged inguinal nodes (see Section 6.2.4). Otherwise, adjuvant chemotherapy or palliative radiotherapy are options (see Sections 6.2.4 and 6.1.6).

6.1.5.4 *Local recurrence after organ-conserving surgery*

A second organ-conserving procedure can be performed if there is no corpus cavernosum invasion [62, 82, 85, 114]. For large or high-stage recurrence, partial or total amputation is required [118]. A total phallic reconstruction may be offered to patients undergoing total/subtotal amputation [119, 120].

6.1.6 **Guidelines for stage-dependent local treatment of penile carcinoma**

Primary tumour	Use organ-preserving treatment whenever possible	LE	GR
Tis	Topical treatment with 5-fluorouracil or imiquimod for superficial lesions with or without photodynamic control.	3	C
	Laser ablation with carbon dioxide (CO ₂) or neodymium:yttrium-aluminium-garnet (Nd:YAG) laser.		
	Glans resurfacing.		
Ta, T1a (G1, G2)	Wide local excision with circumcision, CO ₂ or Nd:YAG laser surgery with circumcision.	3	C
	Laser ablation with CO ₂ or Nd:YAG laser.		
	Glans resurfacing.		
	Glansectomy with reconstructive surgery, with or without skin grafting.		
	Radiotherapy by external beam or as brachytherapy for lesions < 4 cm.		
T1b (G3) and T2 confined to the glans	Wide local excision plus reconstructive surgery, with or without skin grafting.	3	C
	Laser ablation with circumcision.		
	Glansectomy with circumcision and reconstruction.		
	Radiotherapy by external beam or brachytherapy for lesions < 4 cm in diameter.		
T2 with invasion of the corpora cavernosa	Partial amputation and reconstruction or radiotherapy by external beam or brachytherapy for lesions < 4 cm in diameter.	3	C
T3 with invasion of the urethra	Partial penectomy or total penectomy with perineal urethrostomy.	3	C
T4 with invasion of other adjacent structures	Neoadjuvant chemotherapy followed by surgery in responders. Alternative: palliative external beam radiation.	3	C
Local recurrence after conservative treatment	Salvage surgery with penis-sparing treatment in small recurrences or partial amputation.	3	C
	Large or high-stage recurrence: partial or total amputation.		

6.2 Management of regional lymph nodes

The development of lymphatic metastases in penile cancer follows the route of anatomical drainage. Inguinal and pelvic lymph nodes provide the regional drainage system for the penis, and the superficial and deep inguinal lymph nodes are the first regional nodal group to manifest lymphatic metastatic spread, which can be unilateral or bilateral [80].

All inguinal sentinel nodes appear to be located in the superior and central inguinal zones, with most in the medial superior zone [81]. No lymphatic drainage has been observed from the penis to the two inferior regions of the groin and no direct drainage to the pelvic nodes has been visualised. [82, 83]. These findings confirm earlier studies.

The second regional lymph node groups are the ipsilateral pelvic lymph nodes. Pelvic nodal disease does not seem to occur without ipsilateral inguinal lymph node metastasis and there are no reports of crossover metastatic spread from one inguinal side to the other pelvic side. Further metastatic lymph node spread from the pelvic nodes to para-aortic and para-caval nodes is outside the regional lymph node drainage system of the penis and is classified as systemic metastatic disease.

The management of regional lymph nodes is decisive for long-term patient survival. Cure can be achieved in metastatic disease confined to the regional lymph nodes. Lymphadenectomy is the treatment of choice for inguinal lymph node metastases. Multimodal treatment combining surgery and polychemotherapy is often indicated.

Management of regional lymph nodes is stage-dependent. In clinically node-negative patients (cN0), micrometastatic disease occurs in about 25% of cases and is related to the local tumour stage and grade. In clinically positive lymph nodes (cN1/cN2), metastatic disease is highly likely and no time should be wasted on antibiotic treatment. Enlarged fixed inguinal lymph nodes (cN3) require multimodal treatment by chemotherapy and surgery. Even if present in only one node, capsular penetration and extra-nodal extension in lymph node metastasis carries a high-risk of progression and is classified as pN3, which also requires multimodal treatment.

6.2.1 Management of patients with clinically normal inguinal lymph nodes (cN0)

Risk stratification for the management of patients with clinically normal lymph nodes depends on stage, grade and the presence or absence of lymphovascular invasion in the primary tumour [84]. Tumours with low risk of metastatic disease are those with superficial penile cancer (pTa, pTis) and low grade. pT1 tumours are a heterogeneous risk group: low risk if they are well differentiated (pT1G1) intermediate-risk group (pT1G2) [85] or high risk (pT1G3 and all higher stages).

Early inguinal lymphadenectomy in clinically node-negative patients is far superior for long-term patient survival compared to therapeutic lymphadenectomy when regional nodal recurrence occurs [86, 87]. One prospective study comparing bilateral lymphadenectomy, radiotherapy and surveillance in clinically node-negative patients reported that five-year OS was significantly better with inguinal lymphadenectomy vs. immediate inguinal radiotherapy or that observed with a surveillance strategy (74% vs. 66% and 63%, respectively) [88].

6.2.1.1 Surveillance

The surveillance of regional lymph nodes carries the risk of regional recurrence arising later from existing micrometastatic disease. Patient survival is over 90% with early lymphadenectomy and below 40% with lymphadenectomy for later regional recurrence [89, 90]. This risk must be taken into account when considering surveillance and informing the patient. Surveillance can only be recommended in patients with pTis and pTa penile cancer and with the appropriate caveats in pT1G1 tumours [89-91]. A prerequisite for surveillance is good patient information and compliance.

6.2.1.2 Invasive nodal staging

Staging of the inguinal lymph nodes in cN0 penile cancer requires an invasive procedure since all imaging techniques (US, CT, MRI) are unreliable in excluding small and micrometastatic lymph node involvement. Although CT criteria other than size have been defined for retrospective detection of lymph node metastases, these have not been validated prospectively [92]. Nomograms are unreliable in predicting node involvement [89, 93, 94] (LE: 2b). Fine-needle aspiration cytology does not reliably exclude micrometastatic disease and is not recommended. Instead, pathological risk factors are used to stratify node-negative patients [87, 95] (LE: 2b).

There are two invasive diagnostic procedures, whose efficacy is evidence-based: modified inguinal lymphadenectomy (mILND) and dynamic sentinel-node biopsy (DSNB). Both are standard approaches for invasive diagnosis of inguinal lymph nodes in clinically node-negative patients.

Modified ILND is the standard surgical approach. Both the superficial inguinal lymph nodes from at least the central and both superior Daseler's zones are removed bilaterally [80, 96] (LE: 3), leaving behind the greater saphenous vein.

Dynamic sentinel node biopsy (DSNB) is based on the assumption that primary lymphatic drainage from a penile cancer initially goes to one or only a few inguinal sentinel nodes on each side before further dissemination to more inguinal nodes. Technetium-99m (^{99m}Tc) nanocolloid is injected around the penile cancer site on the day before surgery; patent blue can be injected as well before surgery. A gamma-ray detection probe is used intra-operatively to detect the sentinel node in 97% of cases. The protocol has been standardised for routine use and has a short learning curve [97]. Dynamic sentinel node biopsy has a reported high sensitivity (90-94%) [97, 98] (LE: 2b). In a pooled meta-analysis of eighteen studies, pooled sensitivity was 88%, which improved to 90% with the addition of patent blue [99].

Both methods of invasive regional lymph node staging in cN0 patients may miss micrometastatic disease leading to regional recurrence and greatly reduced long-term survival [86]. The false-negative rate may be as high as 12-15% for DSNB, even in experienced centres [90, 91]. The false-negative rate of mILND is unknown. The patient must be informed of the risk of a false-negative result and the method being used. If lymph node metastasis is found with either method, an ipsilateral radical inguinal lymphadenectomy is indicated.

6.2.2 **Management of patients with palpable inguinal nodes (cN1/cN2)**

With uni- or bilateral palpable inguinal lymph nodes (cN1/cN2), metastatic lymph node disease is very likely and the traditional clinical advice to prescribe antibiotic treatment to exclude lymph node enlargement due to infection is no longer correct. Instead, appropriate oncological diagnosis and treatment should be undertaken without delay before further metastatic spread occurs. In clinically doubtful cases, US-guided fine needle aspiration cytology is an option [121].

With palpably enlarged inguinal lymph nodes, additional staging using imaging is not useful, except in very obese patients. However, CT or MRI can provide information about the pelvic nodal status. ^{18}F -FDG PET/CT can identify additional metastases in lymph-node positive patients [122]. Dynamic sentinel node biopsy is not reliable in patients with palpably enlarged and suspicious inguinal lymph nodes and should not be used [123] (LE: 3).

6.2.2.1 *Radical inguinal lymphadenectomy*

In clinically lymph node positive patients, surgical staging by inguinal lymphadenectomy is indicated. Intra-operative frozen sections may be used to confirm lymph node metastasis, for which an ipsilateral radical inguinal lymphadenectomy is necessary [80, 85].

Radical inguinal lymphadenectomy carries a significant morbidity due to impaired lymph drainage from the legs and often problematic wound healing. Morbidity can be as high as 50% [124] in the presence of significant risk factors such as increased body mass index. However, recent series have reported lower morbidities of about 25% [125, 126] (LE: 2b). Therapeutic radical inguinal lymphadenectomy can be life-saving and should not be underused for fear of associated morbidity [127]. Lymph node density is a prognostic factor [128].

Tissue handling must be meticulous and take into account the absence of smooth muscle in lymphatic vessel walls. Lymphatic vessels therefore cannot be electrocoagulated and must be closed by ligation or possibly liberal use of clips [129, 130]. Post-operative morbidity is reduced by additional measures to improve drainage, such as stockings, bandaging, inguinal pressure dressings or vacuum suction [131] and prophylactic antibiotics. Advanced cases may require reconstructive surgery for primary wound closure.

The most commonly reported complications in recent series were wound infections (1.2-1.4%), skin necrosis (0.6-4.7%), lymphoedema (5-13.9%) and lymphocele formation (2.1-4%) [125, 126].

Laparoscopic and robot-assisted inguinal lymphadenectomy is feasible, but may not provide any advantage [132-135].

6.2.2.2 *Pelvic lymphadenectomy*

Patients with positive pelvic nodes have a worse prognosis compared to patients with only inguinal nodal metastasis (five-year CSS 71.0% vs. 33.2%) [136]. In the same study with 142 node-positive patients, significant risk factors for pelvic nodal metastasis were the number of positive inguinal nodes (cut-off three), the diameter of inguinal metastatic nodes (cut-off 30 mm) and extra-nodal extension. The percentage of pelvic nodal metastases was 0% without any of these risk factors and 57.1% with all three risk factors [136].

If two or more positive lymph nodes, or one node with extracapsular extension (pN3), are found unilaterally, an ipsilateral pelvic lymphadenectomy is indicated. There is no direct lymphatic drainage from penile tumours to the pelvic lymph nodes [137] and lymphadenectomy is therefore not indicated if there is no involvement of inguinal nodes on that side. This recommendation is based on a study in which the rate of positive pelvic nodes was found to be 23% in cases with more than two positive inguinal nodes and 56% in those with more than three positive inguinal nodes, or if there was extracapsular involvement in at least one inguinal node [85, 138] (LE: 2b).

Pelvic lymphadenectomy may be performed simultaneously or as a secondary procedure following definitive histology. If bilateral pelvic dissection is indicated, it can be performed through a midline suprapubic extraperitoneal incision. It is important to avoid unnecessary delay if these procedures are indicated [139].

6.2.2.3 *Adjuvant treatment*

In patients with pN2/pN3 disease, adjuvant chemotherapy is recommended [140] (see Section 6.3.1). This is because a retrospective study reported long-term DFS of 84% in node-positive patients with adjuvant chemotherapy after radical lymph node surgery vs. 39% in historical controls without chemotherapy after lymphadenectomy [140].

Although adjuvant radiotherapy has been used after inguinal lymphadenectomy, the data are very limited and it is not generally recommended (see Section 6.2.5). There are no data for neoadjuvant inguinal radiotherapy.

6.2.3 **Management of patients with fixed inguinal nodes (cN3)**

Metastatic disease is always present in these cases. Staging by thoracic, abdominal and pelvic CT scan is necessary to assess the presence of further pelvic nodal disease and systemic metastatic disease. In clinically unequivocal cases, histological verification by biopsy is not required. Rare cases with reasonable doubt require an excisional or core needle biopsy.

These patients have a poor prognosis and are unlikely to be cured by surgery alone. Upfront surgery is not generally recommended as it is non-curative and usually destructive. Multimodal treatment with neoadjuvant chemotherapy followed by radical lymphadenectomy in clinically responsive cases is recommended [141-143]. Responders to neoadjuvant chemotherapy with post-chemotherapy surgery have been reported to achieve long-term survival in 37% of cases [141]. There may be individual patients with reasons for upfront surgery followed by adjuvant treatment.

6.2.4 **Management of lymph node recurrence**

Patients with regional recurrence after surveillance should be treated similarly to patients with primary cN1/cN2 disease (see Section 6.2.2). Patients with regional recurrence following negative invasive staging by DSNB or modified inguinal lymphadenectomy already have disordered inguinal lymphatic drainage and are at a high risk of irregular metastatic progression. Patients with inguinal nodal recurrence after therapeutic radical inguinal lymphadenectomy have a five-year CSS rate of 16% [144].

There is no evidence for the best management in such cases. Multimodal treatment with neoadjuvant and/or adjuvant chemotherapy after radical lymph node surgery is advised.

6.2.5 **The role of radiotherapy for the treatment of lymph node disease**

The use of radiotherapy for nodal disease follows tradition and single-institution policies and is not evidence based. Despite the lack of data, radiotherapy is widely used in some European countries to manage regional lymph node metastasis in penile cancer.

It has not been reported that neoadjuvant or adjuvant radiotherapy improves oncological outcome in node-positive penile cancer [145]. One prospective trial found that inguinal node dissection was superior to inguinal radiotherapy [146]. Another study reported poor long-term survival in patients with adjuvant inguinal and pelvic radiotherapy [147]. Adjuvant chemotherapy has been reported to be far superior to adjuvant radiotherapy after radical inguinal lymphadenectomy in node-positive patients in one retrospective series [140]. Using the National Cancer Institute Surveillance, Epidemiology and End Results (SEER) Program database, treatment results of 2,458 penile cancer patients treated with either surgery alone or surgery plus EBRT showed that the addition of adjuvant radiotherapy 'had neither a harmful nor a beneficial effect on CSS' [148].

Due to the lack of evidence, radiotherapy in the treatment of lymph node disease in penile cancer is not generally recommended. Prophylactic radiotherapy for cN0 disease is not indicated. Adjuvant inguinal radiotherapy may be considered as an option in selected patients with extracapsular nodal extension (cN3) or as a palliative treatment for surgically irresectable disease.

6.2.6 **Guidelines for treatment strategies for nodal metastases**

Regional lymph nodes	Management of regional lymph nodes is fundamental in the treatment of penile cancer	LE	GR
No palpable inguinal nodes (cN0)	Tis, Ta G1, T1G1: surveillance.	2a	B
	> T1G2: invasive lymph node staging by bilateral modified inguinal lymphadenectomy or dynamic sentinel node biopsy.	2a	B
Palpable inguinal nodes (cN1/cN2)	Radical inguinal lymphadenectomy.		
Fixed inguinal lymph nodes (cN3)	Neoadjuvant chemotherapy followed by radical inguinal lymphadenectomy in responders.		
Pelvic lymphadenopathy	Ipsilateral pelvic lymphadenectomy if two or more inguinal nodes are involved on one side (pN2) and if extracapsular nodal metastasis (pN3) is confirmed.	2a	B
Adjuvant chemotherapy	In pN2/pN3 patients after radical lymphadenectomy.	2b	B
Radiotherapy	Do not use for the treatment of nodal disease in penile cancer.		

6.3 Chemotherapy

6.3.1 **Adjuvant chemotherapy in node-positive patients after radical inguinal lymphadenectomy**

Multimodal treatment can improve patient outcome in many tumour types. Adjuvant chemotherapy after resection of nodal metastases in penile carcinoma has been reported in a few small and heterogeneous series [141, 149-152]. Comparing different small-scale clinical studies is fraught with difficulty.

The value of adjuvant chemotherapy after radical inguinal lymphadenectomy in node-positive penile cancer was demonstrated by an Italian group who reported long-term (DFS) of 84% in 25 consecutive patients treated with twelve adjuvant weekly courses of vincristine, bleomycin, and methotrexate (VBM) during the period 1979-1990 and compared this to a historical control group of 38 consecutive node-positive patients with radical lymphadenectomy (with- or without adjuvant inguinal radiotherapy) who had achieved a DFS rate of only 39% [141].

This group has also published results of a chemotherapy regimen adjuvant to radical lymphadenectomy in stage pN2-3 patients receiving three courses of cisplatin and 5-fluorouracil (5-FU) which they had been using since 1991 with lower toxicity and even better results compared to VBM [151] (LE: 2b). The same group has been using an adjuvant taxane-based regimen since 2004, cisplatin, 5-FU plus paclitaxel or docetaxel (TPF), in nineteen node-positive patients receiving three to four cycles of TPF after resection of pN2-3 disease [152]. Of those patients, 52.6% were disease-free after a median follow up of 42 months and tolerability was good. Results of adjuvant treatment with paclitaxel and cisplatin also improved outcome [153].

The use of adjuvant chemotherapy is recommended, in particular when the administration of the triple combination chemotherapy is feasible, and curative treatment is aimed for (LE: 2b). No data for the adjuvant chemotherapeutic treatment of penile carcinoma in stage pN1 are available. The administration of an adjuvant treatment in pN1 disease is therefore recommended only in clinical trials.

6.3.2 **Neoadjuvant chemotherapy in patients with fixed or relapsed inguinal nodes**

Bulky inguinal lymph node enlargement (cN3) indicates extensive lymphatic metastatic disease. Primary lymph node surgery is not generally recommended (GR: B). Complete surgical resection is unlikely and only a few patients will benefit from surgery alone.

Very limited data is available on neoadjuvant chemotherapy before inguinal lymph node surgery. This approach enables early treatment of likely systemic disease and down-staging of inguinal lymph node disease. Complete surgical treatment is possible with a good clinical response.

Results were modest in retrospective studies of five to twenty patients treated with bleomycin-vincristinemethotrexate (BVM) and bleomycin-methotrexate-cisplatin (BMP) treatments [142, 143, 154] and in the confirmatory BMP trial of the Southwest Oncology Group [155]. However, treatment-related toxicity was unacceptable due to bleomycin-related mortality.

Cisplatin/5-FU (PF) chemotherapy achieved a response rate of 25-50% with more acceptable tolerability [156, 157]. Over a period of 30 years, five different neoadjuvant chemotherapy regimens were used in twenty patients [80], with long-term survival in 37% of chemotherapy responders who underwent surgery. In the European Organisation for Research and Treatment of Cancer study 30992, 26 patients with locally advanced or metastatic disease received irinotecan and cisplatin chemotherapy. Although the study did not meet its primary endpoint (response rate), there were three cases of pathologically complete remissions (pCR) [158].

A phase II trial evaluated treatment with four cycles of neoadjuvant paclitaxel, cisplatin, and ifosfamide (TIP). An objective response was reported in fifteen out of 30 patients, including three pCRs, which was a marginally significant predictor of survival. The estimated median time to progression (TTP) was 8.1 months and the median OS rate was 17.1 months [159] (LE: 2a).

Similarities between penile SCC and head and neck SCC led to the evaluation in penile cancer of chemotherapy regimens with an efficacy in head and neck SCC, including taxanes. The combination of cisplatin and 5-FU plus a taxane has been used in a neoadjuvant and adjuvant setting [152]. An overall objective response rate of 44% was reported in 28 patients treated neoadjuvantly, including 14% pCR (LE: 2b).

Similarly, a Cancer Research UK phase II trial with TPF (using only docetaxel) reported an objective response of 38.5% in 29 locally advanced or metastatic patients, although the study did not meet its primary endpoint. However, there was significant toxicity [160] (LE: 2a).

Overall, these results support the use of neoadjuvant chemotherapy in patients with fixed, unresectable nodal disease, particularly with a triple combination, including cisplatin and a taxane, whenever feasible (LE: 2a).

There are hardly any data concerning radiochemotherapy with lymph-node surgery in penile cancer. Radiochemotherapy should only be offered in clinical trials [161].

6.3.3 **Palliative chemotherapy in advanced and relapsed disease**

A recent retrospective study of individual patient data of 140 men with advanced penile SCC reported that visceral metastases and an ECOG-performance status greater than one were independent prognostic factors, and that cisplatin-based regimens had better outcomes than non-cisplatin-based regimens after adjusting for prognostic factors [162] (LE: 3).

In clinical practice, however, first-line chemotherapy regimens are variable. Before taxanes were introduced, the data were limited by small numbers, patient heterogeneity and its retrospective nature (except for the EORTC trial [158]). Initial response rates ranged from 25% to 100%, with very few sustained responses and very few long-term survivors. The introduction of taxanes into penile cancer chemotherapy has enhanced the activity and efficacy of the regimens used [80, 142, 143, 153-160, 163].

There are virtually no data on second-line chemotherapy in penile cancer. One report using second-line paclitaxel monotherapy reported an initial response rate under 30%. Therefore, this may be a reasonable option; however, no patients survived [164] (LE: 2a; GR: B). Anecdotally, a benefit has been observed by combining cisplatin with gemcitabine [165] (LE: 4).

6.3.4 **Intra-arterial chemotherapy**

Intra-arterial chemotherapy has been trialled in locally advanced cases, especially cisplatin and gemcitabine in small case series [166-169]. Apart from a limited clinical response, outcome was not significantly improved.

6.3.5 **Targeted therapy**

Targeted drugs have been used as second-line treatment and they could be considered as single-agent treatment in refractory cases. Anti-epidermal growth factor receptor (EGFR) targeted monotherapy has been trialled as EGFR is expressed in penile SCC [166, 167] and the assumed similarities with head and neck SCC [166, 167]. There have been other studies, particularly with the anti-EGFR monoclonal antibodies, panitumumab and cetuximab. Some activity of tyrosine kinase inhibitors has been reported as well [169]. Further clinical studies are needed (LE: 4).

6.3.6 **Guidelines for chemotherapy in penile cancer patients**

Recommendations	LE	GR
Treat patients with pN2-3 tumours with adjuvant chemotherapy (three-four cycles of cisplatin, 5-fluorouracil, paclitaxel or docetaxel).	2b	C
Treat patients with non-resectable or recurrent lymph node metastases with neoadjuvant chemotherapy (4 cycles of a cisplatin and taxane-based regimen) followed by radical surgery.	2a	B
Treat patients with systemic disease and a limited metastatic load with chemotherapy.	3	C

7. FOLLOW-UP

7.1 Rationale for follow-up

The early detection of recurrence during follow-up increases the likelihood of curative treatment. Local recurrence does not significantly reduce long-term survival if successfully treated. In contrast, disease that has spread to the inguinal lymph nodes greatly reduces the rate of long-term DSS. Follow-up is also important in the detection and management of treatment-related complications.

Local or regional nodal recurrences usually occur within two years of primary treatment [80]. After five years, all recurrences were either local recurrences or new primary lesions [80]. These results support an intensive follow-up regimen during the first two years, with a less intensive follow up after this for a total of at least five years. Follow up after five years may be omitted in motivated patients reliably able to continue to carry out regular self-examination [80].

7.1.1 *When and how to follow-up*

In patients with negative inguinal nodes after local treatment, follow-up should include physical examination of the penis and the groins for local and/or regional recurrence. Additional imaging has no proven benefit.

Follow up also depends on the primary treatment modality. Histology from the glans should be obtained to confirm disease-free status following laser ablation or topical chemotherapy.

After potentially curative treatment for inguinal nodal metastases, CT or MRI imaging for the detection of systemic disease should be performed at three-monthly intervals for the first two years, so patients can benefit from adjuvant chemotherapy.

Although rarely, late local recurrences may still occur, with life-threatening metastases becoming very unusual after five years. This means regular follow up can be stopped after five years, provided the patient understands the need to report any local changes immediately [170]. In patients unlikely to self-examine, long-term follow up may be necessary.

7.1.2 *Recurrence of the primary tumour*

Local recurrence is more likely with all types of local organ-preserving treatment, i.e. after local excision, laser treatment, brachytherapy and associated therapies. However, it is very unlikely to increase the risk of dying from the disease in contrast to regional recurrence [80, 171]. Local recurrence occurred during the first two years in up to 27% of patients treated with penis-preserving modalities [172]. After partial penectomy, the risk of local recurrence is about 4-5% [80, 171, 172].

Local recurrence is easily detected by physical examination by the patient himself or his physician. Patient education is an essential part of follow-up and the patient should be urged to visit a specialist if any changes are seen.

7.1.3 *Regional recurrence*

Most regional recurrences occur during the first two years after diagnosis and treatment, irrespective of whether a surveillance strategy has been used or a sentinel-node based management or modified inguinal lymphadenectomy.

Although very unlikely, regional recurrence can occur unexpectedly after two years. It is therefore wise to continue close follow up in these patients, for whom self-examination is very important [173]. The highest rate of regional recurrence (9%) occurs in patients managed using a surveillance strategy, while the lowest is in patients who have undergone invasive nodal staging by modified inguinal lymphadenectomy or DSNB and whose lymph nodes were negative (2.3%).

The use of US and fine needle aspiration cytology (FNAC) in suspicious cases has improved the early detection rate of regional recurrence [68, 173, 174]. There are no data to support the routine use of CT or MRI for the follow-up of regional nodes.

Patients who have had surgical treatment for lymph node metastases without adjuvant treatment have an increased risk of regional recurrence of 19% [80]. Regional recurrence requires timely treatment by radical inguinal lymphadenectomy and adjuvant therapy (see Section 6).

7.1.4 Guidelines for follow-up in penile cancer

	Interval of follow-up		Examinations and investigations	Minimum duration of follow-up	GR
	Years one to two	Years three to five			
Recommendations for follow-up of the primary tumour					
Penile-preserving treatment	Three months	Six months	Regular physician or self-examination. Repeat biopsy after topical or laser treatment for carcinoma <i>in situ</i> .	Five years	C
Amputation	Three months	One year	Regular physician or self-examination.	Five years	C
Recommendations for follow-up of the inguinal lymph nodes					
Surveillance	Three months	Six months	Regular physician or self-examination.	Five years	C
pN0 at initial treatment	Three months	One year	Regular physician or self-examination. Ultrasound with fine-needle aspiration biopsy optional.	Five years	C
pN+ at initial treatment	Three months	Six months	Regular physician or self-examination. Ultrasound with fine-needle aspiration cytology optional, computed tomography / magnetic resonance imaging optional.	Five years	C

7.2 Quality of life

7.2.1 Consequences after penile cancer treatment

In patients with long-term survival after penile cancer treatment, sexual dysfunction, voiding problems and cosmetic penile appearance may adversely affect the patient's QoL [175]. There is very little data on sexual function and QoL after treatment for penile cancer.

7.2.2 Sexual activity and quality of life after laser treatment

A retrospective interview-based Swedish study after laser treatment for penile CIS [94] in 58 out of 67 surviving patients with a mean age of 63 years, of whom 46 participated, reported a marked decrease in some sexual practices, such as manual stimulation, caressing and fellatio, but a general satisfaction rate with life overall including their sex lives, similar to that of the general Swedish population.

A large study on CO₂ laser treatment of penile cancer in 224 patients reported no problems with erectile capability or sexual function following treatment [86]. In another study [97], no sexual dysfunction occurred in nineteen patients treated.

7.2.3 Sexual activity after glans resurfacing

In one study with ten patients [100], seven out of ten completed questionnaires (International Index of Erectile Function [IIEF-5] and a non-validated 9-item questionnaire) at their six-month follow-up visit. There was no erectile dysfunction according to the median IIEF-5 score of 24. All patients who were sexually active before treatment were active again within three to five months. According to the (non-validated) questionnaire, seven out of seven patients stated that the sensation at the tip of their penis was either no different or better after surgery and that they had erections within two to three weeks of surgery. Six out of seven patients had had sexual intercourse within three months of surgery and five out of seven patients felt that their sex life had improved. Overall patient satisfaction with glans resurfacing was high.

7.2.4 Sexual activity after glansectomy

Two studies reported sexual function after glansectomy [101, 102]. In one study (n = 68) with unclear methodology [102], 79% did not report any decline in spontaneous erection, rigidity and penetrative capacity after surgery, while 75% reported recovery of orgasm. In another study [103], all twelve patients had returned to 'normal' sexual activity one month after surgery.

7.2.5 **Sexual function after partial penectomy**

Sexual function after partial penectomy was reported by three studies [176-178]. The IIEF questionnaire was used in eighteen patients with a mean age of 52 years [176]. Post-operative scores were statistically worse for all domains of sexual function after partial penectomy. After surgery, 55.6% of patients had erectile function that allowed sexual intercourse. In patients who did not resume sexual intercourse after partial penectomy, 50% were ashamed of their small penis and missing glans, while another third blamed surgical complications. Of those who had resumed sexual intercourse, 66.7% reported the same frequency and level of sexual activity as before surgery, while 72.2% continued to have ejaculation and orgasm every time they had sexual activity. Overall, only 33.3% maintained their pre-operative frequency of sexual intercourse and were satisfied with their sex life.

An 'Overall Sexual Functioning Questionnaire' was used in fourteen out of eighteen patients with a median time since surgery of 11.5 months (range 6-72) [177]. Prior to surgery, all patients had normal erectile function and intercourse at least once a month. In nine out of fourteen patients, sexual functioning was 'normal' or 'slightly decreased', while three out of fourteen patients had no sexual intercourse after surgery. Alei *et al.* showed an improvement in erectile function over time [178].

7.2.6 **Quality of life after partial penectomy**

Several qualitative and quantitative instruments were used to assess 'psychological behaviour and adjustment' and 'social activity' as QoL indicators [177]. Patients reported fears of mutilation and of loss of sexual pleasure, as well as fear of dying and what this would mean for their families. Patients said family and partners were important in overcoming difficulties following surgery. The study reported no significant levels of anxiety and depression on the GHQ-12 (General Health Questionnaire) and HAD scale (Hospital Anxiety and Depression Scale), 'Social activity' remained the same after surgery in terms of living conditions, family life and social interactions.

7.3 **Total phallic reconstruction**

There is very limited data about total phallic reconstruction [119, 179, 180] following full- or near-total penile amputation. It is not possible to restore function. Cosmetically acceptable results are obtainable.

7.4 **Specialised care**

It is possible to cure almost 80% of penile cancer patients at all stages. Whenever possible, organ-preserving treatment should be offered [49] as it permits better QoL and sexual function than with partial penectomy. Patients should be referred to an experienced centre. Psychological support is very important for penile cancer patients.

9. CONFLICT OF INTEREST

All members of the Penile Cancer Guidelines working group have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publicly accessible through the European Association of Urology website: <http://uroweb.org/guideline/penile-cancer/>. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a nonprofit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

EAU Guidelines on Management of Non-Neurogenic Male Lower Urinary Tract Symptoms (LUTS), incl. Benign Prostatic Obstruction (BPO)

1. INTRODUCTION

1.1 Aim and objectives

Lower urinary tract symptoms (LUTS) are a common complaint in adult men with a major impact on quality of life (QoL), and substantial economic burden. The present Guidelines offer practical evidence-based guidance on the assessment and treatment of men aged 40 years or older with various non-neurogenic benign forms of LUTS. The understanding of the LUT as a functional unit, and the multifactorial aetiology of associated symptoms, means that LUTS now constitute the main focus, rather than the former emphasis on Benign Prostatic Hyperplasia (BPH). It must be emphasised that clinical guidelines present the best evidence available to the experts. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Non-neurogenic Male LUTS Guidelines Panel consists of an international group of experts with urological and clinical epidemiological backgrounds. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website Uroweb: <http://uroweb.org/guideline/treatment-of-non-neurogenic-male-luts/>.

1.3 Available publications

A quick reference document (Pocket Guidelines) is available, both in print and in a number of versions for mobile devices. These are abridged versions which may require consultation together with the full text version. All documents are accessible through the EAU website Uroweb: <http://www.uroweb.org/guideline/treatment-of-non-neurogenic-male-luts/>.

1.4 Publication history

The Non-neurogenic Male LUTS Guidelines were first published in 2000. Standard procedure for EAU Guidelines includes an annual assessment of newly published literature in the field to guide future updates. The 2017 document presents a comprehensive update of the 2016 publication. The literature was assessed for all chapters.

2. METHODS

2.1 Introduction

For the 2017 Management of Non-Neurogenic Male LUTS Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the Non-Neurogenic Male LUTS Guidelines was performed. The search was limited to studies representing high levels of evidence, i.e. systematic reviews with meta-analysis, randomised controlled trials (RCTs), and prospective non-randomised comparative studies, published in the English language. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between April 1st 2015 and May 31st 2016. A total of 1,622 unique records were identified, retrieved and screened for relevance. A detailed search strategy is available online: <http://www.uroweb.org/guideline/treatment-of-non-neurogenic-male-luts/supplementary-material>.

References used in this text are assessed according to their level of evidence (LE) and Guidelines are given a grade of recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [1]. Additional methodology information can be found in the general Methodology section of this print, and online at the EAU website: <http://www.uroweb.org/guidelines/>. A list of all Associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review

The Non-Neurogenic Male LUTS Guidelines were peer reviewed prior to publication in 2016.

2.3 Patients to whom the guidelines apply

Recommendations apply to men aged 40 years or older who seek professional help for LUTS in various

non-neurogenic and non-malignant conditions such as LUTS/Benign Prostatic Obstruction (BPO), detrusor overactivity/overactive bladder (OAB), or nocturnal polyuria. Men with other contexts of LUT disease (e.g. concomitant neurological diseases, young age, prior LUT disease or surgery) usually require a more extensive work-up, which is not covered in these Guidelines, but may include several tests mentioned in the following sections. EAU Guidelines on Neuro-Urology, Urinary Incontinence, Urological Infections, Urolithiasis, or malignant diseases of the LUT have been developed by other EAU Guidelines Panels and are available online: www.uroweb.org/guidelines/.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOPHYSIOLOGY

Lower urinary tract symptoms can be divided into storage, voiding and post-micturition symptoms [2]. Lower urinary tract symptoms are prevalent, cause bother and impair QoL [3-6]. An increasing awareness of LUTS and storage symptoms in particular, is warranted to discuss management options that could increase QoL [7]. Lower urinary tract symptoms are strongly associated with ageing [3, 4], associated costs and burden are therefore likely to increase with future demographic changes [4, 8]. Lower urinary tract symptoms are also associated with a number of modifiable risk factors, suggesting potential targets for prevention (e.g. metabolic syndrome) [9]. Most elderly men have at least one LUTS [4], however, symptoms are often mild or not very bothersome [6, 7, 10]. Lower urinary tract symptoms progress dynamically: for some individuals LUTS persist and progress over long time periods, and for others they remit [4]. LUTS have traditionally been related to bladder outlet obstruction (BOO), which is often caused by benign prostatic enlargement (BPE) resulting from the histologic condition of BPH [2, 5]. However, recent studies have shown that LUTS are often unrelated to the prostate [4, 11]. Bladder dysfunction may also cause LUTS, including detrusor overactivity/OAB, detrusor underactivity/underactive bladder, as well as other structural or functional abnormalities of the urinary tract and its surrounding tissues [11]. Prostatic inflammation also appears to play a role in BPH pathogenesis and progression [12, 13]. In addition, many non-urological conditions also contribute to urinary symptoms, especially nocturia [4].

The definitions of the most common conditions related to male LUTS are presented below:

- Acute retention of urine is defined as a painful, palpable or percussible bladder, when the patient is unable to pass any urine [2];
- Chronic retention of urine is defined as a non-painful bladder, which remains palpable or percussible after the patient has passed urine. Such patients may be incontinent [2];
- Bladder outlet obstruction is the generic term for obstruction during voiding and is characterised by increasing detrusor pressure and reduced urine flow rate. It is usually diagnosed by studying the synchronous values of flow-rate and detrusor pressure [2];
- Benign prostatic obstruction is a form of BOO and may be diagnosed when the cause of outlet obstruction is known to be BPE [2]. In the Guidelines either the term BPO or BOO is used as reported by the original studies;
- Benign prostatic hyperplasia is a term used (and reserved) for the typical histological pattern, which defines the disease;
- Detrusor overactivity (DO) is a urodynamic observation characterised by involuntary detrusor contractions during the filling phase which may be spontaneous or provoked [2];
- Overactive bladder syndrome is characterised by urinary urgency, with or without urgency urinary incontinence, usually with increased daytime frequency and nocturia, if there is no proven infection or other obvious pathology [14].

Figure 1 illustrates the potential causes of LUTS. In any man complaining of LUTS, it is common for more than one of these factors to be present.

Figure 1: Causes of male lower urinary tract symptoms (LUTS)

4. DIAGNOSTIC EVALUATION

Tests are useful for diagnosis, monitoring, assessing the risk of disease progression, treatment planning, and the prediction of treatment outcomes. The clinical assessment of patients with LUTS has two main objectives:

- to identify the differential diagnoses, since the origin of male LUTS is multifactorial, the relevant EAU Guidelines on the management of applicable conditions should be followed in these cases;
- to define the clinical profile (including the risk of disease progression) of men with LUTS in order to provide appropriate care.

4.1 Medical history

The importance of assessing the patient's history is well recognised [15-17]. A medical history aims to identify the potential causes and relevant comorbidities, including medical and neurological diseases. In addition, current medication, lifestyle habits, emotional and psychological factors must be reviewed. The Panel recognises the need to discuss LUTS and the therapeutic pathway from the patient's perspective. This includes reassuring the patient that there is no definite link between LUTS and prostate cancer (PCa) [18, 19].

As part of the urological/surgical history, a self-completed validated symptom questionnaire (see section 4.2) should be obtained to objectify and quantify LUTS. Voiding diaries are particularly beneficial when assessing patients with nocturia and/or storage symptoms (see section 4.3). When relevant, sexual function should be assessed, preferably with validated symptom questionnaires such as the International Index for Erectile Function (IIEF).

Recommendation	LE	GR
Take a complete medical history from men with LUTS.	4	A*

*Upgraded based on Panel consensus.

4.2 Symptom score questionnaires

All published guidelines for male LUTS/BPH recommend using validated symptom score questionnaires [15, 17]. Several questionnaires have been developed which are sensitive to symptom changes and can be used to monitor treatment [20-26]. Symptom scores are helpful in quantifying LUTS and in identifying which type of symptoms are predominant, yet they are not disease-, or age-specific. A systematic review evaluating the diagnostic accuracy of individual symptoms and questionnaires, compared with urodynamic studies (the reference standard) for the diagnosis of BOO in males with LUTS found that individual symptoms and questionnaires for diagnosing BOO were not significantly associated with one another [27].

4.2.1 *The International Prostate Symptom Score (IPSS)*

The IPSS is an 8-item questionnaire, consisting of seven symptom questions and one QoL question [21]. The IPSS score is categorised as ‘asymptomatic’ (0 points), ‘mildly symptomatic’ (1-7 points), ‘moderately symptomatic’ (8-19 points), and ‘severely symptomatic’ (20-35 points). Limitations include lack of assessment of incontinence, post-micturition symptoms, and bother caused by each separate symptom.

4.2.2 *The International Consultation on Incontinence Questionnaire (ICIQ-MLUTS)*

The ICIQ-MLUTS was created from the ICS Male questionnaire. It is a widely used and validated patient completed questionnaire [22]. It contains 13 items, with subscales for nocturia and OAB, and is available in 17 languages.

4.2.3 *Danish Prostate Symptom Score (DAN-PSS)*

The DAN-PSS [25] is a symptom score used mainly in Denmark and Finland. The ICIQ-MLUTS and DAN-PSS measure the bother of each individual LUTS.

Recommendation	LE	GR
Use a validated symptom score questionnaire including quality of life assessment during the assessment of male LUTS and for re-evaluation during and/or after treatment.	3	B

4.3 Frequency volume charts and bladder diaries

The recording of volume and time of each void by the patient is referred to as a frequency volume chart (FVC). Inclusion of additional information such as fluid intake, use of pads, activities during recording, or symptom scores is termed a bladder diary [2]. Parameters that can be derived from the FVC and bladder diary include: daytime and night-time voiding frequency, total voided volume, the fraction of urine production during the night (nocturnal polyuria index), and volume of individual voids.

The mean 24-hour urine production is subject to considerable variation. Likewise, circumstantial influence and intra-individual variation cause FVC parameters to fluctuate, though there is comparatively little data [28, 29]. The FVC diary is particularly relevant in nocturia, where it underpins the categorisation of underlying mechanism(s) [30-32]. The use of FVCs may cause a ‘bladder training effect’, and influence the frequency of nocturnal voids [33].

The duration of the FVC needs to be long enough to avoid sampling errors, but short enough to avoid non-compliance [34]. A systematic review of the available literature recommended FVC should continue for three or more days [35].

Recommendations	LE	GR
Use a bladder diary to assess male LUTS with a prominent storage component or nocturia.	3	B
Tell the patient to complete a bladder diary for the duration of at least three days.	2b	B

4.4 Physical examination and digital-rectal examination

Physical examination to seek potential influences on LUTS, particularly focusing on the suprapubic area, the external genitalia, the perineum and lower limbs should be performed. Urethral discharge, meatal stenosis, phimosis and penile cancer must be excluded.

4.4.1 *Digital-rectal examination and prostate size evaluation*

Digital-rectal examination (DRE) is the simplest way to assess prostate volume, but the correlation to prostate volume is poor. Quality-control procedures for DRE have been described [36]. Transrectal ultrasound (TRUS) is more accurate in determining prostate volume than DRE. Underestimation of prostate volume by DRE increases with increasing TRUS volume, particularly where the volume is > 30 mL [37]. A model of visual aids

has been developed to help urologists estimate prostate volume more accurately [38]. One study concluded that DRE was sufficient to discriminate between prostate volumes > or < than 50 mL [39].

Recommendation	LE	GR
Perform a physical examination including digital rectal examination in the assessment of male LUTS.	3	B

4.5 Urinalysis

Urinalysis (dipstick or sediment) must be included in the primary evaluation of any patient presenting with LUTS to identify conditions, such as urinary tract infections (UTI), microhaematuria and diabetes mellitus. If abnormal findings are detected further tests are recommended according to other EAU Guidelines, including Guidelines on urinary tract cancers and urological infections [40-43].

Urinalysis is recommended in most Guidelines in the primary management of patients with LUTS [44, 45]. There is limited evidence, yet general expert consensus that the benefits outweigh the costs [46]. The value of urinary dipstick/microscopy for diagnosing UTI in men with LUTS without acute frequency and dysuria has recently been questioned [47].

Recommendation	LE	GR
Use urinalysis (by dipstick or urinary sediment) in the assessment of male LUTS.	3	A*

*Upgraded based on Panel consensus.

4.6 Prostate-specific antigen (PSA)

4.6.1 PSA and the prediction of prostatic volume

Pooled analysis of placebo-controlled BPH trials showed that PSA has a good predictive value for assessing prostate volume, with areas under the curve (AUC) of 0.76-0.78 for various prostate volume thresholds (30 mL, 40 mL, and 50 mL). To achieve a specificity of 70%, whilst maintaining a sensitivity between 65-70%, approximate age-specific criteria for detecting men with prostate glands exceeding 40 mL are PSA > 1.6 ng/mL, > 2.0 ng/mL, and > 2.3 ng/mL, for men with BPH in their 50s, 60s, and 70s, respectively [48].

A strong association between PSA and prostate volume was found in a large community-based study in the Netherlands [49]. A PSA threshold value of 1.5 ng/mL could best predict a prostate volume of > 30 mL, with a positive predictive value (PPV) of 78%. The prediction of prostate volume can also be based on total and free PSA. Both PSA forms predict the TRUS prostate volume (\pm 20%) in > 90% of the cases [50, 51].

4.6.2 PSA and the probability of PCa

The role of PSA in the diagnosis of PCa is presented by the EAU Guidelines on Prostate Cancer [52]. The potential benefits and harms of using serum PSA testing to diagnose PCa in men with LUTS should be discussed.

4.6.3 PSA and the prediction of BPO-related outcomes

Serum PSA is a stronger predictor of prostate growth than prostate volume [53]. In addition, the PLESS study showed that PSA also predicted the changes in symptoms, QoL/bother, and maximum flow-rate (Q_{max}) [54]. In a longitudinal study of men managed conservatively, PSA was a highly significant predictor of clinical progression [55].

In the placebo arms of large double-blind studies, baseline serum PSA predicted the risk of acute urinary retention (AUR) and BPE-related surgery [56, 57]. An equivalent link was also confirmed by the Olmsted County Study. The risk for treatment was higher in men with a baseline PSA of > 1.4 ng/mL [58]. Patients with BPO seem to have a higher PSA level and larger prostate volumes. The PPV of PSA for the detection of BPO was recently shown to be 68% [59]. Furthermore, in an epidemiological study, elevated free PSA levels could predict clinical BPH, independent of total PSA levels [60].

Recommendations	LE	GR
Measure prostate-specific antigen (PSA) if a diagnosis of prostate cancer will change management.	1b	A
Measure PSA if it assists in the treatment and/or decision making process.	1b	A

4.7 Renal function measurement

Renal function may be assessed by serum creatinine or estimated glomerular filtration rate (eGFR). Hydronephrosis, renal insufficiency or urinary retention are more prevalent in patients with signs or symptoms of BPO [61]. Even though BPO may be responsible for these complications, there is no conclusive evidence on the mechanism [62].

One study reported that 11% of men with LUTS had renal insufficiency [61]. Neither symptom score nor QoL was associated with the serum creatinine level. Diabetes mellitus or hypertension were the most likely causes of the elevated creatinine concentration. Comiter *et al.* [63] reported that non-neurogenic voiding dysfunction is not a risk factor for elevated creatinine levels. Koch *et al.* [64] concluded that only those with an elevated creatinine level require investigational ultrasound (US) of the kidney.

In the Olmsted County community-dwelling men, there was a cross-sectional association between signs and symptoms of BPO (though not prostate volume) and chronic kidney disease (CKD) [65]. In 2,741 consecutive patients who presented with LUTS, decreased Q_{max} , a history of hypertension and/or diabetes were associated with CKD [66]. Another study demonstrated a correlation between Q_{max} and eGFR in middle-aged men with moderate-to-severe LUTS [67]. Patients with renal insufficiency are at an increased risk of developing post-operative complications [68].

Recommendation	LE	GR
Assess renal function if renal impairment is suspected based on history and clinical examination, or in the presence of hydronephrosis, or when considering surgical treatment for male LUTS.	3	A*

*Upgraded based on Panel consensus.

4.8 Post-void residual urine

Post-void residual (PVR) urine can be assessed by transabdominal US, bladder scan or catheterisation. Post-void residual is not necessarily associated with BOO, since high PVR volumes can be a consequence of obstruction and/or poor detrusor function (detrusor underactivity) [69, 70]. Using a PVR threshold of 50 mL, the diagnostic accuracy of PVR measurement has a PPV of 63% and a negative predictive value (NPV) of 52% for the predict BOO [71]. A large PVR is not a contraindication to watchful waiting (WW) or medical therapy, although a large PVR may indicate a poor response to treatment and especially to WW. In both the MTOPS and ALTESS studies, a high baseline PVR was associated with an increased risk of symptom progression [56, 57].

Monitoring of changes in PVR over time may allow for identification of patients at risk of acute urinary retention (AUR) [57]. This is of particular importance for the treatment of patients using antimuscarinic medication. In contrast, baseline PVR has little prognostic value for the risk of BPE-related invasive therapy in patients on α 1-blocker or WW [72]. However, due to large test-retest variability and lack of outcome studies, no PVR threshold for treatment decision has yet been established and this is a research priority.

Recommendation	LE	GR
Measure post-void residual in the assessment of male LUTS.	3	B

4.9 Uroflowmetry

Urinary flow rate assessment is a widely used non-invasive urodynamic test. Key parameters are Q_{max} and flow pattern. Uroflowmetry parameters should preferably be evaluated with voided volume > 150 mL. As Q_{max} is prone to within-subject variation [73, 74], it is useful to repeat uroflowmetry measurements, especially if the voided volume is < 150 mL, or Q_{max} or flow pattern is abnormal.

The diagnostic accuracy of uroflowmetry for detecting BOO varies considerably, and is substantially influenced by threshold values. A threshold Q_{max} of 10 mL/s has a specificity of 70%, a PPV of 70% and a sensitivity of 47% for BOO. The specificity using a threshold Q_{max} of 15 mL/s was 38%, the PPV 67% and the sensitivity 82% [75]. If Q_{max} is > 15 mL/s, physiological compensatory processes mean that BOO cannot be excluded. Low Q_{max} can arise as a consequence of BOO [76], detrusor underactivity or an under-filled bladder [77]. Therefore, it is limited as a diagnostic test as it is unable to discriminate between the underlying mechanisms. Specificity can be improved by repeated flow rate testing. Uroflowmetry can be used for monitoring treatment outcomes [78] and correlating symptoms with objective findings.

Recommendation	LE	GR
Uroflowmetry in the initial assessment of male LUTS may be performed and should be performed prior to any treatment.	2b	B

4.10 Imaging

4.10.1 Upper urinary tract

Routine imaging of the upper urinary tract in men with LUTS is not recommended, as these men are not at increased risk for upper tract malignancy or other abnormalities when compared to the overall population [64, 79-81]. Several arguments support the use of renal US in preference to intravenous urography (IVU). Ultrasound allows for better characterisation of renal masses, the possibility of investigating the liver and retroperitoneum, and simultaneous evaluation of the bladder, PVR and prostate, together with a lower cost, radiation dose and less side effects [79].

Recommendation	LE	GR
Perform ultrasound of the upper urinary tract in men with LUTS and a large post-void residual, or haematuria, or a history of urolithiasis.	3	B

4.10.2 Prostate

Imaging of the prostate can be performed by transabdominal US, TRUS, computed tomography (CT), and magnetic resonance imaging (MRI). However, in daily practice, prostate imaging is performed by transabdominal US or TRUS [79].

4.10.2.1 Prostate size and shape

Assessment of prostate size is important for the selection of interventional treatment, i.e. open prostatectomy, enucleation techniques, transurethral resection, transurethral incision of the prostate (TUIP), or minimally invasive therapies. It is also important prior to treatment with 5 α -reductase inhibitors (5-ARIs). Prostate volume predicts symptom progression and the risk of complications [81].

Transrectal US is superior to suprapubic (transabdominal) volume measurement [82, 83]. The presence of a median lobe may guide treatment choice in patients scheduled for a minimally invasive approach.

Recommendations	LE	GR
Perform imaging of the prostate (either by transrectal or transabdominal ultrasound) when considering medical treatment for male LUTS, if it assists in the choice of the appropriate drug.	3	B
Perform imaging of the prostate (either by transrectal or transabdominal ultrasound) when considering surgical treatment.	3	B

4.10.3 Voiding cysto-urethrogram

Voiding cysto-urethrogram (VCUG) is not recommended in the routine diagnostic work-up of men with LUTS, but it may be useful for the detection of vesico-ureteral reflux, bladder diverticula, or urethral pathologies. Retrograde urethrography may additionally be useful for the evaluation of urethral strictures where suspected.

4.11 Urethrocystoscopy

Patients with a history of microscopic or gross haematuria, urethral stricture, or bladder cancer, who present with LUTS, should undergo urethrocystoscopy during diagnostic evaluation.

Shoukry *et al.* evaluated 122 patients with LUTS using uroflowmetry and urethrocystoscopy [84]. The pre-operative Q_{max} was normal in 25% of 60 patients who had no bladder trabeculation, 21% of 73 patients with mild trabeculation and 12% of 40 patients with marked trabeculation on cystoscopy. All 21 patients who presented with diverticula had a reduced Q_{max} .

Anikwe showed that there was no significant correlation between the degree of bladder trabeculation (graded from I to IV), and the pre-operative Q_{max} value in 39 symptomatic men aged 53-83 years [85]. The largest study published on this issue examined the relation of urethroscopic findings to urodynamic studies in 492 elderly men with LUTS [86]. The authors noted a correlation between cystoscopic appearance (grade of bladder trabeculation and urethral occlusion) and urodynamic indices, DO and low compliance. It should be noted, however, that BOO was present in 15% of patients with normal cystoscopic findings, while 8% of patients had no obstruction, even in the presence of severe trabeculation [86].

Recommendation	LE	GR
Perform urethrocytostcopy in men with LUTS to exclude suspected bladder or urethral pathology and/or prior to minimally invasive/surgical therapies if the findings may change treatment.	3	B

4.12 Urodynamics

In male LUTS, the most widespread invasive urodynamic techniques employed are filling cystometry and pressure flow studies (PFS). The major goal of urodynamics is to explore the functional mechanisms of LUTS and to identify risk factors for adverse outcomes (for informed/shared decision-making). Most terms and conditions (e.g. DO, low compliance, BOO/BPO, DUA) are defined by urodynamic investigation.

4.12.1 Diagnosing bladder outlet obstruction

Pressure flow studies are the basis for the definition of BOO, which is characterised by increased detrusor pressure and decreased urinary flow rate during voiding. Bladder outlet obstruction/BPO has to be differentiated from DUA, which signifies decreased detrusor pressure during voiding in combination with decreased urinary flow rate [2].

Urodynamic testing may also identify DO. Studies have described an association between BOO and DO [87, 88]. In men with LUTS attributed to BPE, DO was present in 61% and independently associated with BOO grade and ageing [87].

The prevalence of DUA in men with LUTS is 11-40% [89, 90]. Detrusor contractility does not appear to decline in long-term BOO and surgical relief of BOO does not improve contractility [91, 92]. There are no published RCTs in men with LUTS and possible BPO that compare the standard practice investigation (uroflowmetry and PVR measurement) with PFS with respect to the outcome of treatment but one such study is ongoing in the UK.

A Cochrane meta-analysis was done to determine whether performing invasive urodynamic investigation reduces the number of men with continuing symptoms of voiding dysfunction. Two trials with 350 patients were included. Invasive urodynamic testing changed clinical decision making, patients who underwent urodynamics were less likely to undergo surgery; however, no evidence was found to demonstrate whether this led to reduced symptoms of voiding dysfunction after treatment [93].

Due to the invasive nature of the test, a urodynamic investigation is generally only offered if conservative treatment has failed. The Guidelines Panel attempted to identify specific indications for PFS based on age, findings from other diagnostic tests, and previous treatments. The Panel allocated a different degree of obligation for PFS in men > 80 years and men < 50 years, which may reflect the lack of evidence. In addition, there was no consensus whether PFS should or may be performed when considering surgery in men with bothersome predominantly voiding LUTS and $Q_{max} > 10$ mL/s, although the Panel recognised that with a $Q_{max} < 10$ mL/s, BOO is likely and PFS is not necessarily needed.

Patients with neurological disease, including those with previous radical pelvic surgery, should be assessed according to the EAU Guidelines on Neuro-Urology [94].

4.12.2 Videourodynamics

Videourodynamics provides additional anatomical and functional information and may be recommended if the clinician considers this is needed to understand the pathophysiological mechanism of an individual patient's LUTS.

Recommendations	LE	GR
Perform pressure-flow studies (PFS) only in individual patients with specific indications prior to invasive treatment or when evaluation of the underlying pathophysiology of LUTS is warranted.	3	B
Perform PFS in men who have had previously unsuccessful (invasive) treatment for LUTS.	3	B
When considering invasive treatment, pressure-flow studies may be used for patients who cannot void > 150 mL.	3	C
When considering invasive treatment in men with bothersome voiding LUTS, PFS may be performed in men with a post-void residual > 300 mL.	3	C
When considering invasive treatment in men with bothersome, predominantly voiding LUTS, PFS may be performed in men aged > 80 years.	3	C
When considering invasive treatment in men with bothersome, predominantly voiding LUTS, perform PFS in men aged < 50 years.	3	B

4.13 Non-invasive tests in diagnosing bladder outlet obstruction in men with LUTS

4.13.1 *Prostatic configuration/intravesical prostatic protrusion (IPP)*

Prostatic configuration can be evaluated with TRUS, using the concept of the presumed circle area ratio (PCAR) [95]. The PCAR evaluates how closely the transverse US image of the prostate approaches a circular shape. The ratio tends toward one as the prostate becomes more circular. The sensitivity of PCAR was 77% for diagnosing BPO when PCAR was > 0.8 , with 75% specificity [95].

Ultrasound measurement of IPP assesses the distance between the tip of the prostate median lobe and bladder neck in the midsagittal plane, using a suprapubically positioned US scanner, with a bladder volume of 150-250 mL; grade I protrusion is 0-4.9 mm, grade II is 5-10 mm and grade III is > 10 mm.

Intravesical prostatic protrusion correlates well with BPO (presence and severity) on urodynamic testing, with a PPV of 94% and a NPV of 79% [96]. Intravesical prostatic protrusion may also correlate with prostate volume, DO, bladder compliance, detrusor pressure at maximum urinary flow, BOO index and PVR, and negatively correlates with Q_{max} [97]. Furthermore, IPP also appears to successfully predict the outcome of a trial without catheter (TWOC) after AUR [98, 99]. However, no information with regard to intra- or inter-observer variability and learning curve is yet available. Therefore, IPP may be a feasible option to infer BPO in men with LUTS. The role of IPP as a non-invasive alternative to PFS in the assessment of male LUTS is under evaluation.

4.13.2 *Bladder/detrusor wall thickness and ultrasound-estimated bladder weight*

For bladder wall thickness (BWT) assessment, the distance between the mucosa and the adventitia is measured. For detrusor wall thickness (DWT) assessment, the only measurement needed is the detrusor sandwiched between the mucosa and adventitia [100].

A correlation between BWT and PFS parameters has been reported. A threshold value of 5 mm at the anterior bladder wall with a bladder filling of 150 mL was best at differentiating between patients with or without BOO [101]. Detrusor wall thickness at the anterior bladder wall with a bladder filling > 250 mL (threshold value for BOO > 2 mm) has a PPV of 94% and a specificity of 95%, achieving 89% agreement with PFS [71]. Threshold values of 2.0, 2.5, or 2.9 mm for DWT in patients with LUTS are able to identify 81%, 89%, and 100% of patients with BOO, respectively [102].

All studies found that BWT or DWT measurements have a higher diagnostic accuracy for detecting BOO than Q_{max} or Q_{ave} of free uroflowmetry, measurements of PVR, prostate volume, or symptom severity. One study could not demonstrate any difference in BWT between patients with normal urodynamics, BOO or DO. However, the study did not use a specific bladder filling volume for measuring BWT [103]. Disadvantages of the method include the lack of standardisation, and lack of evidence to indicate which measurement (BWT/DWT) is preferable [104]. Measurement of BWT/DWT is therefore not recommended for the diagnostic work-up of men with LUTS.

Ultrasound-estimated bladder weight (UEBW) may identify BOO with a diagnostic accuracy of 86% at a cut-off value of 35 g [105, 106]. Severe LUTS and a high UEBW (> 35 g) are risk factors for prostate/BPH surgery in men on α -blockers [107].

4.13.3 *Non-invasive pressure-flow testing*

The penile cuff method, in which flow is interrupted to estimate isovolumetric bladder pressure, shows promising data, with good test repeatability [108] and interobserver agreement [109]. A nomogram has also been derived [110] whilst a method in which flow is not interrupted is also under investigation [111].

The data generated with the external condom method [112] correlates with invasive PFS in a high proportion of patients [113]. Resistive index [114] and prostatic urethral angle [115] have also been proposed, but are still experimental.

4.13.4 *The diagnostic performance of non-invasive tests in diagnosing bladder outlet obstruction in men with LUTS compared with pressure-flow studies*

The diagnostic performance of non-invasive tests in diagnosing BOO in men with LUTS compared with PFS has been investigated by a systematic review performed by the Panel [116].

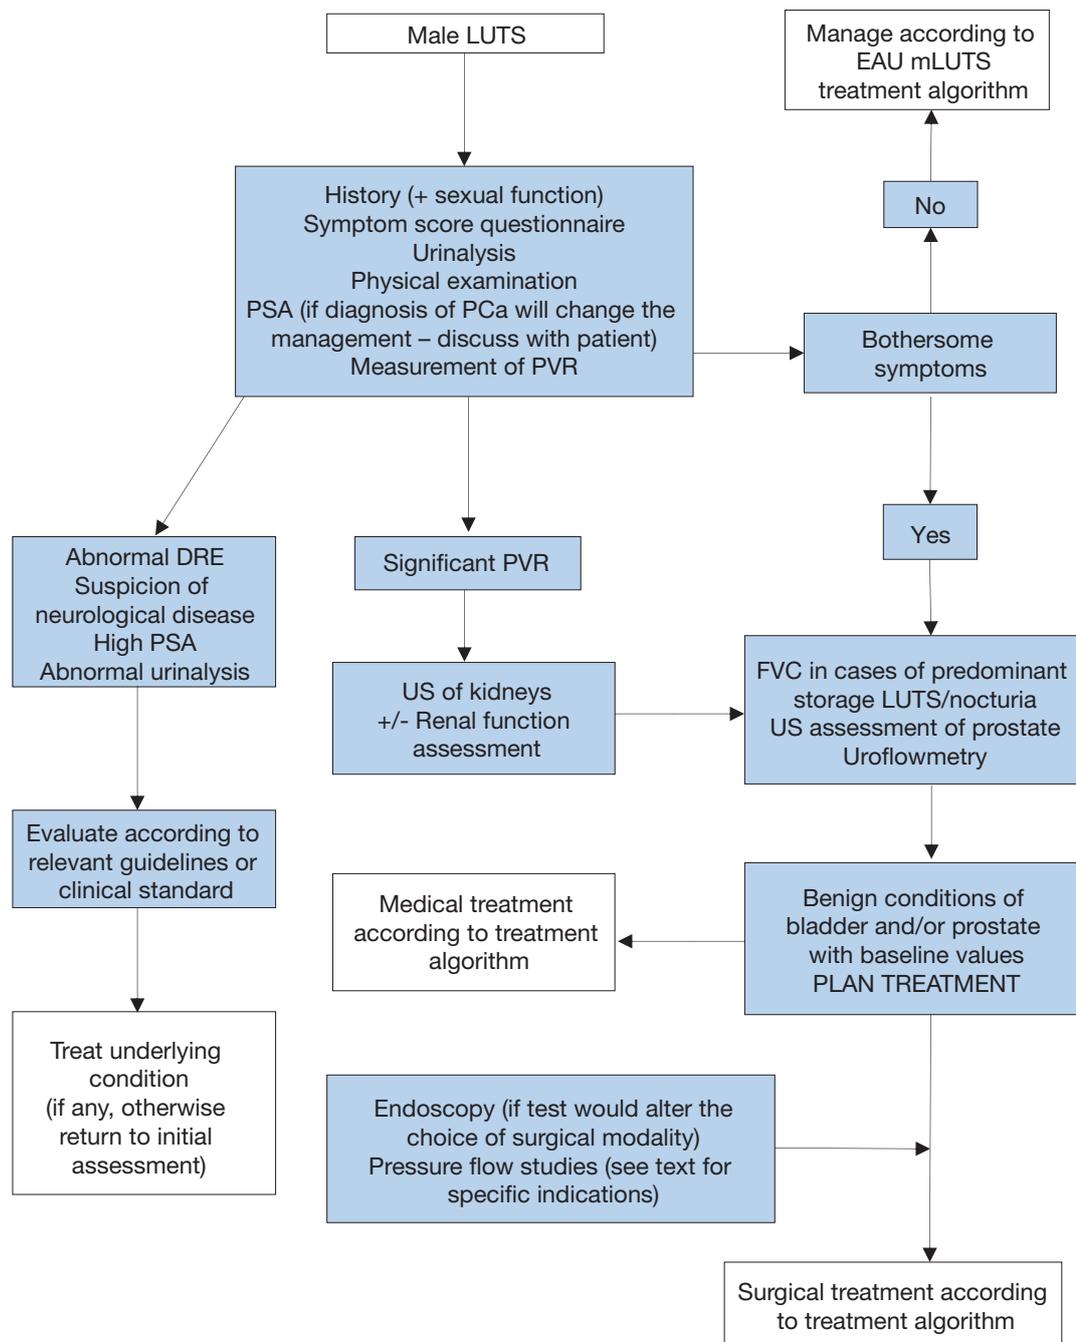

A total of 42 studies were included in this review, this summary print version is supplemented by a detailed online version (<http://uroweb.org/guideline/treatment-of-non-neurogenic-male-luts/>). The majority were prospective cohort studies, and the diagnostic accuracy of the following non-invasive tests were assessed: penile cuff test; uroflowmetry; detrusor/bladder wall thickness; bladder weight; external condom catheter method; IPP; doppler US; prostate volume/height; near-infrared spectroscopy. Overall, although the majority of studies have a low risk of bias, data regarding the diagnostic accuracy of these non-invasive tests is limited by the heterogeneity of the studies in terms of the threshold values used to define BOO, the different urodynamic definitions of BOO used across different studies and the small number of studies for each test. It was found that specificity, sensitivity, PPV and NPV of the non-invasive tests were highly variable. Therefore, even though

several tests have shown promising results regarding non-invasive diagnosis of BOO, invasive urodynamics remains the modality of choice.

Recommendation	LE	GR
None of the non-invasive tests in diagnosing bladder outlet obstruction in men with LUTS can currently be recommended as an alternative to pressure-flow studies.	1a	B

Figure 2: Assessment algorithm of LUTS in men aged 40 years or older

Readers are strongly recommended to read the full text that highlights the current position of each test in detail.

DRE = digital-rectal examination; FVC = frequency volume chart; LUTS = lower urinary tract symptoms; PCa = prostate cancer; PSA = prostate specific antigen; PVR = post-void residual; US = ultrasound.

5. DISEASE MANAGEMENT

5.1 Conservative treatment

5.1.1 Watchful waiting

Many men with LUTS are not troubled enough by their symptoms to need drug treatment or surgical intervention. All men with LUTS should be formally assessed prior to any allocation of treatment in order to establish symptom severity and to differentiate between men with uncomplicated (the majority) and complicated LUTS. Watchful waiting is a viable option for many men with non-bothersome LUTS as few will progress to AUR and complications (e.g. renal insufficiency or stones) [117, 118], whilst others can remain stable for years [119]. In one study, approximately 85% of men with mild LUTS were stable on WW at one year [120].

A study comparing WW and transurethral resection of the prostate (TURP) in men with moderate LUTS showed the surgical group had improved bladder function (flow rates and PVR volumes), especially in those with high levels of bother; 36% of WW patients crossed over to surgery within five years, leaving 64% doing well in the WW group [121, 122]. Increasing symptom bother and PVR volumes are the strongest predictors of clinical failure. Men with mild-to-moderate uncomplicated LUTS who are not too troubled by their symptoms are suitable for WW.

5.1.2 Behavioural and dietary modifications

It is customary for this type of management to include the following components:

- education (about the patient's condition);
- reassurance (that cancer is not a cause of the urinary symptoms);
- periodic monitoring;
- lifestyle advice [119, 120, 123, 124] such as:
 - o reduction of fluid intake at specific times aimed at reducing urinary frequency when most inconvenient (e.g. at night or when going out in public);
 - o avoidance/moderation of intake of caffeine or alcohol, which may have a diuretic and irritant effect, thereby increasing fluid output and enhancing frequency, urgency and nocturia;
 - o use of relaxed and double-voiding techniques;
 - o urethral milking to prevent post-micturition dribble;
 - o distraction techniques such as penile squeeze, breathing exercises, perineal pressure, and mental tricks to take the mind off the bladder and toilet, to help control storage symptoms;
 - o bladder retraining that encourages men to hold on when they have sensory urgency to increase their bladder capacity and the time between voids;
 - o reviewing the medication and optimising the time of administration or substituting drugs for others that have fewer urinary effects (these recommendations apply especially to diuretics);
 - o providing necessary assistance when there is impairment of dexterity, mobility, or mental state;
 - o treatment of constipation.

There now exists evidence (LE: 1b) that self-management as part of WW reduces both symptoms and progression [123, 124] (online supplementary Table S.12). Men randomised to three self-management sessions in addition to standard care had better symptom improvement and QoL than men treated with standard care only for up to a year [123].

5.1.3 Practical considerations

The components of self-management have not been individually studied. The above components of lifestyle advice have been derived from formal consensus methodology [125]. Further research in this area is required.

Recommendations	LE	GR
Offer men with mild/moderate symptoms, minimally bothered by their symptoms, watchful waiting.	1b	A
Offer men with LUTS lifestyle advice prior to or concurrent with treatment.	1b	A

5.2 Pharmacological treatment

5.2.1 α 1-Adrenoceptor antagonists (α 1-blockers)

Mechanism of action: α 1-blockers aim to inhibit the effect of endogenously released noradrenaline on smooth muscle cells in the prostate and thereby reduce prostate tone and BOO [126]. However, α 1-blockers have little effect on urodynamically determined bladder outlet resistance [127], and treatment-associated improvement of LUTS correlates poorly with obstruction [128]. Thus, other mechanisms of action may be relevant.

α 1-adrenoceptors located outside the prostate (e.g. urinary bladder and/or spinal cord) and α 1-adrenoceptor subtypes (α 1B- or α 1D-adrenoceptors) may play a role as mediators of effects. α 1-adrenoceptors in blood vessels, other non-prostatic smooth muscle cells, and the central nervous system may mediate adverse events.

α 1-blockers currently available are: alfuzosin hydrochloride (alfuzosin); doxazosin mesylate (doxazosin); silodosin; tamsulosin hydrochloride (tamsulosin); terazosin hydrochloride (terazosin). α 1-blockers exist in different formulations (online supplementary Table S.13). Although different formulations result in different pharmacokinetic and tolerability profiles, the overall clinical impact of the different formulations is modest.

Efficacy: Indirect comparisons and limited direct comparisons between α 1-blockers demonstrate that all α 1-blockers have a similar efficacy in appropriate doses [129]. Effects take a few weeks to develop fully, but significant efficacy over placebo can occur within hours to days [130].

Controlled studies show that α 1-blockers typically reduce IPSS by approximately 30-40% and increase Q_{max} by approximately 20-25% (online supplementary Table S.14). However, considerable improvements also occurred in the corresponding placebo arms [55, 130]. In open-label studies, an IPSS improvement of up to 50% and Q_{max} increase of up to 40% were documented [55, 130].

α 1-blockers can reduce both storage and voiding LUTS. Prostate size does not affect α 1-blocker efficacy in studies with follow-up periods of less than one year, but α 1-blockers do seem to be more efficacious in patients with smaller prostates (< 40 mL) in longer-term studies [56, 131-134]. α 1-blocker efficacy is similar across age groups [130]. α 1-blockers neither reduce prostate size nor prevent AUR in long-term studies [132-134]. Nevertheless, IPSS reduction and Q_{max} improvement during α 1-blocker treatment appears to be maintained over at least four years.

Tolerability and safety: Tissue distribution, subtype selectivity, and pharmacokinetic profiles of certain formulations may contribute to the tolerability profile of specific drugs. The most frequent adverse events of α 1-blockers are asthenia, dizziness and (orthostatic) hypotension. Vasodilating effects are most pronounced with doxazosin and terazosin, and are less common for alfuzosin and tamsulosin [135]. Patients with cardiovascular comorbidity and/or vaso-active co-medication may be susceptible to α 1-blocker-induced vasodilatation [136]. In contrast, the frequency of hypotension with the α 1A- selective blocker silodosin is comparable with placebo [137]. In a large retrospective cohort analysis of men aged \geq 66 years treated with α 1-blockers, the risks of falling (odds ratio [OR] 1.14) and of sustaining a fracture (OR 1.16) was increased, most likely as a result of induced hypotension [138].

An adverse ocular event termed intra-operative floppy iris syndrome (IFIS) was reported in 2005, affecting cataract surgery [139]. A meta-analysis on IFIS after alfuzosin, doxazosin, tamsulosin or terazosin exposure showed an increased risk for all α 1-blockers [140]. However, the OR for IFIS was much higher for tamsulosin. It appears prudent not to initiate α 1-blocker treatment prior to scheduled cataract surgery, and the ophthalmologist should be informed about α 1-blocker use.

A systematic review concluded that α 1-blockers do not adversely affect libido, have a small beneficial effect on erectile function, but sometimes cause abnormal ejaculation [141]. Originally, abnormal ejaculation was thought to be retrograde, but more recent data demonstrate that it is due to a decrease or absence of seminal fluid during ejaculation, with young age being an apparent risk factor. In a recent meta-analysis ejaculatory dysfunction (EjD) was significantly more common with α 1-blockers than with placebo (OR 5.88). In particular, EjD was significantly more commonly related with tamsulosin or silodosin (OR: 8.57 and 32.5) than placebo, while both doxazosin and terazosin (OR 0.80 and 1.78) were associated with a low risk of EjD [142]. In the meta-regression, the occurrence of EjD was independently associated with the improvement of urinary symptoms and flow rate, suggesting that the more effective the α 1-blocker is the greater the incidence of EjD.

Practical considerations: α 1-blockers are often considered the first line drug treatment of male LUTS because of their rapid onset of action, good efficacy, and low rate and severity of adverse events. However, α 1-blockers do not prevent occurrence of urinary retention or need for surgery. Ophthalmologists should be informed about α 1-blocker use prior to cataract surgery. Elderly patients treated with non-selective α 1-blockers should be informed about the risk of orthostatic hypotension. Sexually active patients treated with selective α 1-blockers should be counselled about the risk of EjD.

Recommendations	LE	GR
Offer α 1-blockers to men with moderate-to-severe LUTS.	1a	A
Counsel patients about the treatment related side effects associated with selective versus non-selective α -blockers.	1a	A

5.2.2 5α -reductase inhibitors

Mechanism of action: Androgen effects on the prostate are mediated by dihydrotestosterone (DHT), which is converted from testosterone by the enzyme 5α -reductase, a nuclear-bound steroid enzyme [143]. Two isoforms of this enzyme exist:

- 5α -reductase type 1, with minor expression and activity in the prostate but predominant activity in extraprostatic tissues, such as skin and liver.
- 5α -reductase type 2, with predominant expression and activity in the prostate.

Two 5α -reductase inhibitors (5-ARIs) are available for clinical use: dutasteride and finasteride (online supplementary Table S.15). Finasteride inhibits only 5α -reductase type 2, whereas dutasteride inhibits 5α -reductase types 1 and 2 with similar potency (dual 5-ARI). 5-ARIs act by inducing apoptosis of prostate epithelial cells [144] leading to prostate size reduction of about 18-28% and a decrease in circulating PSA levels of about 50% after six to twelve months of treatment [145]. Mean prostate volume reduction and PSA decrease may be even more pronounced after long-term treatment. Continuous treatment reduces the serum DHT concentration by approximately 70% with finasteride and 95% with dutasteride. However, prostate DHT concentration is reduced to a similar level (85-90%) by both 5-ARIs.

Efficacy: Clinical effects relative to placebo are seen after a minimum treatment duration of at least six to twelve months. After two to four years of treatment, 5-ARIs improve IPSS by approximately 15-30%, decrease prostate volume by 18-28%, and increase Q_{max} by 1.5-2.0 mL/s in patients with LUTS due to prostate enlargement (online supplementary Table S.16) [56, 133, 134, 146-152]. A indirect comparison and one direct comparative trial (twelve months duration) indicate that dutasteride and finasteride are equally effective in the treatment of LUTS [145, 153]. Symptom reduction depends on initial prostate size.

Finasteride may not be more efficacious than placebo in patients with prostates < 40 mL [154]. However, dutasteride seems to reduce IPSS, prostate volume, and the risk of AUR, and to increase Q_{max} even in patients with prostate volumes of between 30 and 40 mL at baseline [155, 156]. A long-term trial with dutasteride in symptomatic men with prostate volumes > 30 mL and increased risk for disease progression showed that dutasteride reduced LUTS at least as much as, or even more effectively than, the α 1-blocker tamsulosin [133, 152, 157]. The greater the baseline prostate volume (or serum PSA concentration), the faster and more pronounced the symptomatic benefit of dutasteride as compared to tamsulosin.

5-ARIs, but not α 1-blockers, reduce the long-term (> one year) risk of AUR or need for surgery [56, 150, 158]. In the PLESS study, finasteride treatment reduced the relative risk of AUR by 57%, and surgery by 55% at four years, compared with placebo [150]. In the MTOPS study, a significant reduction in the risk of AUR and surgery in the finasteride arm compared with placebo was reported (68% and 64%, respectively) [56]. A pooled analysis of randomised trials with two-year follow-up data, reported that treatment with finasteride significantly decreased the occurrence of AUR by 57%, and surgical intervention by 34%, in moderately symptomatic LUTS [159]. Dutasteride has also demonstrated efficacy in reducing the risks for AUR and BPH-related surgery. Open-label trials have demonstrated relevant changes in urodynamic parameters [160, 161].

Finasteride might reduce blood loss during transurethral prostate surgery, probably due to its effects on prostatic vascularisation [162].

Tolerability and safety: The most relevant adverse effects of 5-ARIs are related to sexual function, and include reduced libido, erectile dysfunction (ED) and less frequently, ejaculation disorders such as retrograde ejaculation, ejaculation failure, or decreased semen volume [56, 134, 145]. The incidence of sexual dysfunction and other adverse events is low and even decreased with trial duration. Gynaecomastia (with breast or nipple tenderness) develops in 1-2% of patients.

Data from two trials on PCa chemoprevention (the Prostate Cancer Prevention Trial and the Reduction by Dutasteride of Prostate Cancer Events trial) found a higher incidence of high-grade cancers in the 5-ARIs arms [163, 164]. Although no causal relationship with high-grade PCa has been proven, men taking 5-ARIs should be followed-up regularly using serial PSA testing and any confirmed PSA increase should be evaluated accordingly. There is a long-standing debate regarding potential cardiovascular side effects of 5-ARIs, in particular dutasteride [165]. In a five year population-based study performed in Taiwan, Hsieh *et al.* could not identify an association between the use of 5-ARIs and increased cardiovascular side effects, in elderly men (> 65 years) [165].

Practical considerations: Treatment with 5-ARIs should be considered in men with moderate-to-severe LUTS

and an enlarged prostate (> 40 mL) and/or elevated PSA concentration (> 1.4-1.6 ng/mL). 5 α -reductase inhibitors can prevent disease progression with regard to acute urinary retention and the need for surgery. Due to the slow onset of action, they are suitable only for long-term treatment (years). Their effect on the serum PSA concentration needs to be considered in relation to PCa screening.

Recommendations	LE	GR
Use 5 α -reductase inhibitors in men who have moderate-to-severe LUTS and an enlarged prostate (> 40 mL).	1b	A
Counsel patients about the delayed symptom improvement with 5 α -reductase inhibitors.	1a	A

5.2.3 Muscarinic receptor antagonists

Mechanism of action: The detrusor is innervated by parasympathetic nerves whose main neurotransmitter is acetylcholine, which stimulates muscarinic receptors (M-cholinoreceptors) on the smooth muscle cells. Muscarinic receptors are also present on other cell types, such as bladder urothelial cells, epithelial cells of the salivary glands, or the peripheral or central nervous system. Five muscarinic receptor subtypes (M1-M5) have been described, of which M2 and M3 are predominant in the detrusor. M2 are more numerous, but the M3 subtype is functionally more important in bladder contractions in healthy humans [166, 167]. Antimuscarinic effects might also be induced or modulated through other cell types, such as the bladder urothelium or by the central nervous system [168, 169].

The following muscarinic receptor antagonists are licensed for treating overactive bladder/storage symptoms (online supplementary Table S.17): darifenacin hydrobromide (darifenacin); fesoterodine fumarate (fesoterodine); oxybutynin hydrochloride (oxybutynin); propiverine hydrochloride (propiverine); solifenacin succinate (solifenacin); tolterodine tartrate (tolterodine); trospium chloride. Transdermal preparations of oxybutynin have been formulated and evaluated in clinical trials [170, 171].

Efficacy: Antimuscarinics were mainly tested in females in the past, as it was believed that LUTS in men were caused by the prostate, so should be treated with prostate-specific drugs. However, there is no scientific data for this assumption [172]. A sub-analysis of an open-label trial of OAB patients showed that age but not gender had an impact on urgency, frequency, or urgency incontinence [173]. In a pooled analysis, which included a sub-analysis of male patients, fesoterodine 8 mg was superior to tolterodine extended release (ER) 4 mg for the improvement of severe urgency episodes/24 hours and the OAB-q Symptom Bother score at week twelve, the urinary retention rate was around 2% [174].

The efficacy of antimuscarinics as single agents in men with OAB in the absence of BOO have been tested (online supplementary Table S.18) [175-180]. Most trials lasted only twelve weeks. Four post hoc analyses of large RCTs on the treatment of OAB in women and men without presumed BOO were performed focusing only on the men [176, 178, 181]. Tolterodine can significantly reduce urgency incontinence, daytime or 24-hour frequency and urgency-related voiding whilst improving patient perception of treatment benefit. Solifenacin significantly improved mean patient perception of bladder condition scores, mean OAB questionnaire scores, and overall perception of bladder problems. Fesoterodine improved micturition frequency, urgency episodes, and urgency urinary incontinence (UUI) episodes. In open-label trials with tolterodine, daytime frequency, nocturia, UUI, and IPSS were significantly reduced compared with baseline values after 12-25 weeks [177, 180].

In the Tolterodine and Tamsulosin in Men with LUTS including OAB: Evaluation of Efficacy and Safety Study, men who received tolterodine monotherapy saw improvement only in urgency incontinence, but not urgency, IPSS (total or storage subscore), or the overall percentage of patients reporting treatment benefit compared with placebo [179].

A further analysis showed that men with PSA levels of < 1.3 ng/mL (smaller prostates) might benefit more from antimuscarinic drugs [182]. Two other studies found a positive effect of antimuscarinics in patients with OAB and concomitant BPO [180, 183]. In a small RCT without placebo, propiverine improved frequency and urgency episodes [183]. In an open-label study, tolterodine decreased 24-hour micturition, nocturia and American Urological Association Symptom Index scores [180].

Tolerability and safety: Antimuscarinic drug trials generally show approximately 3-10% withdrawals, which is similar to placebo. Drug-related adverse events include dry mouth (up to 16%), constipation (up to 4%), micturition difficulties (up to 2%), nasopharyngitis (up to 3%), and dizziness (up to 5%).

Increased PVR in men without BOO is minimal and similar to placebo. Nevertheless, fesoterodine 8 mg showed higher PVRs (+20.2 mL) than placebo (-0.6 mL) or fesoterodine 4 mg (+9.6 mL) [179]. Incidence of urinary retention in men without BOO was similar to placebo for tolterodine (0-1.3% vs. 0-1.4%). With fesoterodine 8 mg, 5.3% had symptoms, which was higher than placebo or fesoterodine 4 mg (both 0.8%).

These symptoms appeared during the first two weeks of treatment and mainly affected men aged 66 years or older.

Theoretically antimuscarinics might decrease bladder strength, and hence might be associated with PVR urine or urinary retention. A twelve week safety study on men with mild to moderate BOO showed that tolterodine increased the PVR (49 mL vs. 16 mL) but not acute urinary retention (3% in both arms) [184]. The urodynamic effects included larger bladder volumes at first detrusor contraction, higher maximum cystometric capacity, and decreased bladder contractility index. Q_{max} was unchanged. This trial indicated that short-term treatment with antimuscarinics in men with BOO is safe [184].

Practical considerations: Not all antimuscarinics have been tested in elderly men, and long-term studies on the efficacy of muscarinic receptor antagonists in men of any age with LUTS are not yet available. In addition, only patients with low PVR volumes at baseline were included in the studies. These drugs should therefore be prescribed with caution, and regular re-evaluation of IPSS and PVR urine is advised. Men should be advised to discontinue medication if worsening voiding LUTS or urinary stream is noted after initiation of therapy.

Recommendations	LE	GR
Use muscarinic receptor antagonists in men with moderate-to-severe LUTS who mainly have bladder storage symptoms.	1b	B
Prescribe antimuscarinics with caution in men with a post-void residual volume > 150 mL.	4	C

5.2.4 Phosphodiesterase 5 inhibitors

Mechanism of action: Phosphodiesterase 5 inhibitors (PDE5Is) increase intracellular cyclic guanosine monophosphate, thus reducing smooth muscle tone of the detrusor, prostate and urethra. Nitric oxide and PDEs might also alter reflex pathways in the spinal cord and neurotransmission in the urethra, prostate, or bladder [185]. Moreover, chronic treatment with PDE5Is seems to increase blood perfusion and oxygenation in the LUT [186]. Finally, PDE5Is could reduce chronic inflammation in the prostate and bladder [187]. The exact mechanism of PDE5Is on LUTS remains unclear.

Available drugs: Although clinical trials of several selective oral PDE5Is have been conducted in men with LUTS, only tadalafil (5 mg once daily) has been licensed for the treatment of male LUTS.

Efficacy: Several RCTs have demonstrated that PDE5Is reduce IPSS, storage and voiding LUTS, and improve QoL (online supplementary Table S.19). However, Q_{max} did not significantly differ from placebo in most trials. In a meta-analysis, PDE5Is were found to improve IPSS and IIEF score, but not Q_{max} [188].

Tadalafil 5 mg reduces IPSS by 22-37% (online supplementary Table S.19), and improvement may be seen within a week of initiation of treatment [189]. A three point or greater total IPSS improvement was observed in 59.8% of tadalafil treated men within one week and in 79.3% within four weeks [190]. The maximum trial (open label) duration was 52 weeks [191]. A subgroup analysis of pooled data from four RCTs demonstrated a significant reduction in LUTS, regardless of baseline severity, age, previous use of α -blockers or PDE5Is, total testosterone level or predicted prostate volume [192]. In a recent post hoc analysis of pooled data from four RCTs, tadalafil was shown to also be effective in men with cardiovascular risk factors/comorbidities except for patients receiving more than one antihypertensive medication. The use of diuretics may contribute to patients' perception of a negated efficacy [193]. Among sexually active men > 45 years with comorbid LUTS/BPH and ED, tadalafil improved both conditions [194].

An integrated data analyses from four placebo controlled clinical studies showed that total IPSS improvement was largely attributed to direct (92.5%, $p < 0.001$) vs. indirect (7.5%, $p = 0.32$) treatment effects via IIEF-EF improvement [195]. Another analysis showed a small but significant increase in Q_{max} without any effect on PVR [196].

A combination of PDE5Is and α -blockers has also been evaluated. A meta-analysis of five RCTs (two studies with tadalafil 20 mg, two with sildenafil 25 mg, and one with vardenafil 20 mg), showed that combination therapy significantly improved IPSS score (-1.8), IIEF score (+3.6) and Q_{max} (+1.5 mL/s) compared with α -blockers alone [188]. The effects of tadalafil 5 mg combined with finasteride 5 mg were assessed in a 26-week placebo-controlled RCT. The combination of tadalafil and finasteride provided an early improvement in urinary symptoms ($p < 0.022$ after 4, 12 and 26 weeks), with a significant improvement of storage and voiding symptoms and QoL. Combination therapy was well tolerated and improved erectile function [197]. However, only tadalafil 5 mg has been licensed in the context of LUTS management while data on combinations of PDE5Is and other LUTS medications is emerging.

Tolerability and safety: Reported adverse effects in RCTs comparing the effect of all PDE5Is vs. placebo in men with LUTS include flushing, gastroesophageal reflux, headache, dyspepsia, back pain and nasal congestion [188]. Discontinuation rate due to adverse effects for tadalafil was 2.0% [198] and did not differ by age, LUTS severity, testosterone levels, or prostate volume in the pooled data analyses [192].

PDE5Is are contraindicated in patients using nitrates, the potassium channel opener nicorandil, or the α 1-blockers doxazosin and terazosin. They are also contraindicated in patients who have unstable angina pectoris, have had a recent myocardial infarction (< three months) or stroke (< six months), myocardial insufficiency (New York Heart Association stage > 2), hypotension, poorly controlled blood pressure, significant hepatic or renal insufficiency, or if anterior ischaemic optic neuropathy with sudden loss of vision is known or was reported after previous use of PDE5Is.

Practical considerations: To date, only tadalafil 5 mg once daily has been officially licensed for the treatment of male LUTS with or without ED. The meta-regression suggested that younger men with low body mass index and more severe LUTS benefit the most from treatment with PDE5Is [188]. Long-term experience with tadalafil in men with LUTS is limited to one trial with a one year follow-up [191], therefore conclusions about its efficacy or tolerability greater than one year are not possible. There is limited information on reduction of prostate size and no data on disease progression.

Recommendation	LE	GR
Use phosphodiesterase type 5 inhibitors in men with moderate-to-severe LUTS with or without erectile dysfunction.	1a	A

5.2.5 **Plant extracts - phytotherapy**

Mechanism of action: Herbal drug preparations are made of roots, seeds, pollen, bark, or fruits. There are single plant preparations (mono-preparations) and preparations combining two or more plants in one pill (combination preparations). The most widely used plants are Cucurbita pepo (pumpkin seeds), Hypoxis rooperi (South African star grass), Pygeum africanum (bark of the African plum tree), Secale cereale (rye pollen), Serenoa repens (syn. Sabal serrulata; saw palmetto) and Urtica dioica (roots of the stinging nettle).

Possible relevant compounds include phytosterols, β -sitosterol, fatty acids, and lectins [199]. *In vitro*, plant extracts can have anti-inflammatory, anti-androgenic and oestrogenic effects; decrease sexual hormone binding globulin; inhibit aromatase, lipoxigenase, growth factor-stimulated proliferation of prostatic cells, α -adrenoceptors, 5 α -reductase, muscarinic cholinceptors, dihydropyridine receptors and vanilloid receptors; and neutralise free radicals [199-201]. These effects have not been confirmed *in vivo*, and the precise mechanisms of plant extracts remain unclear.

Efficacy: The extracts of the same plant produced by different companies do not necessarily have the same biological or clinical effects, therefore the effects of one brand cannot be extrapolated to others [202]. In addition, batches from the same producer may contain different concentrations of active ingredients [203]. A review of recent extraction techniques and their impact on the composition/biological activity of Serenoa repens based available products showed that results from different clinical trials must be compared strictly according to the same validated extraction technique and/or content of active compounds [204]. Thus the pharmacokinetic properties can vary significantly.

Online supplementary Table S.20 presents the trials with the highest LE for each plant extract. In general, no phytotherapeutic agent has been shown to reduce prostate size, and no trial has proven a reduction of BOO or a decrease in disease progression.

A cochrane meta-analyses suggest that men treated with Pygeum africanum were twice as likely to report symptom improvement whilst men treated with Secale cereale were twice as likely to benefit from therapy compared to placebo and that Serenoa repens was not superior to placebo, finasteride, or tamsulosin for IPSS (similar levels of IPSS improvements in trials with finasteride or tamsulosin might be interpreted as treatment equivalence) [205-207].

Recently, short-term studies on the combination of plant extracts with tamsulosin have been published with promising results [208, 209]. Combination treatment with Serenoa Repens (SeR), lycopene (Ly), selenium (Se) and tamsulosin was more effective than single therapies (SeR-Ly-Se or tamsulosin) in improving IPSS and increasing Q_{max} in patients with LUTS at twelve months. The combination treatment of Serenoa repens and tamsulosin was shown to be more effective than tamsulosin monotherapy in reducing storage symptoms but changes in IPSS, voiding subscore, QoL, Q_{max} , PVR, PSA, and prostate volume showed no significant differences between the two groups.

Tolerability and safety: Side-effects during phytotherapy are generally mild and comparable to placebo. Serious adverse events were not related to the study medication. Gastrointestinal complaints were the most commonly reported. In formulations with *Hypoxis rooperi*, ED was reported in 0.5% of patients.

Practical considerations: Phytotherapeutic agents are a heterogeneous group and may contain differing concentrations of active ingredients. Hence, meta-analyses may not be justified and results of any analyses have to be interpreted with caution.

Panel interpretation: The Guidelines Panel has not made any specific recommendations on phytotherapy for the treatment of male LUTS due to product heterogeneity, a limited regulatory framework, and methodological limitations of the published trials and meta-analyses.

5.2.6 **Beta-3 agonist**

Mechanism of action: Beta-3 adrenoceptors are the predominant beta receptors expressed in the smooth muscle cells of the detrusor and their stimulation is thought to induce detrusor relaxation.

Efficacy: Mirabegron 50 mg is the first clinically available beta-3 agonist with approval for use in adults with OAB. Mirabegron has undergone extensive evaluation in RCTs conducted in Europe, Australia, North America and Japan [210-214]. Mirabegron demonstrated significant efficacy in treating the symptoms of OAB, including micturition frequency, urgency incontinence, and urgency and also patient perception of treatment benefit. These studies had a predominantly female study population.

Mirabegron as an add-on therapy has been studied in OAB patients with incontinence despite antimuscarinic therapy [215], again in a predominantly-female study population. An Asian study with a higher proportion of male subjects (approximately one third) reported superiority over placebo in reducing frequency of micturition, but did not report the results separately for the genders [216].

Tolerability and safety: The most common treatment-related adverse events in the mirabegron groups were hypertension, UTI, headache and nasopharyngitis [210-213]. Mirabegron is contraindicated in patients with severe uncontrolled hypertension (systolic blood pressure \geq 180 mmHg or diastolic blood pressure \geq 110 mmHg, or both). Blood pressure should be measured before starting treatment and monitored regularly during treatment. The proportion of patients with dry mouth and constipation in the mirabegron groups was notably lower than reported in RCTs of other OAB agents or of the active control tolterodine [210]. Evaluation of urodynamic parameters in men with combined BOO and OAB concluded that mirabegron did not adversely affect voiding urodynamic parameters compared to placebo in terms of Q_{max} , detrusor pressure at maximum flow and bladder contractility index [217]. The overall change in PVR with mirabegron is small [217].

Practical considerations: Long-term studies on the efficacy and safety of mirabegron in men of any age with LUTS are not yet available. Studies on the use of mirabegron in combination with other pharmacotherapeutic agents for male LUTS are pending. However, pharmacokinetic interaction upon add-on of mirabegron or tamsulosin to existing tamsulosin or mirabegron therapy does not cause clinically relevant changes in safety profiles [218]. One small study has looked at change in symptom scores in men receiving mirabegron with tamsulosin 0.2 mg daily [219]. A phase four study, with a small proportion of male subjects, reported addition of mirabegron in people with persisting urgency despite solifenacin in a Japanese population [220].

Recommendation	LE	GR
Use beta-3 agonists in men with moderate-to-severe LUTS who mainly have bladder storage symptoms.	1b	B

5.2.7 **Combination therapies**

5.2.7.1 *α 1-blockers + 5 α -reductase inhibitors*

Mechanism of action: Combination therapy consists of an α 1-blocker (Section 5.2.1) together with a 5-ARI (Section 5.2.2). The α 1-blocker exhibits clinical effects within hours or days, whereas the 5-ARI needs several months to develop full clinical efficacy. Finasteride has been tested in clinical trials with alfuzosin, terazosin, doxazosin or terazosin, and dutasteride with tamsulosin.

Efficacy: Several studies have investigated the efficacy of combination therapy against an α 1-blocker, 5-ARI or placebo alone (online supplementary Table S.21). Initial studies with follow-up periods of six to twelve months demonstrated that the α 1-blocker was superior to finasteride in symptom reduction, whereas combination therapy of both agents was not superior to α 1-blocker monotherapy [147, 148, 221]. In studies with a placebo

arm, the α 1-blocker was consistently more effective than placebo, but finasteride was not. Data at one year in the MTOPS study showed similar results [56].

Long-term data (four years) from MTOPS, and Combination of Avodart and Tamsulosin (CombAT) studies showed that combination treatment is superior to monotherapy for symptoms and Q_{max} , and superior to α -blocker alone in reducing the risk of AUR or need for surgery [56, 133, 134].

The CombAT study demonstrated that combination treatment is superior to either monotherapy regarding symptoms and flow rate starting from month nine, and superior to α 1-blocker for AUR and the need for surgery after eight months [134]. Thus the differences in MTOPS may reflect different inclusion and exclusion criteria and baseline patient characteristics.

Discontinuation of the α 1-blocker after six to nine months of combination therapy was investigated by an RCT and an open-label multicentre trial [222, 223]. The first trial evaluated the combination of tamsulosin with dutasteride and the impact of tamsulosin discontinuation after six months [222], with almost three-quarters of patients reporting no worsening of symptoms. However, patients with severe symptoms (IPSS > 20) at baseline may benefit from longer combination therapy.

A more recent trial evaluated the symptomatic outcome of finasteride monotherapy at three and nine months after discontinuation of nine-month combination therapy [223]. LUTS improvement after combination therapy was sustained at three months (IPSS difference 1.24) and nine months (IPSS difference 0.4). The limitations of the studies include the short duration and the short follow-up period after discontinuation.

In both the MTOPS and CombAT studies, combination therapy was superior to monotherapy in preventing clinical progression as defined by an IPSS increase of at least four points, AUR, UTI, incontinence, or an increase in creatinine > 50%. The MTOPS study found that the risk of long-term clinical progression (primarily due to increasing IPSS) was reduced by 66% with combined therapy vs. placebo and to a greater extent than with either finasteride or doxazosin monotherapy (34% and 39%, respectively) [56]. In addition, finasteride (alone or in combination), but not doxazosin, significantly reduced both the risks of AUR and the need for BPH related surgery over the four-year study. In the CombAT study, combination therapy reduced the relative risks of AUR by 68%, BPH-related surgery by 71%, and symptom deterioration by 41% compared with tamsulosin, after four years [224]. To prevent one case of urinary retention and/or surgical treatment thirteen patients need to be treated for four years with dutasteride and tamsulosin combination therapy compared to tamsulosin monotherapy while the absolute risk reduction (risk difference) was 7.7%.

The CONDUCT study compared efficacy and safety of a fixed-dose combination of dutasteride and tamsulosin to a WW approach with the potential initiation of tamsulosin (step-up approach) in a two year RCT with a total of 742 patients. In both arms detailed lifestyle advice was given. This fixed-dose combination resulted in a rapid and sustained improvement in men with moderate LUTS at risk of disease progression, the difference in IPSS at 24 months was 1.8 points ($p < 0.001$) [225]. Furthermore, tamsulosin plus dutasteride significantly reduced the relative risk of clinical progression (mainly characterised as a worsening in symptoms) by 43.1% when compared with WW, with an absolute risk reduction of 11.3% (number needed to treat [NNT] = 9).

The influence of baseline variables on changes in IPSS after combination therapy with dutasteride plus tamsulosin or either monotherapy was tested based on the four year results of the CombAT study. Combination therapy provided consistent improvement of LUTS over tamsulosin across all analysed baseline variables at 48 months [226].

More recently, a combination of the 5-ARI, finasteride, and tadalafil 5 mg was tested in a large scale RCT against finasteride monotherapy. This study supports the concept of this novel combination therapy and is described in more detail in the chapter on PDE5Is [197].

Tolerability and safety: Adverse events for both drug classes have been reported with combination treatment [56, 133, 134]. The adverse events observed during combination treatment were typical of α 1-blockers and 5-ARIs. The frequency of adverse events was significantly higher for combination therapy.

Practical considerations: Compared with α 1-blockers or 5-ARI monotherapy, combination therapy results in a greater improvement in LUTS and increase in Q_{max} , and is superior in prevention of disease progression. However, combination therapy is also associated with a higher rate of adverse events. Combination therapy should therefore be prescribed primarily in men who have moderate-to-severe LUTS and are at risk of disease progression (higher prostate volume, higher PSA concentration, advanced age, higher PVR, lower Q_{max} , etc.). Combination therapy should only be used when long-term treatment (more than twelve months) is intended and patients should be informed about this. Discontinuation of the α 1-blocker after six months might be considered in men with moderate LUTS.

Recommendation	LE	GR
Use combination treatment of an α 1-blocker and 5 α -reductase inhibitor in men with moderate-to-severe LUTS and risk of disease progression (e.g. prostate volume > 40 mL).	1b	A

5.2.7.2 α 1-blockers + muscarinic receptor antagonists

Mechanism of action: Combination treatment consists of an α 1-blocker together with an antimuscarinic aiming to antagonise both α 1-adrenoceptors and muscarinic receptors. The possible combinations have not all been tested in clinical trials yet.

Efficacy: Several RCTs and prospective studies investigated combination therapy, lasting four to twelve weeks, either as an initial treatment in men with OAB and presumed BPO or as a sequential treatment for storage symptoms persisting while on an α 1-blocker [179, 180, 224, 227-233] (online supplementary Table S.22). One trial used the α 1-blocker naftopidil (not registered in most European countries) with and without antimuscarinics [234]. A high proportion of men with voiding and storage LUTS need to add anticholinergics after α 1-blocker monotherapy, particularly those with longer duration of symptoms at presentation, and men with storage symptoms and a small prostate volume [235].

Combination treatment is more efficacious in reducing urgency, UUI, voiding frequency, nocturia, or IPSS compared with α 1-blockers or placebo alone, and improves QoL [179, 236]. Symptom improvement is higher regardless of PSA concentration, whereas tolterodine alone improved symptoms mainly in men with a serum PSA of < 1.3 ng/mL [182].

Persistent LUTS during α 1-blocker treatment can be reduced by the additional use of an antimuscarinic, [180, 224, 227, 233, 237, 238]. Two systematic reviews of the efficacy and safety of antimuscarinics in men suggested that combination treatment provides significant benefit [239, 240]. Effectiveness of therapy is evident primarily in those men with moderate-to-severe storage LUTS [241]. Long term use of combination therapy has been reported in patients receiving treatment for up to a year, showing symptomatic response is maintained, with a low incidence of AUR [242]. In men with moderate-to-severe storage symptoms, voiding symptoms and PVR < 150 mL, the reduction in symptoms using combination therapy is associated with patient-relevant improvements in health related quality of life (HRQoL) compared with placebo and α 1-blocker monotherapy [243].

Tolerability and safety: Adverse events of both drug classes are seen with combined treatment using α 1-blockers and antimuscarinics. The most common side-effect is xerostomia. Some side-effects (e.g. xerostomia or ejaculation failure) may show increased incidence which cannot simply be explained by summing the incidence with the drugs used separately. Increased PVR may be seen, but is usually not clinically significant, and risk of AUR is low [239, 240]. Antimuscarinics do not cause evident deterioration in maximum flow rate used in conjunction with an α 1-blocker in men with OAB symptoms [236, 244].

A recent RCT investigated safety in terms of maximum detrusor pressure and Q_{max} for solifenacin (6 mg or 9 mg) with tamsulosin in men with LUTS and BOO compared with placebo [245]. The combination therapy was not inferior to placebo for the primary urodynamic variables; Q_{max} was increased versus placebo [245].

Practical considerations: Class effects are likely to underlie efficacy and QoL using an α 1-blocker and antimuscarinic. Trials used mainly storage symptom endpoints, were of short duration, and included only men with low PVR volumes at baseline. Therefore, measuring PVR is recommended during combination treatment.

Recommendations	LE	GR
Use combination treatment of an α 1-blocker with a muscarinic receptor antagonist in patients with moderate-to-severe LUTS if relief of storage symptoms has been insufficient with monotherapy with either drug.	1b	B
Prescribe combination treatment with caution in men with a post-void residual volume > 150 mL.	2b	B

5.3 Surgical treatment

5.3.1 **Transurethral resection of the prostate and transurethral incision of the prostate**

Mechanism of action: Transurethral resection of the prostate removes tissue from the transition zone of the gland. Transurethral incision of the prostate (TUIP) involves incising the bladder outlet without tissue removal. This technique may replace TURP in selected cases, especially in prostate sizes < 30 mL without a middle lobe.

Efficacy: In a recent analysis of 20 contemporary RCTs with a maximum follow-up of five years, TURP resulted in a substantial mean Q_{max} improvement (+162%), a significant reduction in IPSS (-70%), QoL score (-69%), and PVR (-77%) [246]. TURP delivers durable outcomes as shown by studies with a follow-up of 8-22 years. There are no similar data on durability for any other surgical treatment for BPO [247]. One study with a mean follow-up of thirteen years reported a significant and sustained decrease in most symptoms and improvement in urodynamic parameters. Failures were associated with DUA rather than re-development of BPO [92].

Online supplementary Table S.24 presents RCTs comparing TUIP with TURP [248-255]. A meta-analysis of short- and long-term data from ten RCTs found similar LUTS improvements and lower but insignificant improvements in Q_{max} for TUIP [250]. In this meta-analysis, an upper limit of prostate size was reported as an entry criterion for eight studies with five < 30 mL and three < 60 mL.

A second prostatic operation, usually re-TURP, has been reported at a constant annual rate of approximately 1-2%. A review analysing 29 RCTs found a retreatment rate of 2.6% after a mean follow-up of sixteen months [256]. In a large-scale study of 20,671 men, the overall retreatment rates (re-TURP, urethrotomy and bladder neck incision) were 5.8%, 12.3%, and 14.7%, at one, five, and eight years follow-up, respectively, and the respective incidence of re-TURP was 2.9%, 5.8% and 7.4% [257]. A meta-analysis of six trials showed that re-operation was more common after TUIP (18.4%) than after TURP (7.2%) [250].

Tolerability and safety: Peri-operative mortality and morbidity have decreased over time, but the latter remains considerable (0.1% and 11.1%, respectively) [258]. The possibility of increased long-term mortality compared to open surgery [259] has not been verified [260-262]. Data from 20,671 TURPs and 2,452 open prostatectomies (OP) showed that short- and long-term procedural mortality was similar (0.7% vs. 0.9% at 90 days, 2.8% vs. 2.7% at one year, 12.7% vs. 11.8% at five years, 20% vs. 20.9% at eight years) and that the eight year myocardial infarction rates were identical (4.8% vs. 4.9%) [257].

The risk of TUR-syndrome decreased to < 1.1% [256, 263]. No case has been recorded after TUIP. Data from 10,654 TURPs reported bleeding requiring transfusion in 2.9% [258]. The risk after TUIP is negligible. Similar results for TURP complications were reported by an analysis of contemporary RCTs using TURP as a comparator: bleeding requiring transfusion 2% (0-9%), TUR-syndrome 0.8% (0-5%), AUR 4.5% (0-13.3%), clot retention 4.9% (0-39%), and UTI 4.1% (0-22%) [246]. Long-term complications comprise urinary incontinence (1.8% after TUIP vs. 2.2% after TURP), urinary retention and UTIs, bladder neck contracture (BNC) (4.7% after TURP), urethral stricture (3.8% after TURP vs. 4.1% after TUIP), retrograde ejaculation (65.4% after TURP vs. 18.2% after TUIP), and ED (6.5% after TURP) [256].

Practical considerations: TURP and TUIP are effective treatments for moderate-to-severe LUTS secondary to BPO. The choice should be based primarily on prostate volume (< 30 mL and 30-80 mL suitable for TUIP and TURP, respectively). No studies on the optimal cut-off value exist but the complication rates increase with prostate size [258]. The upper limit for TURP is suggested as 80 mL (based on Panel expert opinion, under the assumption that this limit depends on the surgeon's experience, resection speed, and choice of resectoscope size).

5.3.1.1 Modifications of TURP: bipolar TURP

Mechanism of action: Bipolar TURP (B-TURP) addresses a major limitation of monopolar TURP (M-TURP) by allowing performance in normal saline. Contrary to M-TURP, in B-TURP systems, the energy does not travel through the body to reach a skin pad. Bipolar circuitry is completed locally; energy is confined between an active (resection loop) and a passive pole situated on the resectoscope tip ("true" bipolar systems) or the sheath ("quasi" bipolar systems). Prostatic tissue removal is identical to M-TURP; however, B-TURP requires less energy/voltage because there is a smaller amount of interpolated tissue. Energy from the loop is transmitted to the saline solution, resulting in excitation of sodium ions to form plasma; molecules are then easily cleaved under relatively low voltage enabling resection. During coagulation, heat dissipates within vessel walls, creating a sealing coagulum and collagen shrinkage. The various bipolar devices available differ in the way in which current flow is delivered [264, 265].

Efficacy: Bipolar TURP is the most widely and thoroughly investigated alternative to M-TURP. Results from > 40 RCTs [266] have been reported, of which around half have been pooled in RCT-based meta-analyses [246, 267-270]. Early pooled results concluded that no clinically relevant differences exist in short-term (up to twelve months) efficacy (IPSS, QoL score and Q_{max}) [268]. Subsequent meta-analyses supported these conclusions [246, 267, 269, 270], though trial quality was generally poor. Data from RCTs with a follow-up of 12-60 months show no differences in efficacy parameters (online supplementary Table S.25) [271-277].

A meta-analysis has been recently conducted to specifically evaluate the quasi-bipolar Transurethral Resection in Saline (TURis, Olympus Medical) system vs. M-TURP, (<http://www.nice.org.uk/guidance/mtg23/>

[resources/the-turis-system-for-transurethral-resection-of-the-prostate-64371933166021](http://www.nice.org.uk/guidance/mtg23/resources/the-turis-system-for-transurethral-resection-of-the-prostate-64371933166021)). Ten unique RCTs (1,870 patients) were included. It was concluded that TURis was of equivalent efficacy to M-TURP.

Tolerability and safety: Early pooled results concluded that no differences exist in short-term (up to twelve months) urethral stricture/BNC rates, but B-TURP is preferable due to a more favourable peri-operative safety profile (elimination of TUR-syndrome; lower clot retention/blood transfusion rates; shorter irrigation, catheterisation, and possibly hospitalisation times) [268]. Subsequent meta-analyses supported these conclusions [246, 267, 269, 270]. However, trial quality was relatively poor and limited follow-up might cause under-reporting of late complications, such as urethral stricture/BNC [268]. Data from individual RCTs with a follow-up of 12-60 months showed no differences in urethral stricture/BNC rates [270] (online supplementary Table S.25). However, in a recent RCT, a significantly higher stricture (urethral stricture + BNC) rate was detected for the first time in the B-TURP arm [278]. In this trial, 136 patients were randomised 1:1 to B-TURP (TURis) or M-TURP arm and followed up for 36 months. The primary endpoint was safety, including long-term complications such as strictures (urethral stricture + BNC). A significant difference in stricture rates favouring M-TURP was detected (6.6% vs. 19.0%). When patients were stratified according to prostate volume, no difference was detected in stricture rates between the arms in those with a prostate volume of up to 70 mL (TURis 3/40 [7.5%] vs. M-TURP: 3/39 [7.7%]; $P = 1.00$). However, in patients with prostate volume > 70 mL, a significantly higher stricture rate was seen in those submitted to TURis (9/23 [39.1%] vs. 1/22 [4.6%]; $P = 0.01$). Furthermore, in another RCT, a significantly higher BNC (but not urethral stricture) rate was detected for the first time in the B-TURP arm [279]. In this trial 137 patients were randomised 1:1 to B-TURP (performed with a “true” bipolar system [Gyrus PK SuperPulse, Olympus Medical]) or M-TURP arm and followed up to twelve months [279]. A significant difference in BNC rates favouring M-TURP was detected (0.0% vs. 8.5%; $P=0.02$), reinforcing a previously expressed potential association of BNC formation with the extremely focused electrical activity of a “true” bipolar system at the prostate level and thus, in close proximity to the bladder neck [276].

A RCT using the erectile function domain of the IIEF (IIEF-ED) showed that M-TURP and B-TURP have a similar effect on erectile function [280]. A comparative evaluation of the effects on overall sexual function, quantified with IIEF-15, showed no differences between B-TURP and M-TURP at twelve months follow-up (erection, orgasmic function, sexual desire, intercourse satisfaction, overall satisfaction) [281].

A meta-analysis (<http://www.nice.org.uk/guidance/mtg23/resources/the-turis-system-for-transurethral-resection-of-the-prostate-64371933166021>) has shown that TURis reduces the risk of TUR-syndrome and the need for blood transfusion compared to M-TURP. It is plausible that TURis reduces length of hospital stay and re-admissions after surgery, although the evidence on these outcomes is limited.

Practical considerations: B-TURP offers an attractive alternative to M-TURP in patients with moderate-to-severe LUTS secondary to BPO, with similar efficacy but lower peri-operative morbidity [268]. The duration of improvements with B-TURP were documented in a number of RCTs with a follow-up of greater than twelve months. Mid-term results (up to five years) for B-TURP showed that safety and efficacy are comparable to M-TURP. The choice of B-TURP should be based on equipment availability, surgeon’s experience, and patient’s preference.

Recommendations	LE	GR
Offer transurethral incision of the prostate to surgically treat moderate-to-severe LUTS in men with prostate size < 30 mL, without a middle lobe.	1a	A
Offer bipolar- or monopolar- transurethral resection of the prostate to surgically treat moderate-to-severe LUTS in men with prostate size of 30-80 mL.	1a	A

5.3.2 Open prostatectomy

Mechanism of action: Open prostatectomy is the oldest surgical treatment for moderate-to-severe LUTS secondary to BPO. Obstructive adenomas are enucleated using the index finger, approaching from within the bladder (Freyer procedure) or through the anterior prostatic capsule (Millin procedure). It is used for substantially enlarged glands (> 80-100 mL).

Efficacy: A few RCTs showed that holmium laser enucleation of the prostate (HoLEP), photoselective vaporisation of the prostate (PVP) and more recently, enucleation of the prostate using bipolar circuitry lead to similar outcomes compared to OP in men with large glands at a significantly lower complication rate [282-289]. Open prostatectomy reduces LUTS by 63-86% (12.5-23.3 IPSS points), improves QoL score by 60-87%, increases mean Q_{max} by 375% (+16.5-20.2 mL/s), and reduces PVR by 86-98% [282-284, 290, 291]. Efficacy is maintained for up to six years [292].

Two RCT-based meta-analysis evaluated the overall efficacy of endoscopic enucleation of the

prostate (EEP) vs. OP for treating patients with large glands [293, 294]. The larger study included RCTs involving 758 patients. Five RCTs compared OP with HoLEP [282, 283, 287] and four RCTs compared OP with EEP using bipolar circuitry [272-274, 278]. Open prostatectomy was performed via a transvesical approach in all RCTs. At 3-, 6-, 12- and 24-month follow-up, there were no significant differences in Q_{max} between EEP and OP. Post-void residual, PSA, IPSS and QoL score also showed no significant difference at 1-, 3-, 6- and 12-months. Furthermore, IIEF also showed no significant difference at 3-, 6- and 12- months. It was concluded that EEP appears to be an effective minimally invasive option for treating large prostates.

Tolerability and safety: Open prostatectomy mortality has decreased significantly during the past two decades (< 0.25%) [291]. The estimated transfusion rate is about 7-14% [282, 290, 291, 293]. Long-term complications include transient urinary incontinence (up to 10%), BNC and urethral stricture (about 6%) [282-284, 293, 295].

Two recent RCT-based meta-analysis evaluated the overall safety of EEP vs. OP for treating patients with large glands [293, 294]. Operation time was significantly longer for EEP, due to a significantly longer operation time needed for HoLEP (no difference was detected between OP and EEP using bipolar circuitry). Catheterisation and hospitalisation time was significantly shorter with EEP whilst IIEF-5 showed no significant difference between OP and EEP at twelve months [283, 286, 294]. Endoscopic enucleation of the prostate was also associated with fewer blood transfusions but there were no significant differences regarding other complications. It was concluded that EEP appears to be a minimally invasive option for treating large prostates.

Practical considerations: Open prostatectomy is the most invasive surgical method but it is an effective and durable procedure for the treatment of LUTS/BPO. Endoscopic enucleation techniques require experience and relevant endoscopic skills. In the absence of an endourological armamentarium including a holmium laser or a bipolar system, OP is the surgical treatment of choice for men with prostates > 80 mL.

Recommendation	LE	GR
Offer endoscopic enucleation of the prostate or open prostatectomy to treat moderate-to-severe LUTS in men with prostate size > 80 mL.	1a	A

5.3.3 Transurethral microwave therapy (TUMT)

Mechanism of action: Microwave thermotherapy works by emitting microwave radiation through an intraurethral antenna that delivers heat into the prostate. Tissue is destroyed (coagulation necrosis) by being heated at temperatures above cytotoxic thresholds (> 45°C). The heat may also cause apoptosis and denervation of α -receptors, thereby decreasing the smooth muscle tone of the prostatic urethra.

Efficacy: A systematic review and meta-analysis assessed therapeutic efficacy in different devices/software, including Prostatron (Prostasoft 2.0 and 2.5) and ProstaLund Feedback (online supplementary Table S.27) [281]. Symptom score after TUMT decreased by 65% in twelve months, compared to 77% after TURP. Transurethral resection of the prostate also achieved greater improvement in Q_{max} (119% vs. 70%) [296].

In one pooled analysis of three studies (two RCTs and one cohort study), with a twelve month follow-up, responder rate was 85.3% for ProstaLund Feedback TUMT (PLFT) and 85.9% for TURP [297]. The IPSS showed a subjective, non-inferior improvement with PLFT [297]. However, although both PLFT and TURP improved Q_{max} significantly, PLFT was inferior.

Previously, urinary retention was considered a contraindication for TUMT. Nowadays, LE:2b studies have reported a 77-93% short-term success rate for TUMT, defined as the percentage of patients who regained their ability to void spontaneously [298-301]. In one study with longer follow-up, cumulative retreatment risk at five years was estimated to be 42% for those without retention and 59% for those with retention at the baseline [302].

An RCT-based systematic review [296] (though the trials had different follow-up periods) found that TUMT patients (7.54/100 person-years) were more likely than TURP patients (1.05/100 person-years) to require retreatment for symptoms.

In a multicentre RCT with a five year follow-up, no significant differences were found in Q_{max} and IPSS between TUMT (PLFT; the Core-Therm device) and TURP. Additional treatment was needed in 10% after TUMT and in 4.3% after TURP. However, one must be cautious when interpreting these data because there was substantial loss to follow-up; less than half of the patients were analysed at four to five years. In addition, patients who remained in the study were likely to represent the best data (responders).

Tolerability and safety: Treatment is well tolerated, although most patients experience perineal discomfort and urinary urgency, and require pain medication for therapy. Pooled morbidity data comparing TUMT and TURP have been published [296, 297, 303]. In the Cochrane review of RCTs, catheterisation time, dysuria/urgency

and urinary retention rates were significantly smaller with TURP. On the other hand, hospitalisation time, haematuria, clot retention, transfusion, TUR-syndrome, sexual dysfunction and retreatment rates for urethral stricture/BNC were significantly smaller for TUMT [296].

Practical considerations: Endoscopy prior to TUMT is essential to identify the presence of a prostate middle lobe or an insufficient length of the prostatic urethra. Due to the low peri- and post-operative morbidity and lack of need for anaesthesia, TUMT is a true outpatient procedure and an option for (elderly) patients with comorbidities or greater anaesthesia risks [304].

Recommendations	LE	GR
Transurethral microwave therapy achieves symptom improvement comparable with, transurethral resection of the prostate (TURP) but transurethral microwave therapy is associated with decreased morbidity and lower flow improvements.	1a	A
Durability is in favour of TURP which has lower retreatment rates compared to transurethral microwave therapy.	1a	A

5.3.4 **Transurethral needle ablation of the prostate**

Mechanism of action: The transurethral needle ablation (TUNA™) device delivers low-level radiofrequency energy to the prostate via needles inserted transurethrally into the parenchyma under direct vision using an attachment to the standard cystoscope. The energy induces coagulation necrosis in the transition zone resulting in reduction of prostate volume and BPO.

Efficacy: A meta-analysis of two RCTs, two non-randomised comparative and ten single-arm studies showed that TUNA™ achieved a 50% decrease in IPSS and a 70% improvement in Q_{max} at one year [305]. These findings are supported by a more recent meta-analysis of 35 studies (9 comparative, 26 non-comparative) [306]. Transurethral needle ablation of the prostate significantly improved IPSS and Q_{max} , but compared to TURP these improvements were significantly lower at twelve months. Mean differences in TURP vs. TUNA™ were 4.7 for IPSS and 5.9 mL/s for Q_{max} [306].

Clinical studies on the impact of TUNA™ on BPO [307, 308] showed a significant decrease in maximum detrusor pressure or detrusor pressure at Q_{max} . However, one out of six patients were still obstructed at one year [307].

The overall retreatment rate after TUNA™ was 19% based on an analysis of seventeen non-comparative studies (median follow-up unreported; only three out of seventeen studies had follow-up exceeding two years [306]); a rate considerably higher than that seen with TURP.

Tolerability and safety: Transient urinary retention and storage LUTS are common for weeks post-operatively [309, 310]. Generally, TUNA™ is associated with fewer adverse events compared to TURP, including mild haematuria, UTIs, strictures, incontinence, ED, and ejaculation disorders [305].

Practical considerations: Transurethral needle ablation of the prostate can be performed as a day-case procedure under local anaesthesia or sedation [309]. However, TUNA™ is not suitable for prostates > 75 mL or isolated bladder neck obstruction. In addition, TUNA™ cannot effectively treat prostatic middle lobes. There are also concerns about the durability of the effects achieved by TUNA™.

Recommendations	LE	GR
Transurethral needle ablation is a minimally invasive alternative with decreased morbidity compared to transurethral resection of the prostate (TURP) but with less efficacy	1a	A
Durability is in favour of TURP with lower retreatment rates compared to transurethral needle ablation.	1a	A

5.3.5 **Laser treatments of the prostate**

5.3.5.1 *Holmium laser enucleation and holmium laser resection of the prostate*

Mechanism of action: The holmium:yttrium-aluminium garnet (Ho:YAG) laser (wavelength 2,140 nm) is a pulsed solid-state laser that is absorbed by water and water-containing tissues. Tissue coagulation and necrosis are limited to 3-4 mm, which is enough to obtain adequate haemostasis [311]. Holmium laser resection of the prostate (HoLRP) or holmium laser enucleation of the prostate (HoLEP) result in BPO relief and, secondarily, in LUTS reduction.

Efficacy: In a meta-analysis of studies comparing HoLRP with TURP, no difference in symptom improvement could be detected at six or twelve months post-operatively (online supplementary Table S.29) [312]. One RCT comparing TURP with HoLRP with a minimum follow-up of four years showed no difference in urodynamics after 48 months [313]. Three meta-analyses covering trials on HoLEP vs. TURP found that symptom improvement was comparable or superior with HoLEP (online supplementary Table S.29) [314-316]. One RCT comparing photoselective vaporisation of the prostate (PVP) and HoLEP in patients with prostates > 60 mL showed comparable symptom improvement but significantly higher flow rates and lower PVR volume after HoLEP [317]. Another RCT on HoLAP and 80-W PVP showed comparable functional improvement within a median follow-up of 71 months [318].

RCTs indicate that HoLEP is as effective as OP for improving micturition in large prostates [282, 283], with similar re-operation rates after five years (5% vs. 6.7%, respectively) [282]. One RCT comparing HoLEP with TURP in a small number of patients with a seven year follow-up found that the functional long term results of HoLEP were comparable with TURP [319]. A retrospective study of HoLEP with the longest follow-up of up to ten years (mean 62 months) reported durable functional results with low re-operation rates [320].

Tolerability and safety: Dysuria is the most common post-operative complication [311, 314]. Compared to TURP, HoLRP has shorter catheterisation and hospitalisation times [312, 321]. Potency, continence, and major morbidity at 48 months were identical between HoLRP and TURP [313]. Three meta-analyses found that HoLEP has shorter catheterisation time and hospital stay, reduced blood loss, and fewer blood transfusions, but a longer operation time compared with TURP [314-316]. In a meta-analysis, no significant differences were noted between HoLEP and TURP for urethral stricture (2.6% vs. 4.4%), stress urinary incontinence (1.5% vs. 1.5%), and re-intervention (4.3% vs. 8.8%) [300]. HoLEP is superior to OP for blood loss, catheterisation and hospitalisation time [282, 283].

HoLEP has been safely performed in patients using anticoagulant medications [322, 323]. In a study of 83 patients, blood transfusion was required in seven patients (8%) [324]. A retrospective study compared the safety results of HoLEP in 39 patients who were on anticoagulant therapy at the time of their surgery, and 37 controls [323]. No transfusions were required and bleeding complication rates were not significantly different [323]. Short-term studies showed that patients with urinary retention could be treated with HoLEP [325, 326].

The impact on erectile function and retrograde ejaculation is comparable between HoLEP and TURP/OP [283, 327]. Erectile function did not decrease from baseline in either group; three quarters of sexually active patients had retrograde ejaculation after HoLEP.

Practical considerations: Holmium laser operations are surgical procedures that require experience and relevant endoscopic skills. The experience of the surgeon was the most important factor affecting the overall occurrence of complications [322, 328].

5.3.5.2 532 nm ('Greenlight') laser vaporisation of prostate

Mechanism of action: The Kalium-Titanyl-Phosphate (KTP) and the lithium triborate (LBO) lasers work at a wavelength of 532 nm. Laser energy is absorbed by haemoglobin, but not by water. Vaporisation leads to immediate removal of prostatic tissue, relief of BPO, and reduction of LUTS. In 2016 the standard Greenlight procedure was the 180-W-XPS laser, but the majority of evidence is published with the former 80-W (KTP) or 120-W HPS (LBO) laser systems. These three "Greenlight" laser systems differ not only in maximum power output, but more significantly in fibre design and the associated energy tissue interaction of each.

Efficacy: A meta-analysis of the nine available RCTs comparing PVP using the 80-W and 120-W lasers with TURP was performed in 2012 (online supplementary Table S.29) [329]. No differences were found in Q_{\max} and IPSS between 80-W-PVP and TURP, but only three RCTs provided sufficient twelve month data to be included in the meta-analysis [330-332]. With the 180-W (XPS) laser efficacy is comparable to TURP in terms of IPSS, Q_{\max} , PVR volume, prostate volume reduction, PSA decrease and QoL questionnaires. The XPS laser prostatectomy is superior to TURP in terms of catheterisation time, length of hospital stay and time to stable health status.

The longest RCT using the 80-W KTP laser has a follow-up of only twelve months [330]. A case series showed durable functional outcomes with the 80-W KTP laser, with an overall retreatment rate of 8.9% at five years [333]. Another case series of 500 patients treated with the 80-W system with a mean follow-up of 30.6 months reported a retreatment rate of 14.8% [334]. At twelve months self-reported urinary incontinence was 2.9% with XPS and 3.0% with TURP. Surgical re-intervention was comparably low after twelve months for both XPS and TURP.

Significant improvements in voiding parameters at a follow-up of twelve months were demonstrated urodynamically [335]. The longest RCT comparing the 120-W HPS laser with TURP had a follow-up of 36 months and showed a comparable improvement in IPSS, Q_{\max} , and PVR [336]. The re-operation rate was

higher after PVP (11% vs. 1.8%; $p = 0.04$) [336]. Similar improvement of IPSS, QoL, Q_{max} , or urodynamic parameters was reported from two RCTs with a maximum follow-up of 24 months [331, 337].

A multicentre case series of the 180-W laser demonstrated comparable safety and symptom improvement for the 180-W laser and the former Greenlight laser systems [338].

Tolerability and safety: A meta-analysis of the RCTs comparing the 80-W and 120-W lasers with TURP showed a significantly longer operating time but shorter catheterisation time and length of hospital stay after PVP [329]. Blood transfusions and clot retention were less with PVP. No difference was noted in post-operative urinary retention, infection, meatal stenosis, urethral stricture, or bladder neck stenosis [329]. According to the Goliath Study, 180-W Greenlight laser prostatectomy is non-inferior to TURP in terms of peri-operative complications, including post-operative dysuria rate (XPS 19.1%;TURP 21.8%). Post-operative Clavien III re-interventions are more likely within the first 30 days after TURP compared to XPS (3.8% vs. 9.8%; $p = 0.04$), but comparable after twelve months follow-up. There are more severe bleeding complications within 30 days after TURP and more mild bleeding complications after XPS laser prostatectomy over twelve months, leading to a comparable overall incidence between both techniques.

The Greenlight laser appears to be safe in high-risk patients under anticoagulation treatment [339-343]. In one study, anticoagulant patients had significantly higher rates of bladder irrigation (17.2%) compared with those not taking anticoagulants (5.4%) [342]. Safety in patients with urinary retention, or prostates > 80 mL was shown in various prospective non-randomised trials [343-345].

The impact of Greenlight laser on sexual function and abnormal ejaculation was similar to that of TURP after twelve months [346]. In addition, no difference was reported between OP/TURP and Greenlight PVP for erectile function [347, 348], IIEF-5 scores are maintained after treatment. However, in patients with pre-operative IIEF-5 > 19, the post-operative IIEF-5 scores were significantly decreased at 6, 12, and 24 months [349].

Practical considerations: The 180-W XPS laser should be regarded as the reference for Greenlight laser prostatectomy. However, many former studies were done with the out-dated 80-W and 120-W lasers therefore, results need to be interpreted accordingly. Long-term results from the Goliath Study (180-W XPS vs. TURP) are pending. The intermediate two year follow-up data showed efficacy and safety outcomes similar to TURP [350].

5.3.5.3 Diode laser vaporisation of the prostate

Mechanism of action: For prostate surgery, diode lasers with a wavelength of 940, 980, 1,318, and 1,470 nm (depending on the semiconductor used) are marketed for vaporisation and enucleation. Only a few have been evaluated in clinical trials [351].

Efficacy: Case series, and two comparative studies of vaporisation using a 980 nm diode laser or a 120-W HPS laser, are available [352-358]. Quality of life, IPSS, Q_{max} , and PVR improved significantly in all studies compared to baseline and were similar for both laser, at six and twelve months [352, 353].

One RCT with a twelve month follow-up compared the 980 nm diode laser with bipolar enucleation and found equal clinical outcome [359]. One small RCT with a six month follow-up comparing laser enucleation using a 1,318 nm diode laser with B-TURP reported similar efficacy (online supplementary Table S.29) [360]. This data is further supported by one RCT, comparing 980 nm diode laser vaporisation vs. TURP within a two year follow-up [361]. Redo TURP was more frequent in the diode laser group (online supplementary Table S.29) [359].

Tolerability and safety: Published studies on 980 nm laser vaporisation indicate high haemostatic potential, although anticoagulants or platelet aggregation inhibitors were taken in 24% and 52% of patients, respectively [352, 353]. Post-operatively, a high rate of dysuria was reported [352-354, 361]. Fibre modifications led to a significant reduction in surgical time [355]. Furthermore, the literature on diode vaporisation reports high re-operation rates (8-33%) and persisting stress urinary incontinence (9.1%) [352-354, 361]. In contrast, the two RCTs on diode laser enucleation showed that blood loss, hospitalisation and catheterisation time were in favour of diode laser enucleation, with equivalent clinical outcome for either bipolar enucleation [359] or TURP [360] during follow-up.

Practical considerations: Diode laser vaporisation leads to immediate improvement of LUTS due to BPO and provides good haemostatic properties. Diode laser enucleation seems to offer similar efficacy and safety when compared to either TURP or bipolar enucleation. Based on the limited number, mainly low quality RCTs and controversial data on the retreatment rate, results for diode laser vaporisation should be evaluated in further higher quality RCTs.

5.3.5.4 Thulium:yttrium-aluminium-garnet laser (Tm:YAG)

Mechanism of action: In the Tm:YAG laser, a wavelength between 1,940 and 2,013 nm is emitted in continuous wave mode. The laser is primarily used in front-fire applications [351, 362]. Different applications, ranging from vaporisation (ThuVaP), vaporessection (ThuVaRP), and enucleation (ThuVEP/ThuLEP: similar enucleating techniques) are published.

Efficacy: One RCT with a four year follow-up comparing ThuVARP to M-TURP, showed comparable efficacy and favourable re-operation rates in the ThuVaRP group [363] (online supplementary Table S.29). One RCT and one non-RCT compared ThuVaRP with M-TURP [364, 365], while two RCTs comparing ThuVaRP and B-TURP were published recently [366, 367]. In summary, studies show comparable improvement of symptoms and voiding parameters. There are only a few case studies on ThuVEP showing a significant improvement in IPSS, Q_{max} , and PVR after treatment [368-371]. ThuLEP and HoLEP were compared in one RCT with eighteen months follow-up with comparable outcomes in both arms (online supplementary Table S.29) [356]. Furthermore, ThuLEP and bipolar enucleation were compared in one RCT with twelve months follow-up. The outcome showed no difference with regard to efficacy whilst the decrease in hemoglobin level and catheter time were significantly lower for ThuLEP [372].

Tolerability and safety: Thulium laser prostatectomy shows high intra-operative safety in RCTs [363, 364], as well as in case series in patients with large prostates [368] and anticoagulation or bleeding disorders [369, 373]. Catheterisation time, hospital stay, and blood loss were shorter compared to TURP [364-366]. The rate of post-operative urethral strictures after ThuVaRP was 1.9%, the rate of bladder neck contracture was 1.8%, and the re-operation rate was 0-7.1% during follow-up [364, 365, 374]. Urethral stricture after ThuVEP occurred in 1.6%, and the overall retreatment rate was 3.4% (mean follow-up 16.5 months) [375]. No urethral and bladder neck strictures after ThuLEP were reported during the eighteen months follow-up [376]. Recently, a study focused on post-operative complications after ThuVEP (vapoenucleation) reported adverse events in 31% of cases, with 6.6% complications greater than Clavien grade II [377]. One case control study on ThuVEP with 48-month follow-up reported long-term durability of voiding improvements and overall re-operation rates of 2.4% [373]. Two studies (one case control, one RCT vs. TURP) addressed the impact of ThuVEP on sexual function, demonstrating no effect on erectile function with increased prevalence of retrograde ejaculation post-operatively [378, 379].

A prospective multicentre study on ThuVARP, including 2,216 patients, showed durable post-operative improvement in IPSS, QoL, Q_{max} , and PVR for the entire eight years of follow-up. Urethral stricture and bladder neck contracture accounted for 2.6 % and 1.6 % of patients, respectively. Persistent stress incontinence was found in 0.1 % whilst, re-operation due to BPH recurrence was required in 1.2 % patients [380].

In two RCTs on ThuLEP versus TURP, one RCT on ThuLEP versus bipolar enucleation and one RCT on ThuLEP versus HoLEP, ThuLEP appeared to be equivalent with regard to clinical efficacy and superior with regard to intra-operative haemostasis. The same was demonstrated for ThuVEP vs. TURP in one RCT [381].

Practical considerations: The limited number of RCTs and only a few studies with long-term follow-up (up to 48 months) support the efficacy of thulium laser prostatectomy therefore, there is a need for ongoing confirmation.

Recommendations	LE	GR
Holmium laser enucleation and 532-nm laser vaporisation of the prostate are alternatives to transurethral resection of the prostate (TURP) in men with moderate-to-severe LUTS leading to immediate, objective, and subjective improvements comparable with TURP.	1a	A
The short-term and mid-term functional results of 532-nm laser vaporisation of the prostate are comparable with TURP.	1b	A
The long-term functional results of holmium laser enucleation are comparable with TURP or open prostatectomy.	1b	A
Thulium enucleation may be an alternative to TURP and holmium laser enucleation in men with moderate-to-severe LUTS leading to immediate and mid-term objective and subjective improvements.	1b	A
Diode laser operations lead to short-term objective and subjective improvement.	1b	B
Tm:YAG vaporessection is an alternative to TURP for small- and medium-size prostates.	1b	A
With regard to intra-operative safety and haemostatic properties, diode and thulium lasers appear to be safe.	3	C
With regard to intra-operative safety, 532-nm laser vaporisation is superior to TURP.	1b	A
532-nm laser vaporisation should be considered in patients receiving anticoagulant medication or with a high cardiovascular risk.	3	B

5.3.6 Prostatic stents

Mechanism of action: The use of an endoprosthesis to preserve luminal patency is a well-established concept. Prostatic stents were primarily designed as an alternative to an indwelling catheter but have also been assessed as a primary treatment option in patients without significant comorbidities [382, 383].

A prostatic stent requires a functioning detrusor [384]. Permanent stents are biocompatible, allowing for epithelialisation. Temporary stents do not epithelialise and may be either biostable or biodegradable. Temporary stents can provide short-term relief from BPO in patients temporarily unfit for surgery, or after minimally invasive treatment [384].

Efficacy: Several small case studies on a range of stents of different designs and materials provide low level evidence for their use. Online supplementary Table S.30 describes the most important studies [382, 383, 385-388]. There was a substantial loss to follow-up in all studies. There are no studies comparing stents with sham or other treatment modalities, and only one RCT compared two versions of a prostatic stent for BPO [389].

The main representative of the permanent stents is the UroLume prosthesis. A systematic review identified 20 case series (990 patients), with differing follow-ups [390]. These studies reported relevant symptom improvement and Q_{max} increase [390]. The pooled data from studies with patients who were catheter dependent showed that 84% of patients (148/176) regained the ability to void spontaneously after UroLume treatment [390, 391].

The data on non-epithelialising prostatic stents was summarised in a systematic review on the efficacy of Memokath, a self-expanding metallic prostatic stent [392]. Overall, IPSS was reduced by 11-19 points and Q_{max} increased by 3-11 mL/s [392].

Tolerability and safety: In general, stents are subject to misplacement, migration, and poor tolerability because of exacerbation of LUTS and encrustation [384]. The most immediate and common adverse events include perineal pain or bladder storage symptoms.

Practical considerations: Due to common side effects and a high migration rate, prostatic stents have a limited role in the treatment of moderate-to-severe LUTS. Temporary stents can provide short-term relief from LUTS secondary to BPO in patients temporarily unfit for surgery or after minimally invasive treatment [384].

Recommendation	LE	GR
Offer prostatic stents as an alternative to catheterisation in men unfit for surgery.	3	C

5.3.7 Prostatic urethral lift

Mechanism of action: The prostatic urethral lift (PUL) represents a novel minimally invasive approach under local or general anaesthesia. Encroaching lateral lobes are compressed by small permanent suture-based implants delivered under cystoscopic guidance (Urolift®) resulting in an opening of the prostatic urethra that leaves a continuous anterior channel through the prostatic fossa ranging from the bladder neck to the verumontanum.

Efficacy: The available studies on PUL are presented in online supplementary Table S.31 [393-398]. In general, PUL achieves a significant improvement in IPSS (-39% to -52%), Q_{max} (+32% to +59%) and QoL (-48% to -53%). There is only one RCT comparing PUL with sham [393]. The primary endpoint was met at three months with a 50% reduction in AUA-SI from 22.1 to 11.0 points and remained stable up to twelve months. Change for AUA-SI was 88% greater for the treatment group than sham control. Also Q_{max} increased significantly from 8.1 to 12.4 mL/s relative to baseline at three months and this result could still be confirmed at twelve months. The difference in clinical response for Q_{max} between both groups was of statistical significance. A relevant benefit with regard to PVR was not demonstrated compared to baseline nor relative to sham control.

An RCT of 80 patients, conducted in nine European countries, comparing PUL to TURP was published in 2015. At twelve months, IPSS improvement was -11.4 for PUL and -15.4 for TURP. There was no retrograde ejaculation among PUL patients, while 40% of TURP patients lost the ability to ejaculate. Surgical recovery was measured using a validated instrument and confirmed that recovery from PUL is more rapid and more extensive in the first three to six months [399]. However, TURP resulted in much greater improvements in Q_{max} (+13.7 ± 10.4 mL/s) after twelve months compared to PUL. (4.0 ± 4.8 mL/s).

In a recent meta-analysis of retrospective and prospective trials, pooled estimates showed an overall improvement following PUL, including IPSS (-7.2 to -8.7 points), Q_{max} (3.8 to 4.0 mL/s), and QoL (-2.2 to -2.4 points) [398]. Sexual function was preserved with a small improvement estimated at twelve months.

A multi-centre, randomised and blinded trial of PUL in men with bothersome LUTS due to BPH showed that at three years, average improvements from baseline were significant for total IPSS (41.1%), QoL (48.8%), Q_{max} (53.1%) and individual IPSS symptoms. Symptomatic improvement was independent of prostate size. There were no *de novo*, sustained ejaculatory or erectile dysfunction events and all sexual function assessments showed average stability or improvement after PUL [400].

Tolerability and safety: The most common complications reported post-operatively included haematuria (16-63%), dysuria (25-58%), pelvic pain (5-17.9%), urgency (7.1-10%), transient incontinence (3.6-16%), and UTI (2.9-11%). Most symptoms were mild-to-moderate in severity and resolved within two to four weeks after the procedure.

Prostatic urethral lift seems to have no significant impact on sexual function. Evaluation of sexual function as measured by IIEF-5, Male Sexual Health Questionnaire-Ejaculatory Dysfunction, and Male Sexual Health Questionnaire-Bother in patients undergoing PUL showed that erectile and ejaculatory function were preserved [393-397].

Practical considerations: An obstructed/protruding median lobe cannot be effectively treated, and the effectiveness in large prostate glands has not been shown yet. Long-term studies are needed to evaluate the duration of the effect in comparison to other techniques.

Recommendation	LE	GR
Offer Prostatic urethral lift (Urolift®) to men with LUTS interested in preserving ejaculatory function, with prostates < 70 mL and no middle lobe. Inform patients that long-term effects have not been evaluated.	1a	B

5.3.8 **Novel interventions**

5.3.8.1 *Intra-prostatic injections*

Mechanism of action: Various substances have been injected directly into the prostate in order to improve LUTS, these include Botulinum toxin-A (BoNT-A), NX-1207 and PRX302. The primary mechanism of action of BoNT-A is through the inhibition of neurotransmitter release from cholinergic neurons via cleavage of synaptosome-associated protein 25 (SNAP-25). However, BoNT-A also appears to act at various other levels by modulating the neurotransmissions of sympathetic, parasympathetic and sensory nerve terminals in the prostate, leading to a reduction in growth and apoptosis of the prostate [401]. The detailed mechanisms of action for the injectables NX-1207 and PRX302 are not completely understood, but experimental data associates apoptosis-induced atrophy of the prostate with both drugs [401].

Efficacy: Results from clinical trials have shown only modest clinical benefits, that do not seem to be superior to placebo, for BoNT-A [402, 403] (see online supplementary Table S.32). A recent systematic review and meta-analysis showed no differences in efficacy compared with placebo, and concluded that there is no evidence of clinical benefits in medical practice [404]. With regard to NX-1207 and PRX302, the positive results from Phase II-studies have not been confirmed in Phase III-trials thus far [405, 406].

Safety: Studies including safety assessments have reported only a few mild and self-limiting adverse events for all injectable drugs [401]. Furthermore, a recent systematic review and meta-analysis showed low incident rates of procedure-related adverse events [404].

Practical considerations: Although experimental evidence for compounds such as NX-1207, PRX302 and BoNT-A was promising for their transition to clinical use, randomised, controlled studies of all three of these injectable agents have not been able to reveal any significant clinical benefits.

Recommendation	LE	GR
Do not offer Botulinum toxin injection treatment to patients with male LUTS.	1a	B

5.3.8.2 Minimal invasive simple prostatectomy

Mechanism of action: The term minimal invasive simple prostatectomy (MISP) includes laparoscopic simple prostatectomy (LSP) and robot-assisted simple prostatectomy (RASP). The technique for LSP was first described in 2002 [407], while the first RASP was reported in 2008 [408]. Both LSP and RASP are performed using different personalised techniques, developed based on the transcapsular (Millin) or transvesical (Freyer) techniques of OP. An extraperitoneal approach is mostly used for LSP, while a transperitoneal approach is mostly used for RASP.

Efficacy: A recent systematic review and meta-analysis showed that in 27 observational studies including 764 patients, the mean increase in Q_{max} was 14.3 mL/s (95% CI 13.1-15.6), and the mean improvement in IPSS was 17.2 (95% CI 15.2-19.2). Mean duration of operation was 141 min (95% CI 124-159), and the mean intra-operative blood loss was 284 mL (95% CI 243-325). One hundred and four patients (13.6%) developed a surgical complication. In comparative studies to OP, length of hospital stay (WMD -1.6 days, $p = 0.02$), length of catheter use (WMD -1.3 days, $p = 0.04$) and estimated blood loss (WMD -187 mL, $p = 0.015$) were significantly lower in the MISP group, while the duration of operation was longer than in OP (WMD 37.8 min, $p < 0.0001$). There were no differences in improvements in Q_{max} , IPSS and peri-operative complications between both procedures (see online supplementary Table S.33).

Two recent retrospective series on RASP are now available which were not included in the meta-analysis which confirm these findings [409, 410]. The largest retrospective series reports 1,330 consecutive cases including 487 robotic (36.6%) and 843 laparoscopic (63.4%) simple prostatectomy cases. The authors confirm that both techniques can be safely and effectively done in selected centres [409]. Technical variations also include an intrafascial (IF) approach. Comparing laproscopic, robotic and robotic IF simple prostatectomy, the IF-RSP technique is safe and effective, with results at one year follow-up for continence, IPSS and Sexual Health Inventory for Men scores similar to those for the LSP and RSP techniques [411].

Tolerability and safety: In the largest series, the post-operative complication rate was 10.6% (7.1% for LSP and 16.6% for RASP), most of the complications being of low grade. The most common complications in the RASP series were hematuria requiring irrigation, UTI and AUR; in the LSP series, the most common complications were UTI, ileus and AUR.

Practical considerations: Data on MISP are increasing from selected centres. MISP seems comparable to OP in terms of efficacy and safety, providing similar improvements in Q_{max} and IPSS [412]. However, most studies are of a retrospective nature. High quality studies are needed to compare the efficacy, safety, and hospitalisation times of MISP and both OP and endoscopic methods. Long-term outcomes, learning curve and cost of MISP should also be evaluated.

Evidence Statement	LE
Minimal invasive simple prostatectomy seems to be feasible in men with prostate sizes > 80 mL needing surgical treatment; however, RCTs are needed.	2a

5.4 Patient selection

The choice of treatment depends on the assessed findings of patient evaluation, ability of the treatment to change the findings, treatment preferences of the individual patient, and the expectations to be met in terms of speed of onset, efficacy, side effects, QoL, and disease progression. Online supplementary Table S.34 provides differential information about speed of onset and influence on basic parameters of conservative, medical or surgical treatment options.

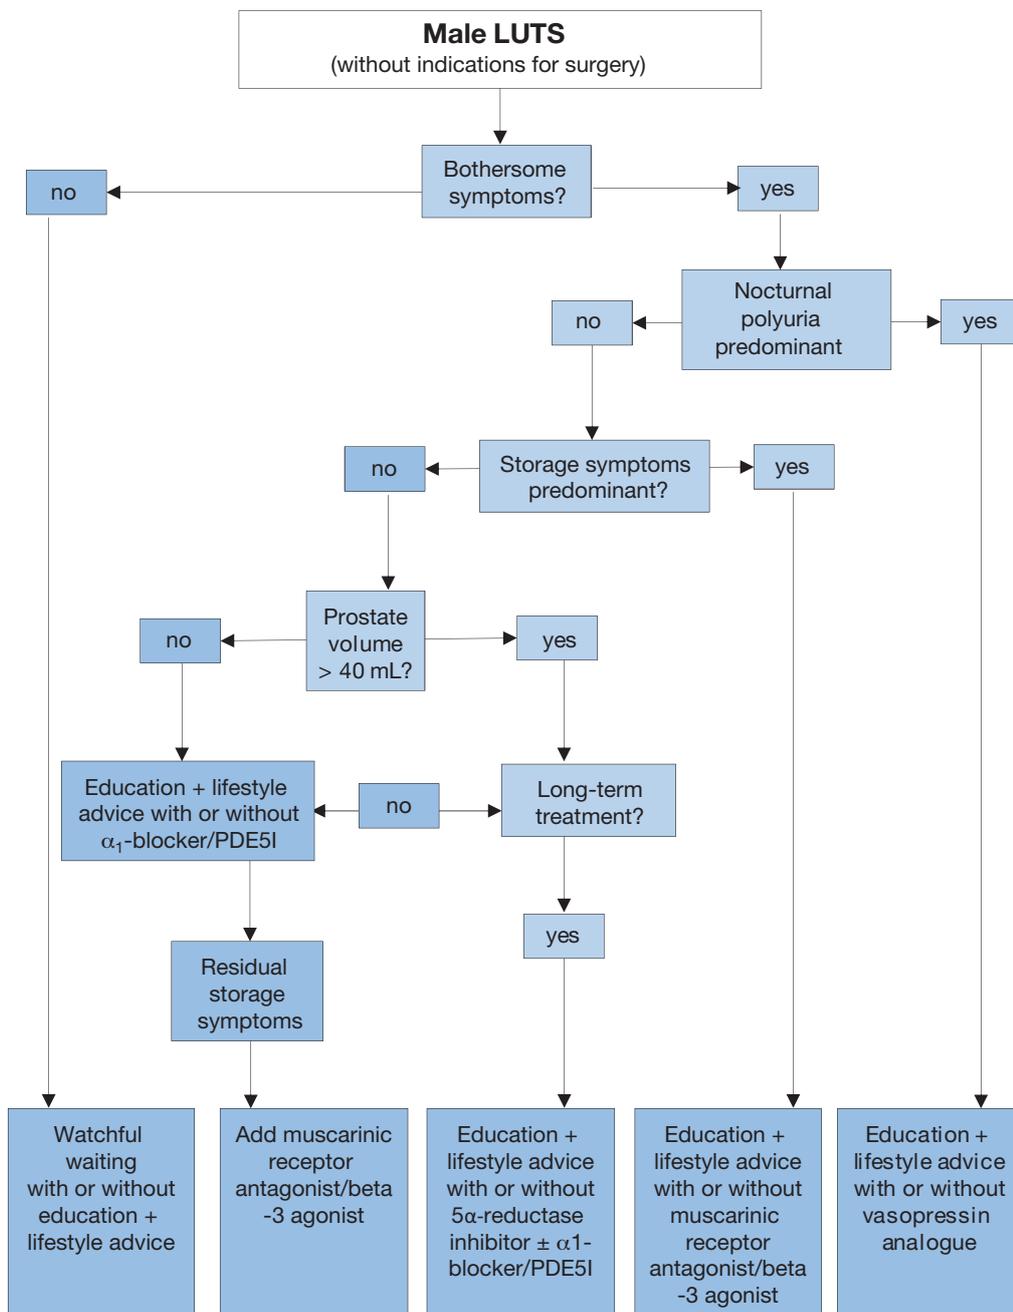

Behavioural modifications, with or without medical treatments, are usually the first choice of therapy.

Figure 3 provides a flow chart illustrating treatment choice according to evidence-based medicine and patient profiles.

Surgical treatment is usually required when patients have experienced recurrent or refractory urinary retention, overflow incontinence, recurrent UTIs, bladder stones or diverticula, treatment-resistant macroscopic haematuria due to BPH/BPE, or dilatation of the upper urinary tract due to BPO, with or without renal insufficiency (absolute operation indications, need for surgery).

Additionally, surgery is usually needed when patients have not obtained adequate relief from LUTS or PVR using conservative or medical treatments (relative operation indications). The choice of surgical technique depends on prostate size, comorbidities of the patient, ability to have anaesthesia, patients' preferences, willingness to accept surgery-associated specific side-effects, availability of the surgical armamentarium, and experience of the surgeon with these surgical techniques. An algorithm for surgical approaches according to evidence-based medicine and the patient's profile is provided in figure 4.

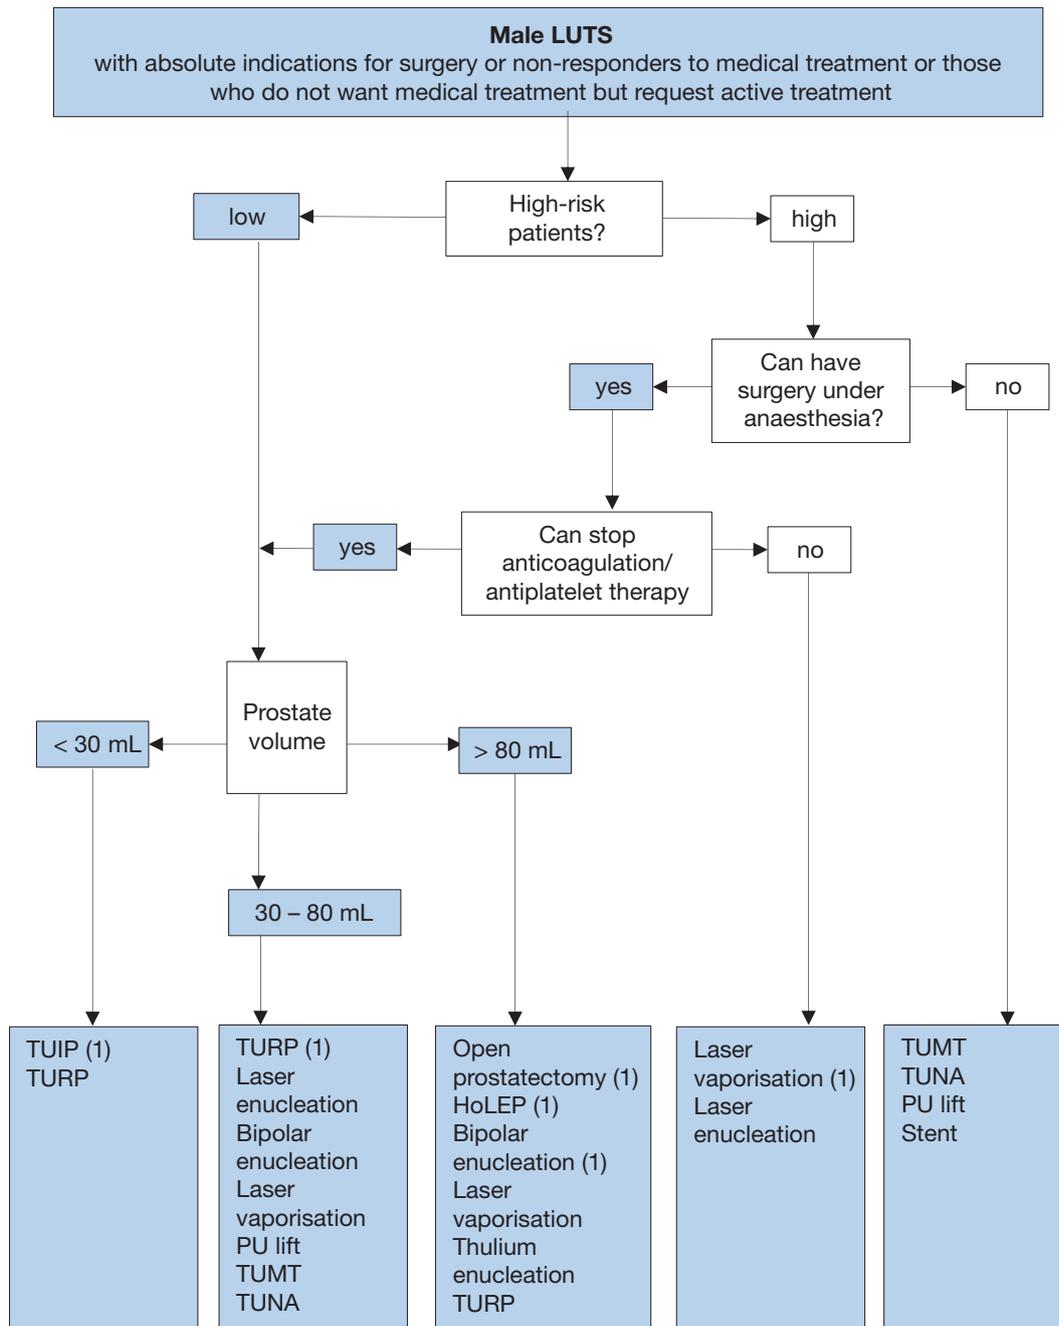

Figure 3: Treatment algorithm of male LUTS using medical and/or conservative treatment options. Treatment decisions depend on results assessed during initial evaluation. Note that patients' preferences may result in different treatment decisions.

LUTS = lower urinary tract symptoms; PDE5I = phosphodiesterase type 5 inhibitors.

Notice: Readers are strongly recommended to read the full text that highlights the current position of each treatment in detail.

Figure 4: Treatment algorithm of bothersome LUTS refractory to conservative/medical treatment or in cases of absolute operation indications. The flowchart was stratified by the patient's ability to have anaesthesia, cardiovascular risk, and prostate size.

(1) Current standard/first choice. The alternative treatments are presented in alphabetical order.
Notice: Readers are strongly recommended to read the full text that highlights the current position of each treatment in detail.

Laser vaporisation includes GreenLight, thulium, and diode lasers vaporisation;

Laser enucleation includes holmium and thulium laser enucleation.

HoLEP = holmium laser enucleation; TUIP = transurethral incision of the prostate; TUMT = transurethral microwave therapy; TUNA = transurethral needle ablation; TURP = transurethral resection of the prostate.

5.5 Management of Nocturia in men with lower urinary tract symptoms

The following section reports a systematic review of therapy for the management of nocturia in men with LUTS. It also emphasises the need to consider the wide range of possible causes of nocturia. This summary

print version is supplemented by a detailed online version (<http://uroweb.org/guideline/treatment-of-non-neurogenic-maleluts/>).

Nocturia is defined as the complaint of waking at night to void [2]. It reflects the relationship between the amount of urine produced while asleep, and the ability of the bladder to store the urine received. Nocturia can occur as part of lower urinary tract dysfunction (LUTD), such as OAB and chronic pelvic pain syndrome. Nocturia can also occur in association with other forms of LUTD, such as BOO, but here it is debated whether the link is one of causation or simply the co-existence of two common conditions. Crucially, nocturia may have behavioural, sleep disturbance (primary or secondary) or systemic causes unrelated to LUTD (Table 1). Differing causes often co-exist and each has to be considered in all cases. Only where LUTD is contributory should nocturia be termed a LUTS.

Table 1: Categories of nocturia

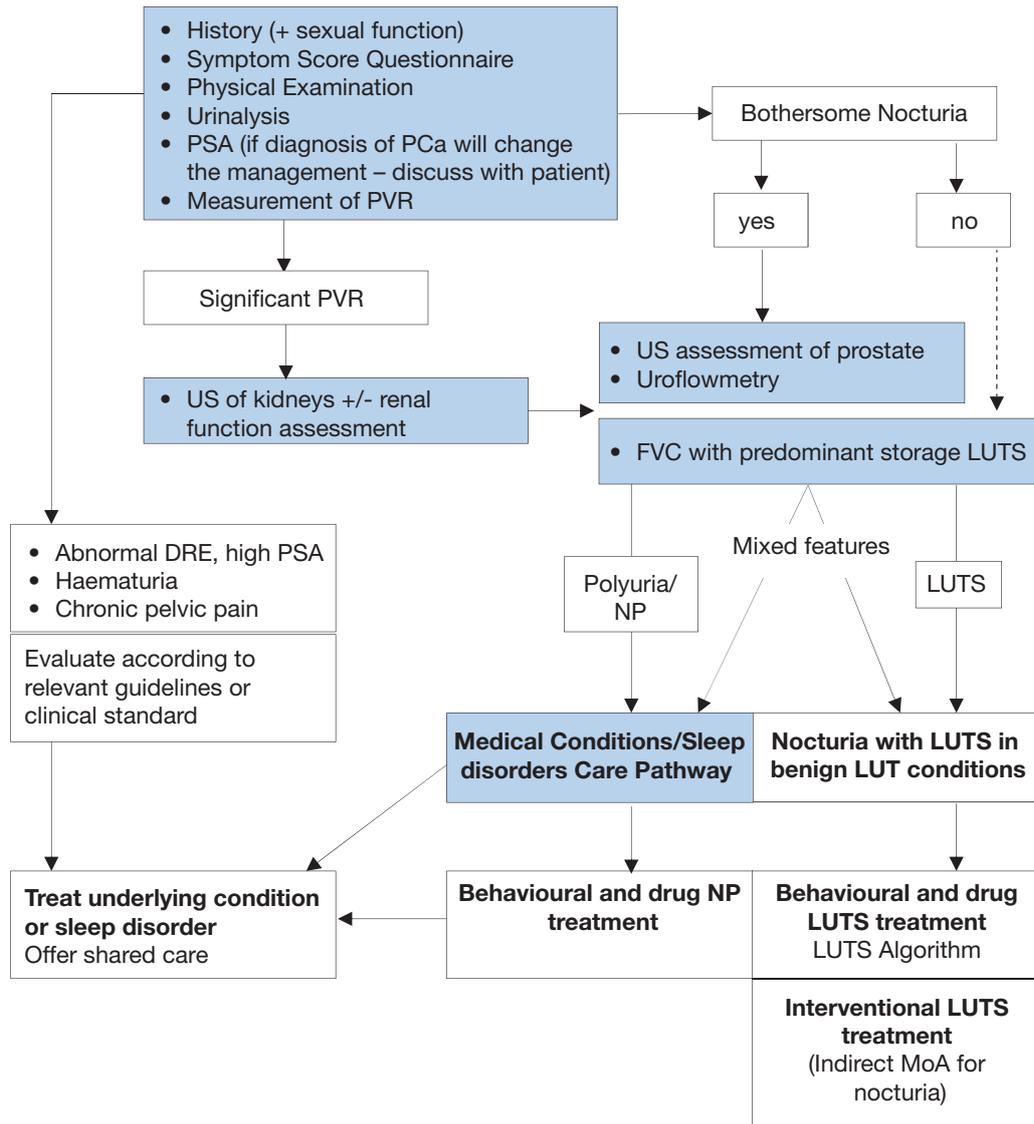

CATEGORY	Disproportionate urine production (at all times, or during sleep)	Low volume of each void (at all times, or overnight)
<i>Behavioural</i>	Inappropriate fluid intake	“Bladder awareness” due to secondary sleep disturbance
<i>Systemic</i>	Water, salt and metabolite output	
<i>Sleep disorder</i>	Variable water and salt output	“Bladder awareness” due to primary sleep disturbance
<i>LUTD</i>		Impaired storage function and increased filling sensation

5.5.1 **Diagnostic assessment**

Evaluation is outlined in Figure 5;

1. Evaluate for LUTD according to the relevant guidelines. The severity and both of individual LUTS should be identified with a symptom score, supplemented by directed questioning if needed. A validated bladder diary is mandatory.
2. Review whether behavioural factors affecting fluid balance and sleep are contributing.
3. Review of medical history and medications, including directed evaluation for key conditions, such as renal failure, diabetes mellitus, cardiac failure, and obstructive sleep apnoea. If systemic factors or sleep disorders are potentially important, consider involving appropriate medical expertise (see Figure 6). This is appropriate where a known condition is sub-optimally managed, or symptoms and signs suggest an undiagnosed condition.

Figure 5. Evaluation of Nocturia in non-neurogenic Male LUTS.

Assessment must establish whether the patient has polyuria, LUTS, sleep disorder or a combination. Therapy may be driven by the bother it causes, but non-bothersome nocturia may warrant assessment of a frequency volume chart (indicated by the dotted line) depending on history and clinical examination since potential presence of a serious underlying medical condition must be considered.

FVC = frequency volume chart; DRE = digital rectal examination; NP = nocturnal polyuria; MoA = mechanism of action; PVR = post-void residual.

5.5.2 Medical conditions and sleep disorders Shared Care Pathway

Causative categories for nocturia comprise [413]:

1. Bladder storage problems;
2. 24-hour (global) polyuria (> 40 mL/kg urine output over a 24-hour period);
3. Nocturnal polyuria (NP; nocturnal output exceeding 20% of 24-hour urine output in the young, or 33% of urine output in people > 65 [2]);
4. Sleep disorders;
5. Mixed aetiology.

Potentially relevant systemic conditions are those which impair physiological fluid balance, including influences on: levels of free water, salt, other solutes and plasma oncotic pressure; endocrine regulation e.g. by antidiuretic hormone (ADH), natriuretic peptides; cardiovascular and autonomic control; renal function; neurological regulation, e.g. circadian regulation of the pineal gland, and renal innervation. As nocturia is commonly referred to the specialty without full insight into cause, the urologist must review the likely mechanisms underlying a presentation with nocturia, and instigate review by relevant specialties accordingly. Thus, the managing urologist needs to evaluate nocturia patients in a context where additional medical

expertise is available (Figure 6). They should not proceed along any LUTD management pathway unless a causative link with LUTD is justifiably suspected, and systemic or sleep abnormalities have been considered.

In patients with non-bothersome nocturia, the medical evaluation (history and physical examination) should consider the possibility of early stages of systemic disease, and whether there is possibility of earlier diagnosis or therapy adjustment.

Some important potentially treatable non-urological causes of nocturia include; obstructive sleep apnoea (OSA), congestive cardiac failure, poorly controlled diabetes mellitus and medications (e.g. diuretics, or lithium).

Figure 6: Shared care pathway for nocturia, highlighting the need to manage potentially complex patients using relevant expertise for the causative factors.

5.5.3 Treatment for Nocturia

5.5.3.1 Antidiuretic therapy

The antidiuretic hormone arginine vasopressin (AVP) plays a key role in body water homeostasis and control of urine production by binding to V2 receptors in the renal collecting ducts. Arginine vasopressin increases water re-absorption and urinary osmolality, so decreasing water excretion and total urine volume. Arginine vasopressin also has V1 receptor mediated vasoconstrictive/hypertensive effects and a very short serum half-life, which makes the hormone unsuitable for treating nocturia/nocturnal polyuria.

Desmopressin is a synthetic analogue of AVP with high V2 receptor affinity and no relevant V1 receptor affinity. It has been investigated for treating nocturia [414], with specific doses, titrated dosing, differing formulations, and options for route of administration. Antidiuretic therapy using desmopressin, with dose titration to achieve clinical response, is more effective than placebo in terms of reduced nocturnal voiding frequency and other outcome measures. Three studies evaluating titrated-dose desmopressin in which men were included, reported seven serious adverse events in 530 patients, with one death. There were seventeen cases of hyponatraemia and seven of hypertension. Headache was reported in 53 and nausea in fifteen.

Practical considerations

Desmopressin is taken once daily before sleeping. Because the optimal dose differs between patients, desmopressin treatment should be initiated at a low dose (0.1 mg/day) and may be gradually increased up to a dosage of 0.4 mg/day every week until maximum efficacy is reached. Patients should avoid drinking fluids at least one hour before and for eight hours after dosing. In men aged 65 years or older, desmopressin should not be used if the serum sodium concentration is below normal: all patients should be monitored for hyponatremia. Men with nocturia should be advised regarding off-label use.

5.5.3.2 Medications to treat LUTD

Where LUTD is diagnosed and considered causative of nocturia, relevant medications for storage (and voiding) LUTS may be considered. However, effect size of these medications is generally small, or not significantly different from placebo when used to treat nocturia. Applicable medications include; selective α 1-adrenergic antagonists [415], antimuscarinics [416-418], 5 α -reductase inhibitors [419] and PDE5Is [420].

5.5.3.3 Other medications

Diuretics, agents to promote sleep [421], diuretics [422], non-steroidal anti-inflammatory agents (NSAIDs) [423] and phytotherapy [424]. Effect size of these medications in nocturia is generally small, or not significantly different from placebo. Larger responses have been reported for some medications, but larger scale confirmatory RCTs are lacking. Agents to promote sleep do not appear to reduce nocturnal voiding frequency, but may help patients return to sleep.

Recommendations	LE	GR
Treatment should aim to address underlying causative factors, which may be behavioural, systemic condition(s), sleep disorders, lower urinary tract dysfunction, or a combination of factors.	4	A*
Discuss lifestyle changes to reduce nocturnal urine volume and episodes of nocturia, and improve sleep quality.	3	A*
Desmopressin may be prescribed to decrease nocturia due to nocturnal polyuria in men under the age of 65. Screening for hyponatremia must be undertaken at baseline, during dose titration and during treatment.	1a	A
α 1-adrenergic antagonists may be offered to men with nocturia associated with LUTS.	1b	B
Antimuscarinic drugs may be offered to men with nocturia associated with overactive bladder.	1b	B
5 α -reductase inhibitors may be offered to men with nocturia who have moderate-to-severe LUTS and an enlarged prostate (> 40 mL).	1b	C
Do not offer phosphodiesterase type 5 inhibitors for the treatment of nocturia.	1b	B
A trial of timed diuretic therapy may be offered to men with nocturia due to nocturnal polyuria. Screening for hyponatremia should be undertaken at baseline and during treatment.	1b	C
Agents to promote sleep may be used to aid return to sleep in men with nocturia.	2	C

*Upgraded based on Panel consensus.

6. FOLLOW-UP

6.1 Watchful waiting (behavioural)

Patients who elect to pursue a WW policy should be reviewed at six months and then annually, provided there is no deterioration of symptoms or development of absolute indications for surgical treatment. The following are recommended at follow-up visits: history, IPSS, uroflowmetry, and PVR volume.

6.2 Medical treatment

Patients receiving α 1-blockers, muscarinic receptor antagonists, beta-3 agonists, PDE5Is or the combination of α 1-blockers and 5-ARIs or muscarinic receptor antagonists should be reviewed four to six weeks after drug initiation to determine the treatment response. If patients gain symptomatic relief in the absence of troublesome adverse events, drug therapy may be continued. Patients should be reviewed at six months and then annually, provided there is no deterioration of symptoms or development of absolute indications for surgical treatment. The following are recommended at follow-up visits: history, IPSS, uroflowmetry, and PVR volume. FVC or bladder diaries should be used to assess response to treatment for predominant storage symptoms or nocturnal polyuria.

Patients receiving 5-ARIs should be reviewed after twelve weeks and six months to determine their response and adverse events. The following are recommended at follow-up visits: history, IPSS, uroflowmetry and PVR volume.

Men taking 5-ARIs should be followed up regularly using serial PSA testing if life expectancy is greater than ten years and if a diagnosis of PCa could alter management. A new baseline PSA should be determined at six months, and any confirmed increase in PSA while on 5-ARIs should be evaluated.

In patients receiving desmopressin, serum sodium concentration should be measured at day three and seven as well as after one month, and if serum sodium concentration has remained normal, every three

months subsequently. The following tests are recommended at follow-up visits: serum-sodium concentration and frequency volume chart. The follow-up sequence should be restarted after dose escalation.

6.3 Surgical treatment

Patients after prostate surgery should be reviewed four to six weeks after catheter removal to evaluate treatment response and adverse events. If patients have symptomatic relief and are without adverse events, no further re-assessment is necessary.

The following tests are recommended at follow-up visit after four to six weeks: IPSS, uroflowmetry and PVR volume.

Recommendation	LE	GR
Follow-up for all conservative, medical, or operative treatment modalities is based on empirical data or theoretical considerations, but not on evidence-based studies.	3-4	C

8. CONFLICT OF INTEREST

All members of the EAU Non-neurogenic Male LUTS Guidelines Panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is publically accessible through the EAU website: <http://www.uroweb.org/guidelines/>. These Guidelines were developed with the financial support of the EAU. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

6.		CONFLICT OF INTEREST	91

1. INTRODUCTION

Urinary incontinence (UI) is an extremely common complaint in every part of the world. It causes a great deal of distress and embarrassment, as well as significant costs, to both individuals and societies. Estimates of prevalence vary according to the definition of incontinence and the population studied. However, there is universal agreement about the importance of the problem in terms of human suffering and economic cost.

1.1 Aim and objectives

These Guidelines from the European Association of Urology (EAU) Working Panel on Urinary Incontinence are written by a multidisciplinary group, primarily for urologists, and are likely to be referred to by other professional groups. They aim to provide sensible and practical evidence-based guidance on the clinical problem of UI rather than an exhaustive narrative review. Such a review is already available from the International Consultation on Incontinence [1], and so the EAU Guidelines do not describe the causation, basic science, epidemiology and psychology of UI. The focus of these Guidelines is entirely on assessment and treatment reflecting clinical practice. The Guidelines also do not consider patients with UI caused by neurological disease, or in children, as this is covered by complementary EAU Guidelines [2, 3].

The elderly

The Panel decided to include a separate but complimentary set of recommendations referring to the elderly population within each section. Older people with UI deserve special consideration for a number of reasons. Physiological changes with natural ageing mean that all types of UI become more common with increasing age. Urinary incontinence commonly co-exists with other comorbid conditions, reduced mobility, and impaired cognition and may require specific interventions, such as assisted toileting.

For the elderly person expectations of assessment and treatment may need to be modified to fit in with specific circumstances, needs, and preferences, while also taking into account any loss of capacity for consent. When the urologist is dealing with a frail elderly patient with urinary incontinence, collaboration with other healthcare professionals such as elderly care physicians is recommended.

It must be emphasised that clinical guidelines present the best evidence available to the experts. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Urinary Incontinence Panel consists of a multidisciplinary group of experts, including urologists, a gynaecologist and a physiotherapist. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: <http://www.uroweb.org/guideline/urinary-incontinence>.

1.3 Available publications

A quick reference document (Pocket Guidelines) is available, both in print and in a number of versions for mobile devices. These are abridged versions which may require consultation together with the full text versions. Two scientific publications in the journal *European Urology* are also available [4, 5]. All documents are accessible through the EAU website: <http://www.uroweb.org/guideline/urinary-incontinence>.

1.4 Publication history

The EAU published the first Urinary Incontinence Guidelines in 2001. This 2017 publication presents a limited update of the 2016 Urinary Incontinence Guidelines.

1.4.1 Summary of changes.

Section 4.2 Pharmacological management has been revised for this 2017 print, including the addition of a new section 4.3.5.1 on Drug therapy.

Changed evidence summaries and recommendations can be found in sections:

4.2.1 *Antimuscarinic drugs*

Summary of evidence	LE
There is limited evidence that one antimuscarinic drug is superior to an alternative antimuscarinic drug for cure or improvement of urgency urinary incontinence.	1b
Higher doses of antimuscarinic drugs are more effective to cure or improve urgency urinary incontinence, but with a higher risk of side effects.	1b
Once daily (extended release) formulations are associated with lower rates of adverse events compared to immediate release ones, although similar discontinuation rates are reported in clinical trials.	1b
Dose escalation of antimuscarinic drugs may be appropriate in selected patients to improve treatment effect although higher rates of adverse events can be expected.	1b
Transdermal oxybutynin (patch) is associated with lower rates of dry mouth than oral antimuscarinic drugs, but has a high rate of withdrawal due to skin reaction.	1b

4.2.3.3 *Recommendations for antimuscarinic drugs*

Recommendations	GR
Offer antimuscarinic drugs for adults with urgency urinary incontinence who failed conservative treatment.	A
Consider extended release formulations in patients who do not tolerate immediate release antimuscarinics.	A
If antimuscarinic treatment proves ineffective, consider dose escalation or offering an alternative treatment.	B
Consider using transdermal oxybutynin if oral antimuscarinic agents cannot be tolerated due to dry mouth.	B
Offer and encourage early review (of efficacy and side effects) of patients on antimuscarinic medication for urgency urinary incontinence.	C

4.2.4 *Antimuscarinic agents: adherence and persistence*

Summary of evidence	LE
Adherence to antimuscarinic treatment is low and decreases over time because of lack of efficacy, adverse events and/or cost.	2
Most patients will stop antimuscarinic agents within the first three months.	2

4.2.5 *Antimuscarinic and beta3 agonist agents, the elderly and cognition*

Summary of evidence	LE
Antimuscarinic drugs are effective in elderly patients.	1b
Mirabegron has been shown to efficacious and safe in elderly patients.	1b
In older people, the cognitive impact of drugs which have anticholinergic effects is cumulative and increases with length of exposure.	2
Oxybutynin may worsen cognitive function in elderly patients.	2
Solifenacin, darifenacin, fesoterodine and trospium have been shown not to cause cognitive dysfunction in elderly people in short-term studies.	1b

4.2.5.2.13 *Additional recommendations for antimuscarinic drugs in the elderly*

Recommendations	GR
In older people being treated for urinary incontinence, every effort should be made to employ nonpharmacological treatments first.	C
Long-term antimuscarinic treatment should be used with caution in elderly patients especially those who are at risk of, or have, cognitive dysfunction.	B*
When prescribing antimuscarinic for urgency urinary incontinence, consider the total antimuscarinic load in older people on multiple drugs.	C
Consider the use of Mirabegron in elderly patients if additional antimuscarinic load is to be avoided.	C

*Recommendation based on expert opinion.

4.2.6 *Mirabegron*

Summary of evidence	LE
Mirabegron is better than placebo and as efficacious as antimuscarinics for improvement of urgency urinary incontinence symptoms.	1a
Adverse event rates with mirabegron are similar to placebo.	1a
Patients inadequately treated with solifenacin 5 mg may benefit more from the addition of mirabegron than dose escalation of solifenacin.	1b

Recommendation	GR
In patients with urgency urinary incontinence and an inadequate response to conservative treatments, offer mirabegron unless they have uncontrolled hypertension.	A

4.2.7 *Drugs for stress urinary incontinence*

Summary of evidence	LE
Duloxetine, 40 mg twice daily improves stress urinary incontinence in women.	1a
Duloxetine causes significant gastrointestinal and central nervous system (CNS) side effects leading to a high rate of treatment discontinuation, although these symptoms are limited to the first weeks of treatment.	1a

Recommendations	GR
Duloxetine can be used with caution to treat women with symptoms of stress urinary incontinence.	A
Duloxetine should be initiated using dose titration because of high adverse event rates.	A

4.2.8 *Oestrogen*

Recommendation	GR
Vaginal oestrogen therapy for vulvovaginal atrophy should be prescribed long-term. In women with a history of breast cancer, the treating oncologist needs to be consulted.	C

4.2.9.2.2 Monitoring for hyponatraemia

Recommendations	GR
Consider offering desmopressin to patients requiring occasional short-term relief from daytime urinary incontinence and inform them that this drug is not licensed for this indication.	A
Monitor plasma sodium levels in patients on desmopressin.	A*

*Recommendation based on expert opinion.

4.2.10 *Drug treatment in mixed urinary incontinence*

Recommendation	GR
Offer antimuscarinic drugs or beta3 agonists to patients with urgency-predominant mixed urinary incontinence.	A*

*Recommendation based on expert opinion.

4.3.5.1 *Drug therapy*

Summary of evidence	LE
Duloxetine, either alone or combined with conservative treatment, can hasten recovery of continence but does not improve continence rate following prostate surgery.	1b

4.3.5.5 Compression devices in males

Recommendation	GR
Consider offering duloxetine to hasten recovery of continence after prostate surgery but inform the patient about the possible adverse events.	B

2. METHODS

2.1 Introduction

For the 2017 Urinary Incontinence Guidelines, the literature has been assessed for Section 4.2 – Pharmacological management. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between January 2012 and April 20th, 2016. A total of 1164 unique records were identified, retrieved and screened for relevance. A detailed search strategy is available online: <https://uroweb.org/guideline/urinary-incontinence/?type=appendices-publications>.

A systematic review was performed assessing nocturia and nocturnal incontinence in both men and women, in collaboration with the EAU Non-Neurogenic Male LUTS Guidelines Panel [6].

Due to the paucity of literature addressing nocturnal incontinence, the Panel did not include new information on this topic. The findings relating to nocturia in males are presented in the Non-Neurogenic Male LUTS Guidelines.

References used in this text are assessed according to their level of evidence (LE) and Guidelines are given a grade of recommendation (GR), according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [7]. Additional methodology information can be found in the general Methodology section of this print, and online at the EAU website: <http://www.uroweb.org/guideline/>. A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.

The current Guidelines provide:

- A clear pathway (algorithm) for common clinical problems. This can provide the basis for thinking through a patient's management and also for planning and designing clinical services.
- A brief but authoritative summary of the current state of evidence on clinical topics, complete with references to the original sources.
- Clear guidance on what to do or not to do, in most clinical circumstances. This should be particularly helpful in those areas of practice for which there is little or no high-quality evidence.

In this edition the Panel has continued to focus, largely, on the management of a 'standard' patient. The Panel has referred in places to patients with 'complicated incontinence', by which we mean patients with associated morbidity, a history of previous pelvic surgery, surgery for UI, radiotherapy and women with associated genitourinary prolapse. An appendix is included on non-obstetric genitourinary fistulae. The subject of prevention of urinary incontinence has not been addressed. A systematic review on nocturnal incontinence found no studies on the topic. The Panel are of the opinion that nocturnal incontinence should be considered in future research studies.

2.2 Review

This document was subjected to peer review prior to publication in 2015. The decision for re-review is made based on the extent of the revision. A major revision resulting in significant changes to the clinical recommendations presented in the text will warrant re-review.

2.3 Terminology

Evidence summaries provide a succinct summary of what the currently available evidence tells us about an individual clinical question. They are presented according to the levels of evidence used by the EAU. Recommendations have been deliberately written as 'action-based' sentences. The following words or phrases are used consistently throughout the Guidelines;

- **Consider** an action. This word is used when there is not enough evidence to say whether the action causes benefit or risk to the patient. However, in the opinion of the Panel, the action may be justified in some circumstances. Action is optional.

- **Offer** an action. This word is used when there is good evidence to suggest that the action is effective, or that, in the opinion of the Panel, it is the best action. Action is advisable.
- **Carry out (perform)** an action. **Do** something. This phrase is used when there is strong evidence that this is the only best action in a certain clinical situation. Action is mandatory.
- **Do not perform** (i.e. avoid) an action. This phrase is used when there is high-level evidence that the action is either ineffective or is harmful to the patient. Action is contraindicated.

Future goals:

- An extended literature search revisiting the topic of female nocturia will be undertaken in collaboration with the Non-neurogenic male LUTS Guidelines Panel.
- An Algorithm for the management of nocturia in both males and females will be presented in the 2018 Urinary Incontinence Guidelines publication.

3. DIAGNOSTIC EVALUATION

3.1 History and physical examination

Taking a careful clinical history is fundamental to the clinical process. Despite the lack of formal evidence, there is universal agreement that taking a history should be the first step in the assessment of anyone with UI. The history should include details of the type, timing and severity of UI, associated voiding and other urinary symptoms. The history should allow UI to be categorised into stress urinary incontinence (SUI), urgency urinary incontinence (UUI) or mixed urinary incontinence (MUI). It should also identify patients who need rapid referral to an appropriate specialist. These include patients with associated pain, haematuria, a history of recurrent urinary tract infection (UTI), pelvic surgery (particularly prostate surgery) or radiotherapy, constant leakage suggesting a fistula, voiding difficulty or suspected neurological disease. In women, an obstetric and gynaecological history may help to understand the underlying cause and identify factors that may impact on treatment decisions. The patient should also be asked about other ill health and for the details of current medications, as these may impact on symptoms of UI.

Similarly, there is little evidence from clinical trials that carrying out a clinical examination improves care, but wide consensus suggests that it remains an essential part of assessment of people with UI. It should include abdominal examination, to detect an enlarged bladder or other abdominal mass, and perineal and digital examination of the rectum (prostate) and/or vagina. Examination of the perineum in women includes an assessment of oestrogen status and a careful assessment of any associated pelvic organ prolapse (POP). A cough test may reveal SUI if the bladder is sufficiently full while pelvic floor contraction together with urethral mobility can be assessed digitally.

3.2 Patient questionnaires

This section includes symptom scores, symptom questionnaires, scales, indexes, patient reported outcome measures (PROMs) and health-related quality of life (HRQoL) measures. The latter include generic or condition specific measures. Questionnaires should have been validated for the language in which they are being used, and, if used for outcome evaluation, must have been shown to be sensitive to change. The US Food and Drug Administration (FDA) published guidance for industry on patient-reported outcome instruments (questionnaires) in 2009 [8].

3.2.1 Questions

- In patients with UI, can the use of Questionnaires/PROMS differentiate between stress, urgency and mixed incontinence, and does this differentiation impact on quality of life (QoL) after treatment?
- In adults with UI, does assessment using either urinary symptom or QoL questionnaires improve treatment outcome for UI?
- In adults with UI, does assessment of the patient perspective (concerns or expectations) improve patient outcomes, regarding either urinary symptoms or QoL, compared to no patient-reported assessment?

3.2.2 Evidence

Although many studies have investigated the validity and reliability of urinary symptom questionnaires and PROMs most of these studies did not include adult patients diagnosed with UI. This limits the extent to which results and conclusions from these studies can be applied in adults with UI. Some questionnaires (QUID, 3IQ) have potential to discriminate UI types in women [9, 10]. In men ICIQ-UI-SF score does not differentiate UI

types [11]. Some questionnaires are responsive to change and may be used to measure outcomes, though evidence on their sensitivity is inconsistent [12-14]. No evidence was found to indicate whether use of QoL or condition specific questionnaires have an impact on outcome of treatment.

Table 1 shows a summary of the ICUD review (2012) with recent additions. Criteria on which questionnaires are assessed include validity, reliability and responsiveness to change.

Table 1: Summary of the ICUD review 2012*.

	Category A (all 3 criteria fulfilled)*	Category B (2 criteria fulfilled)*	Category C (only 1 criterion fulfilled)*
Symptom measures and health-related QOL measures	ICIQ-UI Short Form, ICIQFLUTS, ICIQ-MLUTS IIQ and IIQ-7, I-QOL (ICIQ-Uqol), ISS, KHQ, LIS (?-interview), N-QoL, OAB-q SF, OAB-q (ICIQOABqol), PFDI and PFDI-20, PFIQ and PFIQ-7, PRAFAB, UISS	Contilife, EPIQ, LUTS tool IOQ, YIPS	ABSST ISI, ISQ, UIHI, UIQ
Measure of patient satisfaction (patient's measure of treatment satisfaction)	BSW, OAB-S, OABSAT-q, TBS	PPQ	EPI, GPI, PSQ
Goal attainment scales		SAGA	
Screening tools (used to identify patients with UI)	B-SAQ, OAB-SS, OABV8, OAB-V3, QUID	ISQ, USP 3IQ, CLSS, MESA, PUF	3IQ, CLSS, MESA, PUF
Patient symptom scale			
Assessment of symptom bother and overall bother	PPBC, UDI or UDI-6, LUSQ, PGI-I and PGI-S	PFBQ, SSI and SII	PMSES, POSQ, UI-4
Assessment of the impact of urgency	IUSS, U-IIQ, UU Scale, U-UDI	PPIUS, SUIQ, UPScore, UPScale, UQ, USIQ-QOL, USIQ-S, USS	
Questionnaires to assess sexual function and urinary symptoms		FSFI, ICIQ-VS, PISQ, SQoL-F	SFQ
Treatment adherence Measures		MASRI	

* For all abbreviations please see the Abbreviations list in the Appendix at the end of the full Guidelines.

** Criteria on which questionnaires are assessed include validity, reliability and responsiveness to change.

To date, there is no one questionnaire that fulfils all requirements for assessment of people with UI. Clinicians must evaluate the tools which exist, for use alone or in combination, for assessment and monitoring of treatment outcome [15].

The questionnaires can be found on the following websites: www.iciq.net, www.proqolid.org, www.mapi-institute.com, www.pfizerpatientreportedoutcomes.com, www.ncbi.nlm.nih.gov.

Summary of evidence	LE
Validated condition specific symptom scores assist in the screening for, and categorisation of, urinary incontinence.	3
Validated symptom scores measure the severity of urinary incontinence.	3
Both condition specific and general health status questionnaires measure current health status, and change following treatment.	3

Recommendation	GR
Use a validated and appropriate questionnaire when standardised assessment is required (See Table 1, above).	B*

* Recommendation based on expert opinion.

3.3 Voiding diaries

Measurement of the frequency and severity of LUTS is an important step in the evaluation and management of lower urinary tract (LUT) dysfunction, including UI. Voiding diaries are a semi-objective method of quantifying symptoms, such as frequency of UI episodes. They also quantify urodynamic variables, such as voided volume and 24-hour or nocturnal total urine volume. Voiding diaries are also known as micturition time charts, frequency/volume charts and bladder diaries.

Discrepancy between diary recordings and the patient rating of symptoms, e.g. frequency or UI, can be useful in patient counselling. In addition, voided volume measurement can be used to support diagnoses, such as overactive bladder (OAB) or polyuria. Diaries can also be used to monitor treatment response and are widely used in clinical trials. In patients with severe UI, a voiding diary is unlikely to accurately report 24-hour urine output and so voided volume may be lower than total bladder capacity.

3.3.1 Question

- In adults with UI, what is the reliability, diagnostic accuracy and predictive value of a voiding diary compared to patient history or symptom score?

3.3.2 Evidence

Two articles have suggested a consensus has been reached in the terminology used in voiding [16, 17]. However, the terms micturition diary, frequency voiding chart and voiding diary, have been used interchangeably for many years and include information on fluid intake, times of voiding, voided volumes, incontinence episodes, pad usage, degree of urgency and degree of UI recorded for at least 24 hours. When reviewing the evidence all possible terminology has been included.

Two studies have demonstrated the reproducibility of voiding diaries in both men and women [18, 19]. Further studies have demonstrated variability of diary data within a 24-hour period and compared voided volumes recorded in diaries with those recorded by uroflowmetry [20, 21]. Another study found that keeping a voiding diary had a therapeutic benefit [22].

A number of observational studies have demonstrated a close correlation between data obtained from voiding diaries and standard symptom evaluation [23-26].

Summary of evidence	LE
Voiding diaries of three to seven days duration are a reliable tool for the objective measurement of mean voided volume, day time and night time frequency, and incontinence episode frequency.	2b
Voiding diaries are sensitive to change and are a reliable measure of outcome.	2b

Recommendations	GR
Ask patients with urinary incontinence to complete a voiding diary.	A
Use a diary duration of between three and seven days.	B

3.4 Urinalysis and urinary tract infection

Reagent strip ('dipstick') urinalysis may indicate urinary tract infection (UTI), proteinuria, haematuria or glycosuria requiring further assessment. Refer to the Urological Infections Guidelines for diagnosis and treatment of UTI [27].

3.4.1 Question

- In adults with UI, what is the diagnostic accuracy of urinalysis to detect UTI?
- In adults with UI does treatment of UTI or asymptomatic bacteriuria cure or improve UI compared to no treatment?

3.4.2 Evidence

Urinalysis negative for nitrite and leucocyte esterase reliably excludes UTI in people with UI [28] and should be included, with urine culture when necessary, in the evaluation of all patients with UI. Urinary incontinence may

occur during symptomatic UTI [29] and existing UI may worsen during UTI [30]. The rate and severity of UI was unchanged after eradication of asymptomatic bacteriuria in nursing home residents [31].

Summary of evidence	LE
Urinalysis negative for nitrite and leucocyte esterase reliably excludes urinary tract infection.	1
Urinary incontinence may be a symptom during urinary tract infection.	3
The presence of a symptomatic urinary tract infection worsens symptoms of urinary incontinence.	3
Elderly nursing home patients with urinary incontinence do not benefit from treatment of asymptomatic bacteriuria.	2

Recommendations	GR
Perform urinalysis as a part of the initial assessment of a patient with urinary incontinence.	A*
If a symptomatic urinary tract infection is present with urinary incontinence, reassess the patient after treatment.	A*
Do not routinely treat asymptomatic bacteriuria in elderly patients to improve urinary incontinence.	B

* Recommendation based on expert opinion.

3.5 Post-void residual volume

Post-void residual (PVR) volume is the amount of urine that remains in the bladder after voiding. It indicates poor voiding efficiency, which may result from a number of contributing factors. It is important because it may worsen symptoms and, more rarely, may be associated with UTI, upper urinary tract (UUT) dilatation and renal insufficiency. Both bladder outlet obstruction and detrusor underactivity contribute to the development of PVR. Post-void residual can be measured by catheterisation or ultrasound (US). The prevalence of PVR in patients with UI is uncertain, partly because of the lack of a standard definition of an abnormal PVR volume.

3.5.1 Question

In adults with UI, what is the value of measuring PVR?

3.5.2 Evidence

Most studies investigating PVR have not included patients with UI. Although some studies have included women with UI and men and women with LUTS, they have also included children and adults with neurogenic UI. In general, the data on PVR can be applied with caution to adults with non-neurogenic UI. The results of studies investigating the best method of measuring PVR [32-37] have led to the consensus that US measurement of PVR is preferable to catheterisation.

In peri- and post-menopausal women without significant LUTS or pelvic organ symptoms, 95% of women had a PVR < 100 mL [38]. In women with UUI, a PVR > 100 mL was found in 10% of cases [39]. Other research has found that a high PVR is associated with POP, voiding symptoms and an absence of SUI [38, 40-42].

In women with SUI, the mean PVR was 39 mL measured by catheterisation and 63 mL measured by US, with 16% of women having a PVR > 100 mL [39].

Summary of evidence	LE
Lower urinary tract symptoms coexisting with Urinary incontinence are associated with a higher rate of post-void residual compared to asymptomatic subjects.	2

Recommendations	GR
When measuring post-void residual urine volume, use ultrasound.	A
Measure post-void residual in patients with urinary incontinence who have voiding symptoms.	B
Measure post-void residual when assessing patients with complicated urinary incontinence.	C
Post-void residual should be monitored in patients receiving treatments that may cause or worsen voiding dysfunction, including surgery for stress urinary incontinence.	A*

* Recommendation based on expert opinion.

3.6 Urodynamics

Urodynamic testing is widely used as an adjunct to clinical diagnosis, in the belief that it may help to provide or confirm diagnosis, predict treatment outcome, or facilitate discussion during counselling. For all these reasons, urodynamics is often performed prior to invasive treatment for UI. These Guidelines will focus on invasive tests, including multichannel cystometry, ambulatory monitoring and video-urodynamics, and different tests of urethral function, such as urethral pressure profilometry, Valsalva leak point pressure estimation, and retrograde urethral resistance measurement.

3.6.1 Question

In adults with UI, what is the reproducibility, diagnostic accuracy and predictive value of urodynamic testing?

3.6.2 Evidence

3.6.2.1 Variability

In common with most physiological tests there is variability in urodynamics results. A number of small studies, assessing same-session repeatability of urodynamic testing, present contradictory findings [43, 44]. Measurement of urethral closure pressure (MUCP) correlates poorly with incontinence severity [45] and there is conflicting evidence about its reproducibility [46, 47]. One method of recording MUCP cannot be compared meaningfully to another [48].

Valsalva leak point pressures are not standardised and there is minimal evidence about reproducibility. Valsalva leak point pressure did not reliably assess incontinence severity in a cohort of women selected for surgical treatment of SUI [49]. The predictive value of the tests, regarding the outcome of treatment, remains unclear. No studies on the reproducibility of ambulatory monitoring were found.

3.6.2.2 Diagnostic accuracy

The diagnostic accuracy of urodynamics is assessed in terms of its correlation with clinical diagnosis of UI and incontinence severity. The problem is that clinical diagnosis and urodynamic findings often do not correlate [50, 51], and normal healthy people may have urodynamic abnormalities.

The diagnostic accuracy of urethral pressure profilometry [45] and 'urethral retro-resistance' is generally poor [52]. Urethral reflectometry may have greater diagnostic accuracy but its clinical role remains unclear [53].

Ambulatory urodynamics may detect unexpected physiological variance from normal more often than conventional cystometry, but the clinical relevance of this is uncertain [54, 55].

3.6.2.3 Question

Does urodynamics influence the outcome of conservative therapy?

3.6.2.4 Evidence

A Cochrane review of seven RCTs showed that use of urodynamic tests increased the likelihood of prescribing drugs or avoiding surgery. However, there was no evidence that this influence on decision making altered the clinical outcome of treatment [56]. Subanalysis of an RCT comparing fesoterodine to placebo [57, 58] showed no predictive value for treatment response, by the urodynamic diagnosis of detrusor overactivity (DO).

3.6.2.5 Question

Does urodynamics influence the outcome of surgery for urinary incontinence?

3.6.2.6 Evidence

A high-quality RCT (n = 630) compared office evaluation alone to office evaluation and urodynamics in women with clinical demonstrable SUI about to undergo surgery for SUI. Whilst urodynamics changed the clinical diagnosis in 56% of women [59], there was no difference in levels of UI or any secondary outcome at twelve months follow-up after surgery [60]. Another similar study closed with only 59 women included due to recruitment problems, found that the omission of urodynamics was not inferior in the pre-operative work up of SUI [61]. This study was then redesigned so that patients in whom urodynamics were discordant with clinical assessment (n = 109) were randomly allocated to receive either immediate surgery or individually tailored therapy based on urodynamics. In this trial, performing immediate surgery, irrespective of the result of urodynamics, did not result in inferior outcomes [62].

In observational studies there is no consistent correlation between the result of urethral function tests and subsequent success or failure of SUI surgery [24-27]. The same is true for a secondary analysis of an RCT [63].

Augmentation cystoplasty is only performed in patients with a urodynamic diagnosis of DO, so no statement can be made about predictive value for this group [58].

The Panel recognise that it may be valuable to use urodynamic test results to select the optimum surgical procedure but, at the time of this review, there is inconsistent evidence regarding any predictive value that would support this approach.

3.6.2.7 Question

Does urodynamics help to predict complications of surgery for UI?

3.6.2.8 Evidence

There have been no RCTs designed to answer this question.

The presence of pre-operative DO has been associated with post-operative UUI, but did not predict overall treatment failure following mid-urethral sling [63] or following sling surgery or colposuspension.
