TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aims and scope

The European Association of Urology (EAU) Renal Cell Cancer (RCC) Guidelines Panel has compiled these clinical guidelines to provide urologists with evidence-based information and recommendations for the management of RCC.

It must be emphasised that clinical guidelines present the best evidence available to the experts, but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and references/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Guidelines Panel on RCC consists of an international multidisciplinary group of clinicians, including urological surgeons, oncologists, methodologists, a pathologist and a radiologist, with particular expertise in the field of renal cancer care. Since 2015, the Panel has incorporated two patient advocates to provide a consumer perspective for its guidelines. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU website Uroweb: http://uroweb.org/guideline/renalcellcarcinoma/.

1.3 Available publications

A quick reference document (Pocket Guidelines) is available presenting the main findings of the RCC Guidelines. This is an abridged version which may require consultation together with the full text version. All documents can be accessed on the EAU website: http://uroweb.org/guideline/renal-cell-carcinoma/.

1.4 Publication history and summary of changes

1.4.1 Publication history

The EAU RCC Guidelines were first published in 2000. This 2024 RCC Guidelines document presents a limited update of the 2023 publication.

1.4.2 Summary of changes

All chapters of the 2024 RCC Guidelines have been updated, based on the 2023 version of the Guidelines. References have been added throughout the document. Other key changes incorporated in this publication includes:

- A new section 5.2.3 on other investigations and emerging technologies;
- An update of Table 5.1: Bosniak classification of renal cysts;
- New summary of evidence (SOE) and recommendations for prognostic factors using the Leibovich and VENUSS scoring models;
- A new section 7.1.3.2.8 on off-clamp vs on clamp partial nephrectomy as well as accompanying new SOE and recommendations in section 7.1.3.4;
- A new update in section 7.1.4.3.6 on stereotactic ablative radiotherapy;
- New SOE and recommendations for neoadjuvant therapy in section 7.2.5.5;
- A new section 7.4.2.4 on small molecule inhibitors, as well as new accompanying SOE and recommendation is section 7.4.2.5;
- Updates on the SOE and recommendations in section 7.4.4.1.2;
- Updates to both figure 7.1 and figure 7.2;
- New SOE in section 7.4.4.2.2 as well as in both SOE and recommendation table 7.4.4.2.1;
- A new section 7.4.4.2 on other rare tumours;
- New SOE and recommendation in section 8.3;
- A new section 8.4 on patient involvement including a recommendation table.

2. METHODS

2.1 Data identification

For the 2024 RCC Guidelines, new and relevant evidence has been identified, collated, and appraised through a structured assessment of the literature. A broad and comprehensive scoping exercise covering all areas of the RCC Guidelines was performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between May 24th, 2022 and May 1st, 2023. Databases covered included Medline, EMBASE, and the Cochrane Library. After de-duplication, a total of 1,901 unique records were identified, retrieved and screened for relevance. A search strategy is published online: https://uroweb.org/guidelines/renal-cell-carcinoma/publications-appendices.

Recommendation within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [1];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact and certainty of patient values and preferences on the intervention.

Strong recommendations typically indicate a high degree of evidence quality and/or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [2].

Additional methodology information and a list of associations endorsing the EAU Guidelines can be found in the online: https://uroweb.org/eau-guidelines/methodology-policies.

2.2 Review

All publications ensuing from systematic reviews (SR)s have been peer reviewed. The 2021 print of the RCC Guidelines was peer-reviewed prior to publication.

2.3 Future goals

The RCC Guideline Panel supports the focus on patient-reported outcomes as well as the development of clinical quality indicators. A number of key quality indicators for this patient group have been selected:

- the proportion of patients undergoing thorax computed tomography (CT) for staging of pulmonary metastasis;
- proportion of patients with T1aN0M0 tumours undergoing nephron-sparing surgery (NSS) as first treatment;
- the proportion of patients with metastatic RCC (mRCC) offered systemic therapy;
- the proportion of patients who undergo minimally invasive or operative treatment as first treatment who die within 30 days.

The Panel have set up a database to investigate current practice in follow-up of RCC patients in a number of European centres. Assessing patterns of recurrence and use of imaging techniques are primary outcomes for this project.

In addition, the Panel will collect data from various European datasets on atypical recurrences following minimally invasive renal surgery to establish incidence and insight on potential causes, their management and outcome.

Further, a registry for Bosniak IV cysts with single nodularity will be established to investigate if diameter of the cyst or nodule is leading in clinical management.

The results of ongoing and new systematic reviews will be included in future updates of the RCC Guidelines:

- Systematic review of prevalence of intraperitoneal recurrences following robotic/laparoscopic partial nephrectomy;
- Systematic review of individual, unit and hospital surgical volume for radical and partial nephrectomy and their impact on outcomes;
- RECUR database analysis of recurrent disease/follow-up;
- Systematic review on management of oligometastatic and oligoprogressive disease.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Renal cell carcinoma represents around 3% of all cancers, with the highest incidence occurring in Western countries [3, 4]. In 2020, there were an estimated 431,288 new cases of RCC globally, of which 138,611 in Europe [5]. The higher incidence in Europe and North America is hypothesized to be due to a higher prevalence of small renal masses (SRMs) in settings where abdominal imaging is more ubiquitous. In 2020, Lithuania reported the highest overall rate of RCC, followed by Czechia, with estimated age-standardised rates (ASRs) of 14.5/100,000 and 14.42/100,000, respectively. A person living in Czechia has a 2.83% risk of developing RCC [4, 5]. Generally, during the last two decades until recently, there has been an annual increase of about 2% in incidence both worldwide and in Europe. In 2022, worldwide mortality from RCC was 179,368 deaths (115,600 men and 63,768 women), with a calculated global ASR rate of 1.8/100,000 [5].

There has been a decrease in mortality since the 1980s in Scandinavian countries and since the early 1990s in France, Germany, Austria, the Netherlands, and Italy. However, in some European countries (Croatia, Estonia, Greece, Ireland, Slovakia), mortality rates still show an upward trend [3, 4].

Renal cell carcinoma is the most common solid lesion within the kidney and accounts for approximately 90% of all kidney malignancies. It comprises different RCC subtypes with specific histopathological and genetic characteristics. There is a 1.5–2.0:1 predominance in men over women with a higher incidence in the older population [4-6].

3.2 Aetiology

Established risk factors include lifestyle factors such as smoking (hazard ratio [HR]: 1.23–1.58), obesity BMI (> 35 vs. < 25), (HR: 1.71 [1.06-2.79]), hypertension (HR: 1.70 [1.30-2.22]) and metabolic syndrome (RR 1.62 [1.41-1.87]) [4-10]. 50.2% of patients with RCC are current or former smokers. By histology, the proportions of current or former smokers range from 38% in patients with chromophobe carcinoma (chRCC) to 61.9% in those with collecting duct/medullary carcinoma [11]. In a SR, diabetes was also found to be detrimental [12]. Having a first-degree relative with kidney cancer is also associated with an increased risk of RCC [13]. Moderate alcohol consumption appears to have a protective effect for reasons as yet unknown, while any physical activity level also seems to have some protective effect [4, 5, 12, 14, 15]. A number of other factors have been suggested to be associated with higher or lower risk of RCC, including specific dietary habits and occupational exposure to specific carcinogens, but no high-quality evidence level exists [6, 16]. The most effective prophylaxis is to avoid cigarette smoking and reduce obesity [4-7]. Genetic risk factors are known to play a role in the development of RCC (see Section 3.5.6 - Hereditary kidney tumours).

3.3 Screening

Despite a growing interest from both patients and clinicians in RCC screening programmes, there is a relative lack of studies reporting the efficacy, cost-effectiveness, and optimal modality for RCC screening. Urinary dipstick is an inadequate screening tool due to low sensitivity and specificity. Also incidence of RCC with non-visible haematuria is low; 0.58% [17]. No clinically validated urinary or serum biomarkers have as yet been identified. Computed tomography cannot be recommended due to cost, radiation dose and the increased potential for other incidental findings. Ultrasound (US) could be used and has acceptable sensitivity and specificity, although it is tumour size and operator dependant. Major barriers to population screening include the relatively low prevalence of the disease, the potential for false positives and over-diagnosis of slow-growing kidney tumours. Targeting high-risk individuals and/or combining detection of RCC with other routine health screenings may represent pragmatic options to improve the cost-effectiveness and reduce the potential harms of RCC screening [18-20]. Targeting of high-risk patient groups e.g., those with end-stage renal disease (ESRD) which is associated with a 10-fold increased risk of developing RCC may also be a valid approach (see Section

3.5.2) [21]. There is currently no evidence to support primary screening in the general population.

3.3.1 Summary of evidence and recommendations for epidemiology, aetiology and screening

Summary of evidence	LE
Several verified risk factors have been identified including smoking, obesity and hypertension. These are considered definite risk factors for RCC.	2a
There is no evidence to support primary screening for RCC.	4

Recommendations	Strength rating
Increase physical activity, eliminate cigarette smoking and in obese patients reduce weight are the primary preventative measures to decrease risk of RCC.	Strong
Do not routinely screen any population for primary RCC.	Weak

3.4 Histological diagnosis

Renal cell carcinomas and other renal tumours comprise a broad spectrum of histopathological entities described in the 5th edition of the World Health Organization (WHO) classification of urogenital tumours published in 2022 [22-24]. The 5th edition presents standard morphologic diagnostic criteria, combined with immunohistochemistry and relevant molecular tests was significantly revised as compared to the 2016 classification [25]. The global application of next-generation sequencing (NGS) will result in a diagnostic shift from morphology to molecular analyses. Therefore, a molecular-driven renal tumour classification has been introduced in addition to morphology-based renal tumours (Table 3.1). Examples of molecularly-defined epithelial renal tumours include SMARCB1-deficient renal medullary carcinoma, TFE3- and TFEB-rearranged RCC, ALK-rearranged RCC, and elongin C (ELOC)-mutated RCC. The most profound changes in the 2022 WHO classification mainly relate to rare kidney tumours.

There are three main RCC types: clear cell (ccRCC), papillary (pRCC no longer divided into type I and II) and chRCC. The RCC type classification has been confirmed by cytogenetic and genetic analyses [25, 26] (LE: 2b). The 5-year overall survival (OS) for non-metastatic (including N0-N1) chromophobe, papillary, clear-cell and collecting duct RCC is 91%, 82%, 81% and 44%, respectively [27]. Sarcomatoid RCC is not a specific subtype, but essentially represents a pattern of de-differentiation associated with adverse outcome and poor cancer-specific survival (CSS), irrespective of the underlying RCC subtype; it should be graded as WHO/ISUP (International Society of Urological Pathology) grade IV. Multilocular cystic renal neoplasm of low malignant potential is a new subtype of cRCC in the 2022 classification. A new group "oncocytic and chromophobe tumours" encompass oncocytoma together with chRCC and other oncocytic tumours. Other oncocytic tumours include tumours that do not strictly fit into either the oncocytoma or chRCC subtypes [22, 28].

Histological diagnosis includes, besides RCC type; evaluation of ISUP nuclear grade, sarcomatoid features, vascular invasion, tumour necrosis, and invasion of the collecting system and peri-renal fat, pT, or even pN categories. The four-tiered WHO/ISUP grading system has replaced the Fuhrman grading system [22, 25].

Table 3.1 World Health Organization classification of renal tumours 2022 [22, 23]

WHO classification of renal tumours 2022	
1. Renal Cell Tumours	
01.I	Clear cell renal tumours
	Clear cell RCC
	Multilocular cystic renal neoplasm of low malignant potential
01.II	Papillary renal tumours
	Papillary adenoma
	Papillary RCC
01.III	Oncocytic and chromophobe renal tumours
	Oncocytoma of the kidney
	Chromophobe RCC
	Other oncocytic tumours of the kidney
01.IV	Collecting duct tumours

	Collecting duct carcinoma
01.V	Other renal tumours
	Clear cell papillary renal cell tumour
	Mucinous tubular and spindle cell carcinoma
	Tubulocystic RCC
	Acquired cystic disease-associated RCC
	Eosinophilic solid and cystic (ESC) RCC
	RCC NOS (Not Otherwise Specified)
01.VI	Molecularly defined renal tumours
	TFE3-rearranged RCCs
	TFEB-altered RCC (*TFEB*-rearranged RCC and *TFEB* amplified RCC)
	ELOC (formerly *TCEB1*)-mutated RCC
	Fumarate hydratase-deficient RCC
	Succinate dehydrogenase-deficient RCC
	ALK-rearranged RCCs
	SMARCB1-deficient renal medullary carcinoma
2. Metanephric tumours	
	Metanephric adenoma
	Metanephric adenofibroma
	Metanephric stromal tumour
3. Mixed epithelial and stromal tumour family	
	Mixed epithelial and stromal tumour
	Adult cystic nephroma
4. Renal mesenchymal tumours	
04.I	Adult renal mesenchymal tumours
	Classic angiomyolipoma/PEComa of the kidney
	Epitheloid angiomyolipoma/epithelioid PEComa of the kidney
	Renal haemangioblastoma
	Juxtaglomerular cell tumour
	Renomedullary interstitial cell tumour
04.II	Paediatric renal mesenchymal tumours
	Ossifying renal tumour of infancy
	Congenial mesoblastic nephroma
	Rhabdoid tumour of kidney
	Clear cell sarcoma of kidney
5. Embryonal neoplasms of the kidney	
Nephroblastic tumours	
	Nephrogenic rests
	Pediatric cystic nephroma
	Cystic partially differentiated nephroblastoma
	Nephroblastoma
6. Miscellaneous tumours	
Germ cell tumours of the kidney	

3.4.1 ***Clear-cell RCC***

Overall, ccRCC representing about 70% of RCC [23], is well circumscribed with a pseudocapsule. The cut surface is golden-yellow, often with haemorrhage and necrosis. Loss of chromosome 3p and mutation of the von Hippel-Lindau (VHL) gene at chromosome 3p25 are frequently found. The loss of von Hippel-Lindau protein function

contributes to tumour initiation, progression, and metastases. The 3p locus harbours additional ccRCC tumour suppressor genes (*UTX, JARID1C, SETD2, PBRM1, BAP1*) [22]. For details about prognosis, see Section 6.3.

3.4.1.1 Multilocular cystic renal neoplasm of low malignant potential (MCNLMP)

Indolent, exclusively cystic, multiloculated renal tumour devoid of any expansile solid growth, with clear cells lining and low grade nuclei. Detection of small solid expansive nodules and tumour necrosis are incompatible with MCNLMP. It represents 0.5-2.5% of all renal tumours and is a benign lesion. There are no reports of progression, metastases or cancer-related death with long-term follow-up [22, 23].

*3.4.2 **Papillary RCC***

Papillary RCC (pRCC) is the second-most encountered morphotype of RCC accounting for 13-20% of renal epithelial tumours. It is usually circumscribed and characterised by papillary or tubulopapillary architecture, without specific features of other RCCs with papillary architecture [22, 23]. Papillary RCC has traditionally been subdivided into two types; Type I and II pRCC [25]. However, in the new 2022 WHO classification, the former pRCC type I is now referred to as "pRCC of classic pattern". Three additional morphologic patterns of pRCC have been introduced including: a) bi-phasic (alveolo-squamoid) pattern exhibiting mostly solid growth; b) papillary neoplasm with reverse nuclear polarity, previously described as "oncocytic low-grade pRCC"; and c) Warthin-like pRCC that exhibits brisk inflammation mimicking Warthin tumour of the salivary gland.

Genetic changes of pRCC include trisomies and tetrasomies of chromosomes 7 and 17 and loss of Y-chromosome. Mesenchymal-epithelial Transition (MET) gene mutations are more frequent in low-grade pRCC.

The typical histology of classical pattern pRCC, formally type I pRCC, (narrow papillae without any binding, and only microcapillaries in papillae) explains its typical clinical signs. Narrow papillae without any binding and a tough pseudo-capsule explain the ideal rounded shape (Pascal's law) and fragility (specimens have a "minced meat" structure). Tumour growth causes necrotisation of papillae, which is a source of hyperosmotic proteins that cause subsequent "growth" of the tumour, fluid inside the tumour, and only a serpiginous, contrast-enhancing margin. Stagnation in the microcapillaries explains the minimal post-contrast attenuation on CT. Classical pattern pRCC can imitate a pathologically changed cyst (Bosniak IIF or III). The typical signs of classical pattern pRCC are an ochre colour, frequently exophytic, extra-renal growth and low grade. A risk of renal tumour biopsy tract seeding exists (12.5%), probably due to the fragility of the tumour papillae [29].

*3.4.3 **Chromophobe RCC***

Chromophobe RCC is now grouped in "Oncocytic and chromophobe tumours". Most chRCCs are discovered incidentally in asymptomatic patients [22, 23]. Overall, chRCC presents as a pale tan, relatively homogenous and tough, well-demarcated mass without a capsule. Most tumours are sporadic. Rare hereditary forms include Birt-Hogg-Dubé (BHD) syndrome with mutations in folliculin and Cowden syndrome with mutations in PTEN see Section 3.5.6 for further information [22, 23]. Chromophobe RCC cannot be graded by the WHO/ISUP (formerly Fuhrman) grading system because of its innate nuclear atypia. An alternative grading system has been proposed, but has yet to be validated [22, 23]. Loss of chromosomes-Y, 1, 2, 6, 10, 13, 17 and 21 are typical genetic changes [22, 23]. The prognosis is relatively good, with high 5-year recurrence-free survival (RFS), and 10-year CSS. The five- and 10-year RFS rates were 94.3% and 89.2%, respectively. Recurrent disease developed in 5.7% of patients, and 76.5% presented with distant metastases with 54% of metastatic disease diagnoses involving a single organ, most commonly bone. Recurrence and death after surgically resected chRCC are rare. For completely excised lesions < pT2a without coagulative necrosis or sarcomatoid features, the prognosis is excellent [30].

3.5 Other renal tumours

Other renal tumours constitute the remaining renal cortical tumours. These include a variety of uncommon, sporadic, and familial carcinomas/tumours, some only recently described, as well as a group of unclassified carcinomas. A summary of these tumours is provided in Table 3.1, but some clinically relevant tumours and extremely rare entities are mentioned below. About 15% of excised renal masses are benign [31].

*3.5.1 **Renal medullary carcinoma (SMARCB1-deficient renal medullary carcinoma)***

Renal medullary carcinoma (RMC) (referred to as SMARCB1-deficient renal medullary carcinoma in the 2022 WHO Classification) is a very rare tumour, comprising < 0.5% of all RCCs [32], predominantly diagnosed in young adults of African ancestry (median age 28 years) with sickle haemoglobinopathies (including sickle cell trait). It has a male predominance of 2:1 and is mainly centrally located with ill-defined borders. Renal medullary carcinoma is one of the most aggressive RCCs [33, 34] and most patients (~67%) will present with metastatic disease [33, 35]. Even patients who present with seemingly localised disease may develop unequivocal

metastases shortly (within weeks) after diagnosis (for treatment see Chapter 7). Apart from the RMC described above, some patients present with identical tumours without haemoglobinopathy. Such tumours have been described as "unclassified RCC with medullary phenotype" [22].

3.5.2 Carcinoma associated with end-stage renal disease; acquired cystic disease-associated RCC

Cystic degenerative changes (acquired cystic kidney disease [ACKD]) and a higher incidence of RCC, are typical features of ESRD. Renal cell carcinomas of native end-stage kidneys are found in approximately 4% of patients with ESRD. Their lifetime risk of developing RCCs is at least ten times higher than in the general population. Compared with sporadic RCCs, RCCs associated with ESRD are generally multicentric and bilateral, found in younger patients (mostly male), and are less aggressive. Whether the relatively indolent outcome of tumours in ESRD is due to the mode of diagnosis or a specific ACKD-related molecular pathway still has to be determined. Although the histological spectrum of ESRD tumours is like that of sporadic RCC; pRCC occur relatively more frequently [28, 36]. A specific subtype of RCC occurring only in end-stage kidneys has been described as "acquired cystic disease-associated RCC" (ACD-RCC). Tumours present exclusively in patients with ACKD, usually after long-term dialysis. The vast majority occur in men. Tumours are often multiple and bilateral and, in most cases, have an indolent clinical behaviour; although, aggressive courses have been documented [22].

3.5.3 Papillary adenoma

These tumours have a papillary or tubular architecture of low nuclear grade and may be up to 15 mm in diameter, or smaller, according to the 2022 WHO classification [22].

3.5.4 Renal oncocytoma

Oncocytoma is a benign tumour representing 4-7% of all solid renal tumours and 30% of benign surgically removed kidney masses are contributed to oncocytoma [25, 37]. The diagnostic accuracy of imaging modalities (CT, magnetic resonance imaging [MRI]) in renal oncocytoma is limited and histopathology remains the only reliable diagnostic modality [25, 37]. However, ^{99m}Tc-sestamibi (SestaMIBI, MIBI) SPECT/CT has shown promising initial results for the differentiation between benign and low-grade RCC [38-41]. Standard treatment for renal oncocytoma is similar to that of other renal tumours; surgical excision by partial- or radical nephrectomy (RN) with subsequent histopathological verification. However, due to the inability of modern imaging techniques to differentiate benign from malignant renal masses, there is a renewed interest in renal mass biopsy (RMB) prior to surgical intervention. Accuracy of the biopsy and management of advanced/progressing oncocytomas need to be considered in this context since oncocytic renal neoplasms diagnosed by RMB at histological examination after surgery showed oncocytoma in only 64.6% of cases. The remainder of the tumours were mainly chRCC (18.7% including 6.3% hybrid oncocytic/chromophobe tumours which have now been grouped histologically with chRCC) [22, 23], other RCCs (12.5%), and other benign lesions (4.2%) [42, 43]. The 2022 WHO classification strictly excludes that a definitive diagnosis of oncocytoma be done on a needle-core biopsy. The majority of oncocytomas slowly progress in size with an annual growth rate of approximately 2 mm [37]. Preliminary data show that active surveilnace (AS) may be a safe option to manage oncocytoma in appropriately selected patients. Potential triggers to change management of patients on AS are not well defined [44, 45].

3.5.5 Other oncocytic tumours of the kidney

Other oncocytic tumours of the kidney are a heterogeneous group of oncocytic tumours not classifiable as oncocytoma, chRCC, or other tumour types with eosinophilic features. These tumours are typically indolent, so it is important to distinguish such low-grade tumours from the high-grade unclassified RCCs that typically behave aggressively. In the setting of Birt–Hogg–Dubé syndrome (see Section 3.5.6), tumours with such intermediate features (hybrid oncocytic tumours) also exist, typically being multifocal and bilateral. As this is a heterogeneous tumour group, it is likely that new subtypes of renal neoplasia will emerge. There are already two emerging entities: eosinophilic vacuolated tumour (EVT) and low-grade oncocytic tumour (LOT) [22].

3.5.6 Hereditary kidney tumours

Five to eight percent of RCCs are hereditary; to date there are ten hereditary RCC syndromes associated with specific germline mutations, RCC histology, and comorbidities. Hereditary RCC syndromes are often suggested by family history, age of onset and presence of other lesions typical for the respective syndromes. Median age for hereditary RCC is 37 years; 70% of hereditary RCC tumours are found in the lowest decile (age 46 years or younger) of all RCC tumours [46]. Hereditary kidney tumours are found in the following entities: VHL syndrome; hereditary pRCC; Birt-Hogg-Dubé syndrome; Fumarate hydratase-deficient RCC (FHD-RCC), previously called hereditary leiomyomatosis and RCC (HLRCC); tuberous sclerosis; germline succinate dehydrogenase (SDH) mutation; non-polyposis colorectal cancer syndrome; hyperparathyroidism-jaw tumour syndrome; phosphatase and tensin homolog (PTEN) hamartoma syndrome (PHTS); constitutional chromosome 3 translocation; familial

non-syndromic ccRCC and BAP1-associated RCC [47]. Renal medullary carcinoma can be included because of its association with hereditary haemoglobinopathies [48-51].

Patients with hereditary kidney cancer syndromes may require repeated surgical intervention [52, 53]. In most hereditary RCCs nephron-sparing approaches are recommended. The exceptions are FHD-RCC and SDH syndromes for which immediate surgical intervention is recommended due to the aggressive nature of these tumours. For other hereditary syndromes such as VHL, surveillance is recommended until the largest tumour reaches 3 cm in diameter; this to limit the number of repeat interventions [54, 55]. Active surveillance for VHL, SDH and FHD-RCC should, in individual patients, follow the size, growth rate and location of the tumours, rather than applying a standardised follow-up interval. Regular screening for both renal and extra-renal lesions should follow international guidelines for these syndromes [55]. Multidisciplinary and co-ordinated care should be offered, where appropriate [56]. In FHD-RCC, renal screening in relatives has shown benefit in detecting early-stage RCCs [57], with HLRCCs appearing to have unique molecular profiles.

Although not hereditary, somatic fusion translocations of *TFE3* and *TFEB* may affect 15% of patients with RCC younger than 45 years and 20-45% of children and young adults diagnosed with RCC [58].

A phase II trial demonstrated clinical activity of an oral HIF-2α (hypoxia-inducible factor) inhibitor MK-6482 (belzutifan) in VHL patients [59]. Additional information on treatment of VHL can be found in Section 7.4.4.

*3.5.7 **Classical Angiomyolipoma***

Classical angiomyolipoma (AML)/PEComa of the kidney is a benign mesenchymal tumour, which can occur sporadically or as part of tuberous sclerosis complex [60]. Overall prevalence is 0.44%, with 0.6% in female and 0.3% in male populations. Only 5% of these patients present with multiple AMLs [61]. Angiomyolipoma belongs to a family of so-called PEComas (perivascular epithelioid cell tumours), characterised by the proliferation of perivascular epithelioid cells. Some PEComas can behave aggressively and even metastasise, while classic AMLs are completely benign [25, 48, 62]. Ultrasound, CT, and MRI often lead to the diagnosis of AMLs due to the presence of adipose tissue; however, in fat-poor AML, diagnostic imaging cannot reliably identify these lesions. Percutaneous biopsy is rarely useful. Renal tumours that cannot be clearly identified as benign during the initial diagnostic work-up should be treated according to the recommendations provided for the treatment of RCC. In tuberous sclerosis, AML can be found in enlarged lymph nodes (LNs), which does not represent metastatic spread but a multicentric spread of AMLs. In rare cases, an extension of a non-malignant thrombus into the renal vein or inferior vena cava (IVC) can be found, associated with an angiotrophic-type growth of AML. Epithelioid AML, a very rare variant of AML, consists of at least 80% epithelioid cells and with mean age of onset of 50 years (range 30-80 years), without gender predilection [48, 62]. Epithelioid AMLs are potentially malignant with a variable proportion of cases with aggressive behaviour [63]. Criteria to predict the biological behaviour in epithelioid AML were proposed by the WHO 2022 [22, 23]. Angiomyolipoma, in general, has a slow and consistent growth rate, and minimal morbidity [64]. Subtypes of AML are oncocytic AML and AML with epithelial cysts [22].

In some cases, larger AMLs can cause local pain. The main complication of AMLs is spontaneous bleeding in the retroperitoneum or into the collecting system, which can be life threatening. Bleeding is caused by spontaneous rupture of the tumour. Little is known about the risk factors for bleeding, but it is believed to increase with tumour size and may be related to the angiogenic component of the tumour that includes irregular blood vessels [64]. The major risk factors for bleeding are tumour size, grade of the angiogenic component, and the presence of tuberous sclerosis.

3.5.7.1 Treatment of angiomyolipoma

Active surveillance is the most appropriate option for most AMLs (48%). In a group of patients on AS, only 11% of AMLs showed growth, and spontaneous bleeding was reported in 2%, resulting in active treatment in 5% of patients [64] (LE: 3). The association between AML size and the risk of bleeding remains unclear and the traditionally used 4-cm cut-off should not per se trigger active treatment [64]. When surgery is indicated, NSS is the preferred option, if technically feasible. Main disadvantages of less invasive selective arterial embolisation (SAE) are more recurrences and a need for secondary treatment (0.85% for surgery vs. 31% for SAE). For thermal ablation only limited data are available, and this option is used less frequently [64].

Active treatment (SAE, surgery or ablation) should be instigated in case of persistent pain, ruptured AML (acute or repeated bleeding) or in case of a very large AML. Specific patient circumstances may influence the choice to offer active treatment, such as patients at high risk of abdominal trauma, females of childbearing age or patients in whom follow-up or access to emergency care may be inadequate. Selective arterial embolisation is an option in case of life-threatening AML bleeding.

In patients diagnosed with tuberous sclerosis, size reduction of often bilateral AMLs can be induced by inhibiting the mTOR pathway using everolimus, as demonstrated in RCTs [65, 66]. In a small phase II trial

(n = 20), efficacy of everolimus was demonstrated in sporadic AML as well. A 25% or greater reduction in tumour volume at four and six months was demonstrated in 55.6% and 71.4% of patients, respectively. However, 20% of patients were withdrawn due to toxicities and 40% self-withdrew from the study due to side effects [67].

Table 3.2: Other renal cortical tumours and recommendations for treatment (strength rating: weak)

Entity	Clinical relevant notes	Malignant potential	Treatment
Collecting duct carcinoma	Formerly bellini duct carcinoma. No hemoglobinopathy or *SMARCB1* abnormality. Rare, often presenting at an advanced stage (N+ 44% and M1, 33% at diagnosis). The HR CSS in comparison with ccRCC is 4.49 [22, 23, 68].	High, very aggressive. Median survival 30 months [69].	Surgery. Systemic therapy and surgery in metastatic disease [70].
Clear-cell papillary renal cell tumour	Patient with ACKD, 100 times greater risk compared with general population [23].	Indolent	Surgery, NSS, discuss active surveilance.
Mucinous tubular and spindle cell carcinoma	Tumour is associated with the loop of Henle. < 1% of renal neoplasm. Female predilection (3–4:1) [23].	Intermediate	Surgery, NSS.
Tubulocystic RCC	Rare (< 1%). Mainly men, imaging can be Bosniak III or IV.	Low (90% indolent)	Surgery, NSS.
Eosinophilic solid and cystic RCC (ESC RCC)	Usually alteration of TCS genes. Predominantly in adult women. Some with TSC (tuberous sclerosis complex) syndrome.	Rarely metastatic.	NSS.
TFE3 re-arranged RCC	Gene fusions involving *TFE3* with one of many different partner genes. Formerly translocation RCC (TRCC) Xp11.2. Appr. 40 % of paediatric RCC and 1.6–4% of adult RCC [24].	Survival similar to clear cell RCC	Surgery. Systemic therapy in metastatic disease.
TFEB altered (re-arranged and amplified) RCC	Gene fusions involving the *TFEB* transcription factor, typically via a t(6;11)(p21;q12) translocation resulting in a *MALAT1-TFEB* gene fusion. Formerly translocation RCC t(6;11). Less common than *TFE3*-re-arranged RCC. Appr. 100 cases in the literature [23]. *TFEB*-amplified in older patient and has a worse prognosis.	More indolent than the TFE3-rearranged RCC, with fewer than 10% of cases resulting in patient death.	Surgery. Systemic therapy in metastatic.
ELOC (formerly *TCBE1*)-mutated RCC	Twenty cases described in literature. Typically T1.	Indolent. Only 2 metastatic cases described.	NSS.
Fumarate hydratase-deficient RCC	Formerly hereditary leiomyomatosis and RCC-associated RCC. Alterations in the *FH* gene. Autosomal dominant. 21–30% lifetime risk of RCC [57]. Cutanous leiomyomas, female uterine leiomyoma or leiomyosarcoma. More common in males. Median age 44 years [22, 28, 71].	Often aggressive.	Immediate surgery. No data about treatment of metastatic disease. Genetic counselling in the family. Imaging screening in relatives [57].

Succinate dehydrogenase-deficient RCC (SDH-deficient RCC)	Rare. 0.05–0.2 % of all RCCs.	A metastatic rate of 11%	Surgery, NSS. Long-term follow-up and surveillance for other SDH-deficient neoplasms (i.e. paraganglioma, SDH-deficient gastrointestinal stromal tumour, and pituitary adenoma) is indicated for cases associated with germline mutation [23].
ALK-rearranged RCC	Gene fusions involving anaplastic lymphoma kinase gene (ALK) at chromosome *2p23*. Appr. 40 cases described.	Low (90% indolent)	Surgery, NSS.
Metanephric tumours	Divided into metanephric adenoma, adenofibroma, and metanephric stromal tumours.	Benign	NSS.
Mixed epithelial and stromal renal tumour	It encompasses 2 benign leasions - mixed epithelial and stromal tumour of the kidney (MEST) and adult cystic nephroma. Imaging – Bosniak type III or IIF/IV. Overwhelmingly in women (7:1).	Benign	Active surveillance. NSS.
Renal cysts/cystic lesions	Simple cysts are frequently occurring, while occurring septa, calcifications and solid components require follow-up and/or management.	Mostly benign	Treatment or follow-up recommendation based on Bosniak classification.

3.5.8 ***Cystic renal tumours***

Cystic renal lesions are classified according to the Bosniak classification (see Section 5.2.5). Bosniak I and II cysts are benign lesions which do not require follow-up [72]. Bosniak IV cysts are mostly (83%) malignant tumours with pseudo-cystic changes only [73]. Bosniak IIF and III cysts remain challenging for clinicians. The differentiation of benign and malignant tumour in categories IIF/III is based on imaging, mostly CT, with an increasing role of MRI and contrast-enhanced US (CEUS). Computed tomography shows poor sensitivity (36%) and specificity (76%; κ [kappa coefficient] = 0.11) compared with 71% sensitivity and 91% specificity (κ = 0.64) for MRI and 100% sensitivity and 97% specificity for CEUS (κ = 0.95) [74]. Surgical and radiological cohorts pooled estimates show a prevalence of malignancy of 0.51 (0.44-0.58) in Bosniak III and 0.89 (0.83-0.92) in Bosniak IV cysts, respectively. In a SR, less than 1% of stable Bosniak IIF cysts showed malignancy during follow-up. Twelve percent of Bosniak IIF cysts had to be reclassified to Bosniak III/IV during radiological follow-up, with 85% of these showing malignancy, which is comparable to the malignancy rates of Bosniak IV cysts [72]. The updated Bosniak classification strengthens the classification and includes also MRI [75] and even CEUS diagnostic criteria [76].

The most common histological types for Bosniak III cysts is ccRCC with pseudo-cystic changes and low malignant potential [77, 78]; multilocular cystic renal neoplasm of low malignant potential, see Section 3.4.1.1; classical pattern pRCC (very low malignant potential); benign multilocular cyst; benign group of mixed epithelial and stromal renal tumour (mixed epithelial and stromal tumour of the kidney and adult cystic nephroma); and other rare entities. Surgery in Bosniak III cysts will result in over-treatment in 49% of the tumours which are lesions with a low malignant potential. In view of the excellent outcome of these patients in general, a surveillance approach is an alternative to surgical treatment [72, 75, 79, 80].

3.6 Summary of evidence and recommendations for the management of other renal tumours

Summary of evidence	LE
A variety of renal tumours exist of which approximately 15% are benign .	3
The most common renal tumours are three malignant types of RCC (clear cell, papillary and chromophobe) and two benign renal tumours: oncocytoma and angiomyolipoma.	3
A definitive histopathological diagnosis of oncocytoma cannot be made on a needle-core biopsy, because chRCC can show intratumoural heterogeneity with areas very similar to oncocytoma.	3
Histological work up and results of AS of Bosniak III cysts shows low risk of malignant potential/ course.	2

Recommendations	Strength rating
Manage Bosniak type III cysts the same as localised RCC, or offer active surveillance (AS).	Weak
Manage Bosniak type IV cysts the same as localised RCC.	Strong
Offer AS to patients with biopsy-proven oncocytoma or other oncocytic renal tumours as an acceptable alternative to surgery or ablation.	Weak
Treat angiomyolipoma (AML) with selective arterial embolisation or nephron-sparing surgery, in: • large tumours (a recommended threshold of intervention does not exist); • females of childbearing age; • patients in whom follow-up or access to emergency care may be inadequate; • persistent pain or acute or repeated bleeding episodes.	Weak
Offer systemic therapy (everolimus) to patients at need for therapy with surgically unresectable AMLs not amendable to embolisation.	Weak

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Staging

The Tumour Node Metastasis (TNM) classification system is recommended for clinical and scientific use [81]. A supplement was published in 2012, and the latter's prognostic value was confirmed in single- and multi-institution studies [82, 83]. Tumour size, venous invasion, renal capsular invasion, adrenal involvement, LN and distant metastasis are included in the TNM classification system (Table 4.1). However, some uncertainties remain:

- The sub-classification of T1 tumours using a cut-off of 4 cm might not be optimal in NSS for localised cancer [84];
- The value of size stratification of T2 tumours has been questioned [85];
- Renal sinus fat invasion might carry a worse prognosis than perinephric fat invasion, but, is nevertheless included in the same pT3a stage group [86-89] (LE: 3);
- Sub T-stages (pT2b, pT3a, pT3c and pT4) may overlap [83];
- For adequate M staging, accurate pre-operative imaging (chest and abdominal CT) should be performed [90, 91] (LE: 4).

A proposed imaging analysis of Tumor Contour Irregularity might be a valuable tool to enhance the preoperative staging between T1 and T3a RCCs for treatment decisions [92].

The TNM classification should not be considered the only criterion for clinical decision-making, but patient's condition, comorbidities and wishes are of fundamental importance to select the most optimal treatment. A clinically-guided RCC staging classification was proposed in 2022 by the EAU Panel, based on changes observed in the management of SRM, locally advanced and metastatic disease [84].

Table 4.1: 2017 TNM classification system [93]

T - Primary tumour				
TX	Primary tumour cannot be assessed			
T0	No evidence of primary tumour			
T1	Tumour ≤ 7 cm or less in greatest dimension, limited to the kidney			
	T1a	Tumour ≤ 4 cm or less		
	T1b	Tumour > 4 cm but ≤ 7 cm		
T2	Tumour > 7 cm in greatest dimension, limited to the kidney			
	T2a	Tumour > 7 cm but ≤ 10 cm		
	T2b	Tumours > 10 cm, limited to the kidney		
T3	Tumour extends into major veins or perinephric tissues but not into the ipsilateral adrenal gland and not beyond Gerota fascia			
	T3a	Tumour extends into the renal vein or its segmental branches, or invades the pelvicalyceal system or invades perirenal and/or renal sinus fat*, but not beyond Gerota fascia*		
	T3b	Tumour grossly extends into the vena cava below diaphragm		
	T3c	Tumour grossly extends into vena cava above the diaphragm or invades the wall of the vena cava		
T4	Tumour invades beyond Gerota fascia (including contiguous extension into the ipsilateral adrenal gland)			
N - Regional Lymph Nodes				
NX	Regional lymph nodes cannot be assessed			
N0	No regional lymph node metastasis			
N1	Metastasis in regional lymph node(s)			
M - Distant metastasis				
M0	No distant metastasis			
M1	Distant metastasis			
pTNM stage grouping				
Stage I	T1	N0	M0	
Stage II	T2	N0	M0	
Stage III	T3	N0	M0	
	T1, T2, T3	N1	M0	
Stage IV	T4	Any N	M0	
	Any T	Any N	M1	

A help desk for specific questions about TNM classification is available at http://www.uicc.org/tnm.
**Adapted based on the American Joint Committee on Cancer (AJCC), 8th Edn. 2017 [94].*

4.2 Anatomic classification systems

Objective anatomic classification systems, such as the Preoperative Aspects and Dimensions Used for an Anatomical (PADUA) classification system, the R.E.N.A.L. nephrometry score, the C-index, an Arterial Based Complexity (ABC) Scoring System and Zonal NePhRO scoring system, have been proposed to standardise the description of renal tumours [95-97]. These systems include assessment of tumour size, exophytic/endophytic properties, proximity to the collecting system and renal sinus, and anterior/posterior or lower/upper pole location.

The use of such a system is helpful as it allows objective prediction of potential morbidity of NSS and tumour ablation techniques. These tools provide information for treatment planning, patient counselling, and comparison of PN and tumour ablation series. However, when selecting the most optimal treatment option, anatomic scores must be considered together with patient features and surgeon experience.

5. DIAGNOSTIC EVALUATION

5.1 Symptoms

Many renal masses remain asymptomatic until the late disease stages. The majority of RCCs are detected incidentally by non-invasive imaging investigating various non-specific symptoms and other abdominal diseases [98] (LE: 3). In a prospective observational cohort study, 60% of patients overall, 87% of patients with stage 1a renal tumours and 36% of patients with stage III or IV disease presented incidentally [99]. The classic triad of flank pain, visible haematuria, and palpable abdominal mass is rare (6-10%) and correlates with aggressive histology, advanced disease, and poorer outcomes [99-101] (LE: 3). Paraneoplastic syndromes are found in approximately 30% of patients with symptomatic RCCs [102] (LE: 4). Some symptomatic patients present with symptoms caused by metastatic disease, such as bone pain or persistent cough [103] (LE: 3).

*5.1.1 **Physical examination***

Physical examination has a limited role in RCC diagnosis. However, the following findings should prompt radiological examinations:

- palpable abdominal mass;
- palpable cervical lymphadenopathy;
- non-reducing varicocele and bilateral lower extremity oedema, which suggests venous involvement.

*5.1.2 **Laboratory findings***

Commonly assessed laboratory parameters are serum creatinine, glomerular filtration rate (GFR), complete cell blood count, erythrocyte sedimentation rate, liver function study, alkaline phosphatase, lactate dehydrogenase (LDH), serum corrected calcium [104], coagulation study, and urinalysis (LE: 4). For central renal masses abutting or invading the collecting system, urinary cytology and possibly endoscopic assessment should be considered in order to exclude urothelial cancer (LE: 4).

Split renal function should be estimated using renal scintigraphy in the following situations [105, 106] (LE: 2b):

- when renal function is compromised, as indicated by increased serum creatinine or significantly decreased GFR;
- when renal function is clinically important; e.g., in patients with a solitary kidney or multiple- or bilateral tumours.

Renal scintigraphy is an additional diagnostic option in patients at risk of future renal impairment due to comorbid disorders.

5.2 Imaging investigations

Most renal tumours are diagnosed by abdominal US or CT performed for other medical reasons [98] (LE: 3). Renal masses are classified as solid or cystic based on imaging findings.

*5.2.1 **Presence of enhancement***

With solid renal masses, the most important criterion for differentiating malignant lesions is the presence of enhancement [107] (LE: 3). Traditionally, US, CT and MRI are used for detecting and characterising renal masses. Most renal masses are diagnosed accurately by imaging alone.

*5.2.2 **Computed tomography or magnetic resonance imaging***

Computed tomography or MRI are used to characterise renal masses. Imaging must be performed unenhanced, in an early arterial phase, and in a parenchymal phase with intravenous contrast material to demonstrate enhancement. In CT imaging, enhancement in renal masses is determined by comparing Hounsfield units (HU) before, and after, contrast administration. A change of fifteen HU, or more, in the solid tumour parts demonstrates enhancement and thus vital tumour parts [108] (LE: 3). Computed tomography or MRI allows accurate diagnosis of RCC but cannot reliably distinguish oncocytoma and fat-free AML from malignant renal neoplasms [109-112] (LE: 3). Abdominal CT provides information on [113]:

- function and morphology of the contralateral kidney [114] (LE: 3);
- primary tumour extension;
- venous involvement;
- enlargement of locoregional LNs;
- condition of the adrenal glands and other solid organs (LE: 3).

Abdominal contrast-enhanced CT angiography is useful in selected cases when detailed information on the renal vascular supply is needed [115, 116]. If the results of CT are indeterminate, CEUS is a valuable alternative to further characterise renal lesions [117-120] (LE: 1b).

Magnetic resonance imaging may provide additional information on venous involvement if the extent of an IVC tumour thrombus is poorly defined on CT [121-124] (LE: 3). In MRI, especially high-resolution T2-weighted images provide a superior delineation of the uppermost tumour thrombus, as the inflow of the enhanced blood may be reduced due to extensive occlusive tumour thrombus growth in the IVC. The T2-weighted image with its intrinsic contrast allows a good delineation [124].

Magnetic resonance imaging is indicated in patients who are allergic to intravenous CT contrast medium and in pregnancy without renal failure [124, 125] (LE: 3). Magnetic resonance imaging allows the evaluation of a dynamic enhancement without radiation exposure. Advanced MRI techniques such as diffusion-weighted (DWI) and perfusion-weighted imaging are being explored for renal mass assessment [126]. Recently, the use of multiparametric MRI (mpMRI) to diagnose ccRCC via a clear cell likelihood score (ccLS) in SRMs was reported [127]. The ccLS is a 5-tier classification that denotes the likelihood of a mass representing ccRCC, ranging from 'very unlikely' to 'very likely'. The authors prospectively validated the diagnostic performance of ccLS in 57 patients with cT1a tumours and found a high diagnostic accuracy. The diagnostic performance of mpMRI-based ccLS was further validated in a larger retrospective cohort (n = 434) across all tumour sizes and stages [128], and ccLS was found to be an independent prognostic factor for identifying ccRCC.

For the diagnosis of complex renal cysts (Bosniak IIF–III) MRI may be preferable. The accuracy of CT is limited in these cases, with poor sensitivity (36%) and specificity (76%; κ = 0.11); MRI, due to a higher sensitivity for enhancement, showed a 71% sensitivity and 91% specificity (κ = 0.64). Contrast-enhanced US showed high sensitivity (100%) and specificity (97%), with a negative predictive value of 100% (κ = 0.95) [74].

In younger patients who are worried about the radiation exposure of frequent CT scans, MRI may be offered as alternative although only limited data exist correlating diagnostic radiation exposure to the development of secondary cancers [129].

A SR and meta-analysis [130] compared the diagnostic performance of CEUS vs. contrast-enhanced CT (CECT) and contrast-enhanced MRI (CEMRI) in the assessment of benign and malignant cystic and solid renal masses. Sixteen studies were included in the pooled analysis. The results suggested comparable diagnostic performance of CEUS compared with CECT (pooled sensitivity 0.96 [95% CI: 0.94-0.98], vs. 0.90 [95% CI: 0.86-0.93], for studies with a final diagnosis of benign or malignant renal masses by pathology), and CEUS vs. CEMRI (pooled sensitivity 0.98 [95% CI: 0.94-1.0], vs. 0.78 [95% CI: 0.66-0.91], for studies with final diagnosis by pathology report or reaffirmed diagnosis by follow-up imaging without pathology report). However, there were significant limitations in the data, including very few studies for CEMRI, clinical and statistical heterogeneity and inconsistency, and high risks of confounding.

*5.2.3 **Other investigations and emerging technologies***

Renal arteriography and inferior venacavography have a limited role in the work-up of selected RCC patients (LE: 3). In patients with any sign of impaired renal function, an isotope renogram and total renal function evaluation should be considered to optimise treatment decision-making [105, 106] (LE: 2a). 18FDG Positron-emission tomography (PET) is not recommended in primary staging. [117, 131] (LE: 1b).

Emerging technologies for differentiation of RCC subtypes has a growing body of evidence with regard to prostate-specific membrane antigen (PSMA) positron emission tomography (PET)-CT [132], ^{99}TC sestamibi SPECT/CT and ^{89}Zr-DFO-Girentuximab PET-CT [39, 40, 133]. Additionally some of these modalities are being evaluated for staging purposes [40]. Currently, the level of published evidence is not sufficient in terms of external validation to allow any guideline recommedation to be made.

*5.2.4 **Radiographic investigations to evaluate RCC metastases***

Chest CT is accurate for chest staging [90, 91, 134-136] (LE: 3). Use of nomograms to calculate risk of lung metastases have been proposed based on tumour size, clinical stage and presence of systemic symptoms [137, 138]. These are based on large, retrospective datasets, and suggest that chest CT may be omitted in patients with cT1a and cN0, and without systemic symptoms, anaemia or thrombocythemia, due to the low incidence of lung metastases (< 1%) in this group of patients. There is a consensus that most bone metastases are symptomatic at diagnosis; thus, routine bone imaging is not generally indicated [134, 139, 140] (LE: 3). However, bone scan, brain CT, or MRI may be used in the presence of specific clinical or laboratory signs and symptoms [139, 141, 142] (LE: 3). A prospective comparative blinded study involving 92 consecutive mRCC patients treated

with first-line vascular endothelial growth factor receptor (VEGFR)-tyrosine kinase inhibitor (TKI) (median follow-up 35 months) found that whole-body DWI/MRI detected a statistically significant higher number of bony metastases compared with conventional thoraco-abdomino-pelvic contrast-enhanced CT, with higher number of metastases being an independent prognostic factor for progression-free survival (PFS) and overall survival (OS) [143].

The incidence of brain metastasis without neurological symptoms was retrospectively evaluated in 1,689 mRCC patients, selected to be included in 68 clinical trials between 2001-2013 [144]. All patients had a mandatory brain screening by CT/MRI. Seventy-two patients (4.3%) were diagnosed with occult brain metastases, of whom 39% multi-focal. Most patients (61%) were International Metastatic Renal Cancer Database Consortium (IMDC) intermediate risk and 26% were favourable risk. A majority (86%) of the patients had > 2 extracranial metastatic sites, including lung metastases in 92%. After predominantly radiotherapy, performed in 93% of patients, a median OS of 10.3 months (range 7.0–17.9 months) was observed.

*5.2.5 **Bosniak classification of renal cystic masses***

This system classifies renal cysts into five categories, based on CT imaging appearance, to predict malignancy risk [145, 146] (LE: 3), and also advocates treatment for each category (Table 5.1). An updated Bosniak classification (2019) strengthened the classification and included MRI diagnostic criteria [75]; however, it requires further validation. According to a Meta-analysis based on 471 patients, the risk of maliganacy of Bosniak IIF-III, may be higher than with the old classification [147]. Until further validation, the imaging report should therefore identify which classification has been used. Lastly, the management of cystic renal tumours is also discussed in Section 3.5.8.

Table 5.1: Bosniak classification of renal cysts updated 2019 [75]

Bosniak classification / Imaging modality	**CT**	**MRI**
1 (Benign)	Well-defined, thin (≤ 2 mm) smooth wall; homogeneous simple fluid (-9 to 20 HU); no septa or calcifications; the wall may enhance	Well-defined, thin (≤ 2 mm) smooth wall; homogeneous simple fluid (signal intensity similar to CSF); no septa or calcifications; the wall may enhance
2 (Benign)	1. Cystic masses with thin (≤ 2 mm) and few (1–3) septa; septa and wall may enhance; may have calcification of any type 2. Homogeneous hyperattenuating (≥ 70 HU) masses at non-contrast CT 3. Homogeneous non-enhancing masses. 20 HU at renal mass protocol CT, may have calcification of any type† 4. Homogeneous masses -9 to 20 HU at non-contrast CT 5. Homogeneous masses 21 to 30 HU at portal venous phase CT 6. Homogeneous low-attenuation masses that are too small to characterise	1. Cystic masses with thin (≤ 2 mm) and few (1-3) enhancing septa; any non-enhancing septa; may have calcification of any type 2. Homogeneous masses markedly hyperintense at T2-weighted imaging (similar to CSF) at non-contrast MRI 3. Homogeneous masses markedly hyperintense at T1-weighted imaging (approximately 32.5 normal parenchymal signal intensity) at non-contrast MRI

2F (Follow-up, up to five years. Some are malignant.)	Cystic masses with a smooth minimally thickened (3 mm) enhancing wall, or smooth minimal thickening (3 mm) of one or more enhancing septa, or many (≥ 4 mm) smooth thin (≤ 2 mm) enhancing septa	1. Cystic masses with a smooth minimally thickened (3 mm) enhancing wall, or smooth minimal thickening (3 mm) of one or more enhancing septa, or many (≥ 4 mm) smooth thin (≤2 mm) enhancing septa 2. Cystic masses that are heterogeneously hyperintense at unenhanced fat-saturated T1-weighted imaging
3 (Surgery or AS – see Chapter 7. Over 50% are malignant.)	One or more enhancing thick (≥ 4 mm width) or enhancing irregular (displaying ≤ 3 mm obtusely margined convex protrusion[s]) walls or septa	One or more enhancing thick (≥ 4 mm width) or enhancing irregular (displaying ≤ 3 mm obtusely margined convex protrusion[s]) walls or septa
4 (Surgery. Most are malignant.)	One or more enhancing nodule(s) (≥4 mm convex protrusion with obtuse margins, or a convex protrusion of any size that has acute margins	One or more enhancing nodule(s) (≥4 mm convex protrusion with obtuse margins, or a convex protrusion of any size that has acute margins)

5.3 Renal tumour biopsy

*5.3.1 **Indications and rationale***

Percutaneous renal tumour biopsy can reveal histology of radiologically indeterminate renal masses and can be considered in patients who are candidates for AS of small masses, to obtain histology before ablative treatments, and to select the most suitable medical and surgical treatment strategy in the setting of metastatic disease [148-153] (LE: 3).

A multicentre study assessing 542 surgically removed SRMs showed that the likelihood of benign findings at pathology is significantly lower in centres where biopsies are performed (5% vs. 16%), suggesting that biopsies can reduce surgery for benign tumours and the potential for short-term and long-term morbidity associated with these procedures [154]. In a recent series of patients who underwent a percutaneous biopsy for a SRM, active treatment (surgery or cryotherapy) was avoided in 50/182 patients (27.5%) because of a benign diagnosis at biopsy [155].

Renal biopsy is not indicated in comorbid and frail patients who can be considered only for conservative management (watchful waiting) regardless of biopsy results. Due to the high diagnostic accuracy of abdominal imaging, renal tumour biopsy is not necessary in patients with a contrast-enhancing renal mass for whom surgery is planned (LE: 4).

Core biopsies of cystic renal masses have a lower diagnostic yield and accuracy and are not recommended, unless areas with a solid pattern are present (Bosniak IV cysts) [148, 151, 156] (LE: 2b/3). Histological characterisation by percutaneous biopsy of undefined retroperitoneal masses at imaging may be useful for decision making, especially in the younger patient population.

*5.3.2 **Technique***

Percutaneous sampling can be performed under local anaesthesia with needle core biopsy and/or fine needle aspiration (FNA). Biopsies can be performed under US or CT guidance, with a similar diagnostic yield [151, 157] (LE: 2b). Eighteen-gauge needles are ideal for core biopsies, as they result in low morbidity and provide sufficient tissue for diagnosis [148, 152, 158] (LE: 2b). A coaxial technique allowing multiple biopsies through a coaxial cannula should always be used to avoid potential tumour seeding [148, 152] (LE: 3).

Core biopsies are preferred for the characterisation of solid renal masses while a combination with FNA can provide complimentary results and improve accuracy for complex cystic lesions [156, 159, 160] (LE: 2a). A SR and meta-analysis of the diagnostic performance and complications of renal tumour biopsy was performed by the Panel, including 57 publications and a total of 5,228 patients. Needle core biopsies were found to have better accuracy for the diagnosis of malignancy compared with FNA [156]. Other studies showed that solid pattern, larger tumour size and exophytic location are predictors of a diagnostic core biopsy [148, 151, 157] (LE: 2b).

*5.3.3 **Diagnostic yield and accuracy***

In experienced centres, core biopsies have a high diagnostic yield, specificity, and sensitivity for the diagnosis of malignancy. The above-mentioned meta-analysis showed that sensitivity and specificity of diagnostic core

biopsies for the diagnosis of malignancy are 99.1% and 99.7%, respectively [156] (LE: 2b). However, 0–22.6% of core biopsies are non-diagnostic (8% in the meta-analysis) [149-153, 157, 158, 161] (LE: 2a). If a biopsy is non-diagnostic, and radiologic findings are suspicious for malignancy, a further biopsy or surgical exploration should be considered (LE: 4). Repeat biopsies have been reported to be diagnostic in a high proportion of cases (83–100%) [148, 162-164].

Accuracy of renal tumour biopsies for the diagnosis of tumour histotype is good. The median concordance rate between tumour histotype on renal tumour biopsy and on the surgical specimen of the following PN or RN was 90.3% in the pooled analysis [156].

Assessment of tumour grade on core biopsies is challenging. In the pooled analysis the overall accuracy for nuclear grading was poor (62.5%), but significantly improved (87%) using a simplified two-tier system (high vs. low grade) [156] (LE: 2a).

The ideal number and location of core biopsies are not defined. However, at least two good quality cores should be obtained and necrotic areas should be avoided to maximise diagnostic yield [148, 151, 165, 166] (LE: 2b). Peripheral biopsies are preferable for larger tumours, to avoid areas of central necrosis [167] (LE: 2b). In cT2 or greater renal masses, multiple core biopsies taken from at least four separate solid enhancing areas in the tumour were shown to achieve a higher diagnostic yield and a higher accuracy to identify sarcomatoid features, without increasing the complication rate [168].

*5.3.4 **Morbidity***

Overall, percutaneous biopsies have a low morbidity [156]. Tumour seeding along the needle tract has been regarded as anecdotal in large series and pooled analyses on renal tumour biopsies. Especially the coaxial technique has been regarded as a safe method to avoid any seeding of tumour cells. However, authors recently reported on seven patients in whom tumour seeding was identified on histological examination of the resection specimen after surgical resection of RCC following diagnostic percutaneous biopsy [169]. Six of the seven cases were of the pRCC type. The clinical significance of these findings is still uncertain but only one of these patients developed local tumour recurrence at the site of the previous biopsy [169].

Spontaneously resolving subcapsular/perinephric haematomas are reported in 4.3% of cases in a pooled analysis, but clinically significant bleeding is unusual (0-1.4%; 0.7% in the pooled analysis) and generally self-limiting [156].

Percutaneous biopsy of renal hilar masses is technically feasible with a diagnostic yield similar to that of cortical masses, but with significantly higher post-procedural bleeding compared with cortical masses [170].

*5.3.5 **Genetic assessment***

Renal cancer can be related to an inherited or *de novo* monogenic germline alteration and this recognition has significant implications [171]. Hereditary kidney cancer is thought to account for 5-8% of all kidney cancer cases, although this number is likely an underestimation since a more recent study found germline mutations in up to 38% of all metastatic kidney cancer patients [172] (see Section 3.4.4. - Hereditary kidney tumours). Patients with a germline predisposition to kidney cancer often require multidisciplinary approaches, it is critical for clinicians to be familiar with how and when referral for counselling is warranted, methods of genetic testing, implications of the findings, screening of at-risk (non-renal) organs, and the screening protocol for family members. Well-defined renal cancer management strategies exist, and specific therapeutic strategies are available or in development (see Section 3.4.4). Lack of a syndromic manifestation does not exclude a genetic contribution to cancer development. Moreover, other genetic components or polymorphisms are heritable and may confer a mildly increased risk. When several risk alleles are present, they can significantly increase cancer risk.

Many factors are associated with an increased risk of hereditary renal cancer syndromes. For instance, even in the absence of clinical manifestations and personal/family history, an age of onset of 46 years or younger should trigger consideration for genetic counselling/germline mutation testing [46]. Moreover, presence of bilateral or multifocal tumours/cysts and/or a first- or second-degree relative with RCC and/or a close blood relative with a known pathogenic variant significantly increases the risk to detect hereditary cancer. The presence of renal cysts can be associated with BHD and VHL, and form part of the clinical diagnostic spectrum. Moreover, specific histologic characteristics can support differential diagnosis of a particular RCC syndrome (e.g., multifocal papillary histology, hereditary fumarate hydratase-deficient RCC, RCC with fumarate hydratase deficiency, multiple chromophobe, oncocytoma or oncocytic hybrid, succinate dehydrogenase-deficient RCC histology). Finally, additional tuberous sclerosis complex criteria should be assessed in individuals with AML [46, 173-181].

If additional risk factors are established in a patient, referral to a comprehensive clinical care centre, or a hospital with demonstrated expertise in managing hereditary cancer syndromes, will provide a dedicated working team, tailored clinical decisions, research translational programme, appropriate patient psychosocial support, and prospective collection of clinical data and biological samples. This can contribute to a better patient's care and further improvements in cancer care.

5.4 Summary of evidence and recommendations for the diagnostic assessment of RCC

Summary of evidence	LE
Contrast enhanced multi-phasic CT has a high sensitivity and specificity for characterisation and detection of RCC, invasion, tumour thrombus and mRCC.	2a
Magnetic resonance imaging has a slightly higher sensitivity and specificity for small cystic renal masses and tumour thrombi as compared to CT.	2a
Contrast enhanced US has a high sensitivity and specificity for characterisation of renal masses.	2a
Renal mass biopsies are associated with reduced overtreatment of benign masses and offers patients additional information (i.e. grade, subtype) for an informed decision regarding optimal management.	3
Ultrasound, power-Doppler US and positron-emission tomography CT have a low sensitivity and specificity for detection and characterisation of RCC.	2a

Recommendations	Strength rating
Use multi-phasic contrast-enhanced computed tomography (CT) of abdomen and chest for the diagnosis and staging of renal tumours.	Strong
Omit chest CT in patients with incidentally noted cT1a disease due to the low risk of lung metastases in this cohort.	Weak
Use magnetic resonance imaging (MRI) to better evaluate venous involvement, reduce radiation or avoid intravenous CT contrast medium.	Weak
Use non-ionising modalities, including MRI and contrast-enhanced ultrasound, for further characterisation of small renal masses, tumour thrombus and differentiation of unclear renal masses, in case the results of contrast-enhanced CT are indeterminate.	Strong
Offer brain CT/MRI in metastatic patients when systemic therapy or cytoreductive nephrectomy is considered.	Weak
Do not routinely use bone scan and/or positron-emission tomography CT for staging of renal cell carcinoma.	Weak
Perform a renal tumour biopsy before ablative therapy and systemic therapy without previous pathology.	Strong
Perform a percutaneous biopsy in select patients who are considering active surveillance.	Weak
Use a coaxial technique when performing a renal tumour biopsy.	Strong
Do not perform a renal tumour biopsy of cystic renal masses unless a significant solid component is visible at imaging.	Strong
Use a core biopsy technique rather than fine needle aspiration for histological characterisation of solid renal tumours.	Strong

5.5 Summary of evidence and recommendations for genetic assessment of RCC

Summary of evidence	LE
Hereditary kidney cancer is thought to account for 5-8% of all kidney cancer cases, though that number is likely an underestimate.	3
In case of renal cancer, if patient's age is 46 years or younger, and/or with bilateral or multifocal tumours and/or with a first or second-degree relative with RCC and/or with a close blood relative with a known pathogenic variant and/or with specific histologic characteristics (see text), the risk of hereditary cancer is significantly higher.	3
Hereditary RCC detection has unique implications for decision-making and follow-up.	3

Recommendations	Strength rating
Perform a genetic evaluation in patients aged ≤ 46 years, with bilateral or multifocal tumours and/or a first- or second-degree relative with RCC and/or a close blood relative with a known pathogenic variant and/or specific histologic characteristics which suggest the presence of a hereditary form of RCC.	Strong
Refer patients to a cancer geneticist or to a Comprehensive Clinical Care Centre in case of suspected hereditary RCC.	Strong

6. PROGNOSTIC FACTORS

6.1 Classification

Prognostic factors can be classified into: anatomical, histological, clinical, and molecular.

6.2 Anatomical factors

Tumour size, venous invasion and extension, collecting system invasion, perinephric- and sinus fat invasion, adrenal involvement, and LN and distant metastasis are included in the TNM classification system [182, 183] (Table 4.1).

6.3 Histological factors

Histological factors include tumour grade, RCC subtype, lymphovascular invasion, tumour necrosis, and invasion of the collecting system [184, 185]. Tumour grade is considered one of the most important histological prognostic factors. Fuhrman nuclear grade [186] has now been replaced by the WHO/ISUP grading classification [187]. This relies solely on nucleolar prominence for grade 1-3 tumours, allowing for less inter-observer variation [188]. It has been shown that the WHO/ISUP grading provides superior prognostic information compared to Fuhrman grading, especially for grade 2 and grade 3 tumours [189]. Rhabdoid and sarcomatoid changes can be found in all RCC types and are equivalent to grade 4 tumours. Sarcomatoid changes are more often found in chRCC than other subtypes [190]. The percentage of the sarcomatoid component appears to be prognostic as well, with a larger percentage of involvement being associated with worse survival. There is no agreement on the optimal prognostic cut-off for sub-classifying sarcomatoid changes [191, 192], although 20% has been suggested to distinguish focal and extensive amount of sarcomatoid features [193]. The WHO/ISUP grading system is applicable to both ccRCC and pRCC. It is currently not recommended to grade chRCC. However, a recent study suggested a two-tiered chRCC grading system (low vs. high grade) based on the presence of sarcomatoid differentiation and/or tumour necrosis, which was statistically significant on multivariable analysis [194]. Both the WHO/ISUP and chRCC grading systems need to be validated for prognostic systems and nomograms [187].

Renal cell carcinoma subtype is regarded as another important prognostic factor. On univariable analysis, patients with chRCC vs. pRCC vs. ccRCC had a better prognosis [195, 196] (Table 6.1). However, prognostic information provided by the RCC type is lost when stratified according to tumour stage [196, 197] (LE: 3).

In a recent cohort study of 1,943 patients with ccRCC and pRCC significant survival differences were only shown between pRCC type I and ccRCC [198]. Papillary RCC has been traditionally divided into type 1 and 2, but a subset of tumours shows mixed features. For more details, see Section 3.2 – Histological diagnosis. Data also suggest that type 2 pRCC is a heterogeneous entity with multiple molecular subgroups [199]. Some studies suggest poorer survival for type 2 than type 1 [200], but this association is often lost in the multivariable analysis [201]. A meta-analysis did not show a significant survival difference between both types [202, 203].

TFE3 re-arranged RCC (formerly called RCC with Xp11.2 translocation) has a poor prognosis [204]. Its incidence is low, but its presence should be systematically assessed in young patients. Renal cell carcinoma type classification has been confirmed by cytogenetic and genetic analyses [205-207] (LE: 2b). Surgically excised malignant complex cystic masses contain ccRCC in the majority of cases, and more than 80% are pT1. In a recent series, 5-year CSS was 98% [208]. Differences in tumour stage, grade and CSS between RCC types are illustrated in Table 6.1.

Table 6.1: Baseline characteristics and cancer-specific survival of surgically treated patients by RCC type [145]

Survival time	% RCC	% Sarcomatoid	% T3-4	% N1	% M1	% 10 year CSS (%)
Clear-cell RCC	80	5	33	5	15	62
Papillary RCC	15	1	11	5	3	86
Chromophobe RCC	5	8	15	4	4	86

CSS = cancer-specific survival.

In all RCC types, prognosis worsens with stage and histopathological grade (Table 6.2). The 5-year OS for all types of RCC is 49%, which has improved since 2006, probably due to an increase in incidentally detected RCCs and new systemic treatments [209, 210]. Although not considered in the current N classification, the number of metastatic regional LNs is an important predictor of survival in patients without distant metastases [211].

Table 6.2: Cancer-specific survival by stage [212]

Grade	HR (95% CI)
T1N0M0	Referent
T2N0M0	2.71 (2.17–3.39)
T3N0M0	5.20 (4.36–6.21)
T4N0M0	16.88 (12.40–22.98)
N+M0	16.33 (12.89–20.73)
M+	33.23 (28.18–39.18)

CI = confidence interval; HR = hazard ratio.

6.4 Clinical factors

Clinical factors include performance status (PS), local symptoms, cachexia, anaemia, platelet count, neutrophil count, lymphocyte count, C-reactive protein (CRP) [213], albumin, and various indices deriving from these factors such as the neutrophil-to-lymphocyte ratio (NLR) [103, 214-219] (LE: 3). As a marker of systemic inflammatory response, a high pre-operative NLR has been associated with poor prognosis [220], but there is significant heterogeneity in the data and no agreement on the optimal prognostic cut-off. Even though obesity is an aetiological factor for RCC, it has also been observed to provide prognostic information. A high body mass index (BMI) appears to be associated with improved survival outcomes in both non-metastatic and metastatic RCC [221-223]. This association is linear with regards to cancer-specific mortality (CSM), while obese RCC patients show increasing all-cause mortality with increasing BMI [224]. There is also evolving evidence on the prognostic value of body composition indices measured on cross-sectional imaging, such as sarcopenia and fat accumulation [219, 225, 226].

6.5 Molecular factors

Numerous molecular markers such as carbonic anhydrase IX (CaIX), VEGF, HIF, Ki67 (proliferation), p53, p21 [227], PTEN (phosphatase and tensin homolog) cell cycle [228], E-cadherin, osteopontin [229] CD44 (cell adhesion) [230, 231], CXCR4 [232], PD-L1 [233], miRNA, SNPs, gene mutations, and gene methylations have been investigated (LE: 3) [234]. While the majority of these markers are associated with prognosis and many improve the discrimination of current prognostic models, there has been very little emphasis on external validation studies. Furthermore, there is no conclusive evidence on the value of molecular markers for treatment selection in mRCC [213, 233, 235]. Their routine use in clinical practice is therefore not recommended.

Several prognostic and predictive marker signatures have been described for specific systemic treatments in mRCC. In the JAVELIN Renal 101 trial (NCT02684006), a 26-gene immunomodulatory gene signature predicted PFS in those treated with avelumab plus axitinib, while an angiogenesis gene signature was associated with PFS for sunitinib. Mutational profiles and histocompatibility leukocyte antigen (HLA) types were also associated with PFS, while programmed death-ligand 1 (PD-L1) expression and tumour mutational burden were not [236]. In IMmotion151 (NCT02420821), a T effector/IFN-γ-high or angiogenesis-low gene expression signature predicted improved PFS for atezolizumab plus bevacizumab compared to sunitinib. The angiogenesis-high gene expression signature correlated with longer PFS in patients treated with sunitinib [237]. In CheckMate 214 (NCT02231749), a higher angiogenesis gene signature score was associated with better overall response rates

and PFS for sunitinib, while a lower angiogenesis score was associated with higher ORR in those treated with nivolumab plus ipilimumab. Progression-free survival > 18 months was more often seen in patients with higher expression of Hallmark inflammatory response and Hallmark epithelial mesenchymal transition gene sets [219].

Urinary and plasma Kidney-Injury Molecule-1 (KIM-1) has been identified as a potential diagnostic and prognostic marker. KIM-1 concentrations were found to predict RCC up to five years prior to diagnosis and were associated with a shorter survival time [238]. KIM-1 is a glycoprotein marker of acute proximal tubular injury and therefore mainly expressed in RCC derived from the proximal tubules such as ccRCC and pRCC [239]. While early studies are promising, more high-quality research is required. Several retrospective studies and large molecular screening programmes have identified mutated genes and chromosomal changes in ccRCC with distinct clinical outcomes. The expression of the BAP1 and PBRM1 genes, situated on chromosome 3p in a region that is deleted in more than 90% of ccRCCs, have shown to be independent prognostic factors for tumour recurrence [240-242]. These published reports suggest that patients with BAP1- mutant tumours have worse outcomes compared with patients with PBRM1-mutant tumours [241]. Loss of chromosome 9p and 14q have been consistently shown to be associated with poorer survival [243-245]. The TRACERx renal consortium has proposed a genetic classification based on RCC evolution (punctuated vs. branched vs. linear), which correlates with tumour aggressiveness and survival [244]. Additionally, a 16-gene signature was shown to predict disease-free survival (DFS) in patients with non-metastatic RCC [246]. However, these signatures have not been validated by independent researchers yet.

6.6 Prognostic models

Prognostic models combining independent prognostic factors have been developed and externally validated [247-254]. These models are more accurate than TNM stage or grade alone for predicting clinically relevant oncological outcomes (LE: 3). Before being adopted, new prognostic models should be evaluated and compared to current prognostic models with regards to discrimination, calibration and net benefit. Pathological prognostic factors are used in the Leibovich 2003 score/groups for clear cell [250]. There are prognostic models for non-clear cell RCC, like the VENUSS score for papillary RCC [201]. Although both were validated in several studies and showed superior discrimination to other prognostic models, molecular markers are needed [255-258]. In metastatic disease, risk groups assigned by the Memorial Sloan Kettering Cancer Centre (MSKCC) (primarily created in the pre-targeted therapy era and validated in patients receiving targeted therapy) and the IMDC (initially created in the targeted therapy era) differ in 23% of cases [259]. The IMDC model has been used in most of the recent RCTs, including those with immune checkpoint inhibitors (ICIs), and may therefore be the preferred model for clinical practice. The discrimination of the IMDC models improves by additional variables, such as presence of brain metastasis, bone metastasis, liver metastasis, NLR and platelet count [260-263]. Tables 6.3 and 6.4 summarise the current most relevant prognostic models.

6.7 Summary of evidence and recommendations for prognostic factors

Summary of evidence	LE
In RCC patients, TNM stage, tumour size, grade, and RCC subtype provide important prognostic information.	2a
The 2003 Leibovich score is a validated prognostic model to predict the short- and long-term risk of metastasis in individual patients with sporadic, unilateral pT1-4 N0/+ M0 clear cell renal cell carcinoma.	2b
The VENUSS score is a validated prognostic model to predict the short- and long-term risk of disease recurrence in individual patients with sporadic, unilateral pT1-4 N0/+ M0 papillary renal cell carcinoma.	2b

Recommendations	Strength rating
Use the current Tumour, Node, Metastasis classification system.	Strong
Use the WHO/ISUP grading system and classify renal cell carcinoma type.	Strong
Use prognostic models in localised and metastatic disease.	Strong
Use the 2003 Leibovich scoring model for risk stratification of localised and locally advanced clear cell renal cell carcinoma.	Weak
Use the VENUSS scoring model for risk stratification of localised and locally advanced papillary renal cell carcinoma.	Weak
Do not routinely use molecular markers to assess prognosis.	Strong

7. DISEASE MANAGEMENT

7.1 Treatment of localised RCC

7.1.1 ***Introduction***

Sections 7.1.2 and 7.2.4.2 are underpinned by a SR which includes all relevant published literature comparing surgical management of localised RCC (T1–2N0M0). Randomised or quasi-RCTs were included. However, due to the very limited number of RCTs, non-randomised studies (NRS), prospective observational studies with controls, retrospective matched-pair studies, and comparative studies from the databases of well-defined registries were also included. Historically, surgery has been the benchmark for the treatment of localised RCC.

*7.1.2 **Surgical treatment***

7.1.2.1 Nephron-sparing surgery versus radical nephrectomy in localised RCC

7.1.2.1.1 T1 RCC

Outcome 1: Cancer-specific survival

Most studies comparing the oncological outcomes of PN and RN are retrospective and include cohorts of varied and, overall, limited size [270, 271]. There is only one, prematurely closed, prospective RCT including patients with organ-confined RCCs of limited size (< 5 cm) published, showing comparable non-inferiority of CSS for PN vs. RN (HR: 2.06 [95% CI: 0.62–6.84]) [272].

Outcomes 2 & 3: Overall mortality and renal function

Partial nephrectomy preserved kidney function better after surgery, thereby potentially lowering the risk of development of cardiovascular disorders [270, 273-277]. When compared with a radical surgical approach, several retrospective analyses of large databases have suggested a decreased cardiovascular-specific mortality [274, 278] as well as improved OS for PN compared to RN. However, in some series this held true only for younger patients and/or patients without significant comorbidity at the time of the surgical intervention [279, 280]. An analysis of the U.S. Medicare database [281] could not demonstrate an OS benefit for patients ≥ 75 years of age when RN or PN were compared with non-surgical management.

Conversely, another series that addressed this question and included Medicare patients, suggested an OS benefit in older patients (75-80 years) when subjected to surgery rather than non-surgical management. Shuch *et al.*, compared patients who underwent PN for RCC with a non-cancer healthy control group via a retrospective database analysis; showing an OS benefit for the cancer cohort [282]. These conflicting results may be an indication that unknown statistical confounders hamper the retrospective analysis of population-based tumour registries. In the only prospectively randomised, but prematurely closed, heavily underpowered, trial, PN seems to be less effective than RN in terms of OS in the intention to treat (ITT) population (HR: 1.50 [95% CI: 1.03–2.16]). However, in the targeted RCC population of the only RCT, the trend in favour of RN was no longer significant [272]. Taken together, the OS advantage suggested for PN vs. RN remains an unresolved issue.

Patients with a normal pre-operative renal function and a decreased GFR due to surgical treatment (either RN or PN), generally present with stable long-term renal function [277]. Adverse OS in patients with a pre-existing GFR reduction does not seem to result from further renal function impairment following surgery, but rather from other medical comorbidities causing pre-surgical chronic kidney disease (CKD) [283]. However, in particular in patients with pre-existing CKD, PN is the treatment of choice to limit the risk of development of ESRD which requires haemodialysis. Huang *et al.*, found that 26% of patients with newly diagnosed RCC had an GFR ≤ 60 mL/min, even though their baseline serum creatinine levels were in the normal range [106].

Outcomes 4 & 5: Peri-operative outcomes and quality of life

In terms of the intra- and peri-operative morbidity/complications associated with PN vs. RN, the European Organisation for Research and Treatment of Cancer (EORTC) randomised trial showed that PN for small, easily resectable, incidentally discovered RCC, in the presence of a normal contralateral kidney, can be performed safely with slightly higher complication rates than after RN [284].

Only a limited number of studies are available addressing quality of life (QoL) following PN vs. RN, irrespective of the surgical approach used (open vs. minimally invasive). Quality of life was ranked higher following PN as compared to RN, but in general patients' health status deteriorated following both approaches [284, 285].

In view of the above, and since oncological safety (CSS and RFS) of PN, so far, has been found non-differing from RN outcomes, PN is the treatment of choice for T1 RCC since it preserves kidney function better and in the long term PN potentially limits the incidence of cardiovascular disorders and

development of ESRD and the need for haemodialysis. Irrespective of the available data, in frail patients, treatment decisions should be individualised, weighing the risks and benefits of PN vs. RN, the increased risk of peri-operative complications, and the risk of developing or worsening of CKD post-operatively.

7.1.2.1.2 T2 RCC

There is very limited evidence on the optimal surgical treatment for patients with larger renal masses (T2). Some retrospective comparative studies of PN vs. RN for T2 RCC have been published [286]. A trend for lower tumour recurrence- and CSM is reported in PN groups. The estimated blood loss is reported to be higher for PN groups, as is the likelihood of post-operative complications [286]. A multicentre study compared the survival outcomes in patients with larger (> 7 cm) ccRCC treated with PN vs. RN with long-term follow- up (median 102 months). Compared to the RN group, the PN group had a significantly longer median OS (p = 0.014) and median CSS (p = 0.04) [287]. Retrospective comparative studies of cT1 and cT2 RCC patients upstaged to pT3a RCC show contradictory results: some reports suggest similar oncologic outcomes between PN and RN [288], whilst another recent report suggests that PN of clinical T1 in pathologically upstaged pT3a of cT1 RCC is associated

with a significantly shorter RFS than RN [289]. Overall, the level of the evidence is low. These studies including T2 masses all have a high risk of selection bias due to imbalance between the PN and RN groups regarding patient's age, comorbidities, tumour size, stage, and tumour position. These imbalances in covariation factors may have a greater impact on patient outcome than the choice of PN or RN. The Panel's confidence in the results is limited and the true effects may be substantially different.

In view of the above, the risks and benefits of PN should be discussed with patients with T2 tumours. In this setting PN should be considered, if technically feasible, in patients with a solitary kidney, bilateral renal tumours or CKD with sufficient parenchymal volume preserved to allow sufficient post-operative renal function.

7.1.2.1.3 T3 RCC

A meta-analysis of nine articles including 1,278 patients with PN and 2,113 patients with RN for pT3a RCC showed no difference in CSS, OS, CSM and RFS, indicating that PN techniques can be used for functional benefits and if technically feasible [290].

7.1.2.2 Associated procedures

7.1.2.2.1 Adrenalectomy

One prospective NRS compared the outcomes of RN with, or without, ipsilateral adrenalectomy [291]. Multivariable analysis showed that upper pole location was not predictive of adrenal involvement, but tumour size was. No difference in OS at five or ten years was seen with, or without, adrenalectomy. Adrenalectomy was justified using criteria based on radiographic- and intra-operative findings. Only 48 of 2,065 patients underwent concurrent ipsilateral adrenalectomy of which 42 of the 48 interventions were for benign lesions [291].

7.1.2.2.2 Lymph node dissection for clinically negative lymph nodes (cN0)

The indication for LN dissection (LND) together with PN or RN is still controversial [292]. The clinical assessment of LN status is based on the detection of an enlargement of LNs either by CT/MRI or intra-operative palpability of enlarged nodes. Less than 20% of suspected metastatic nodes (cN+) are positive for metastatic disease at histopathological examination (pN+) [293]. Both CT and MRI are unsuitable for detecting malignant disease in nodes of normal shape and size [294]. For clinically positive LNs (cN+) see Section 7.2.2.

Smaller retrospective studies have suggested a clinical benefit associated with a more or less extensive LND, preferably in patients at high risk for lymphogenic spread. In a large retrospective study, the outcomes of RN with, or without, LND, in patients with high-risk non-mRCC were compared using a propensity score analysis. In this study LND was not significantly associated with a reduced risk of distant metastases, cancer- specific or all-cause mortality. The extent of the LND was not associated with improved oncologic outcomes [295]. The number of LN metastases (< / > 4) as well as the intra- and extra-capsular extension of intra-nodal metastasis correlated with the patients´ clinical prognosis in some studies [294, 296-298]. Better survival outcomes were seen in patients with a low number of positive LNs (< 4) and no extra-nodal extension. Based on a retrospective Surveillance, Epidemiology and End Results (SEER) database analysis of > 9,000 patients no effects of an extended LND (eLND) on the disease-specific survival (DSS) of patients with pathologically- confined negative nodes was demonstrated [299]. However, in patients with pathologically proven lymphogenic spread (pN+), an increase of 10 for the number of nodes dissected resulted in a 10% absolute increase in DSS.

In addition, in a larger cohort of 1,983 patients, Capitanio *et al.*, demonstrated that eLND results in a significant prolongation of CSS in patients with unfavourable prognostic features (e.g., sarcomatoid differentiation, large tumour size) [300]. As to morbidity related to eLND, a retrospective propensity score analysis from a large single-centre database showed that eLND is not associated with an increased risk of Clavien grade > 3 complications. Furthermore, LND was not associated with length of hospital stay or estimated blood loss [301].

Only one prospective RCT evaluating the clinical value of LND combined with surgical treatment of primary RCC has been published so far. With an incidence of LN involvement of only 4%, the risk of lymphatic spread appears to be very low. Recognising the latter, only a staging effect was attributed to LND [293]. This trial included a very high percentage of patients with pT2 tumours, which are not at increased risk for LN metastases. Only 25% of patients with pT3 tumours underwent a complete LND and the LN template used by the authors was not clearly stated.

The optimal extent of LND remains controversial. Retrospective studies suggest that an eLND should involve the LNs surrounding the ipsilateral great vessel and the inter-aortocaval region from the crus of the diaphragm to the common iliac artery. Involvement of inter-aortocaval LNs without regional hilar involvement is reported in up to 35-45% of cases [294, 302, 303]. At least fifteen LNs should be removed [300, 304]. Sentinel LND is an investigational technique [305, 306].

7.1.2.2.3 Embolisation

Before routine nephrectomy, tumour embolisation has no benefit [307, 308]. In patients unfit for surgery, or with non-resectable disease, embolisation can control symptoms, including visible haematuria or flank pain [309]. These indications will be revisited in Sections 7.2 and 7.3 with cross reference to the summary of evidence and recommendations below.

7.1.2.2.4 Summary of evidence and recommendations for the treatment of localised RCC

Summary of evidence	LE
The oncological outcome in terms of OS following PN equals that of RN in patients with c/p T1 RCC.	1b
Retrospective studies suggest that oncological outcomes are similar following PN vs. RN in patients with larger (≥ 7 cm) RCC. Post-operative complication rates are higher in PN patients.	3b
Ipsilateral adrenalectomy during RN or PN has no survival advantage in the absence of clinically evident adrenal involvement.	3
In patients with localised disease without radiographic evidence of LN metastases, a survival advantage of LND in conjunction with RN is not demonstrated in RCTs.	2b
Retrospective studies suggest a clinical benefit associated with LND in high-risk patients.	2b
In patients unfit for surgery with massive haematuria or flank pain, embolisation can be a beneficial palliative approach.	3

Recommendations	Strength rating
Offer surgery to achieve cure in localised renal cell cancer.	Strong
Offer partial nephrectomy (PN) to patients with T1 tumours.	Strong
Offer PN to patients with T2 tumours and a solitary kidney or chronic kidney disease, if technically feasible.	Weak
Do not perform ipsilateral adrenalectomy if there is no clinical evidence of invasion of the adrenal gland.	Strong
Do not offer an extended lymph node dissection to patients with organ-confined disease.	Weak
Offer embolisation to patients unfit for surgery presenting with massive haematuria or flank pain.	Weak

*7.1.3 **Radical and partial nephrectomy techniques***

7.1.3.1 Radical nephrectomy techniques

7.1.3.1.1 Open versus laparoscopic or robotic approach

No RCTs have assessed the oncological outcomes of laparoscopic vs. open RN. A retrospective comparative study with data retrieved from a national database studying the OS of open vs. minimally-invasive RN (laparoscopic RN or RARN) showed an OS benefit in the minimally invasive RN group, as well as in hospital stay, re-admission rate, and 30-day and 90-day mortality rate [310]. However, a SR did not demonstrate any survival difference in LRN and ORN [311].

Data from one SR [311] and two NRS [312, 313] showed a significantly shorter hospital stay and lower analgesic requirement for the laparoscopic RN group as compared with the open group. Convalescence time was also significantly shorter [313]. Surgical complication rates were low with very wide confidence intervals. There was no difference in complications, but operation time was significantly shorter in the open nephrectomy arm. Quality of life and perioperative outcomes were inconsistently defined, measured, or reported [270, 311] (LE: 2b, based on 1 low quality SR).

7.1.3.1.2 Laparoscopic versus robotic approach

Data of a large retrospective cohort study on robot-assisted laparoscopic vs. laparoscopic RN showed robot-assisted laparoscopic RN was not associated with increased risk of any or major complications but had a longer operating time and higher hospital costs compared with laparoscopic RN [314]. A SR and meta-analysis of seven studies including 1,832 patients showed no difference between the two approaches in peri-operative outcomes, including operative time, blood loss, conversion rates and complications [315]. A SR reported on robot-assisted laparoscopic vs. conventional laparoscopic RN, showing no substantial differences in local recurrence rates, nor in all-cause CSM [316].

7.1.3.1.3 Laparoscopic single port versus laparoscopic multiport approach

Similar results were seen in observational cohort studies comparing 'portless' and 3-port laparoscopic RN, with similar peri-operative outcomes [317, 318].

7.1.3.2 Partial nephrectomy techniques

7.1.3.2.1 Open versus laparoscopic approach

Studies comparing laparoscopic and open PN found no difference in PFS [319-322] and OS [321, 322] in centres with laparoscopic expertise. However, the oncological safety of laparoscopic vs. open PN has, so far, only been addressed in studies with relatively limited follow-up [323]. However, the higher number of patients treated with open surgery in this series might reflect a selection bias by offering laparoscopic surgery in case of a less complex anatomy [323]. The mean estimated blood loss was found to be lower with the laparoscopic approach [319, 321, 324], while post-operative mortality, deep vein thrombosis, and pulmonary embolism events were similar [319, 321]. Operative time is generally longer with the laparoscopic approach [320, 322] and warm ischaemia time is shorter with the open approach [319, 321, 324, 325]. The results for GFR decline are debatable, an RCT reported greater 3-12 months kidney function reduction in the open group [326] whilst in a matched-pair comparison, GFR decline was greater in the laparoscopic PN group in the immediate post-operative period [322], but not after 3.6 years follow-up. In another comparative study, the surgical approach was not an independent predictor for post-operative CKD [325]. Retroperitoneal and transperitoneal laparoscopic PN have similar peri-operative outcomes [327]. Simple tumour enucleation also had similar PFS and CSS rates compared to standard PN and RN in a large study [328]. The feasibility of laparo-endoscopic single-site PN has been shown in selected patients, but larger studies are needed to confirm its safety and clinical role [329].

7.1.3.2.2 Open versus robotic approach

One study prospectively compared the peri-operative outcomes of a series of robot-assisted and open PN performed by the same experienced surgeon. Robot-assisted PN was superior to open PN in terms of lower estimated blood loss and shorter hospital stay. Warm ischaemia time, operative time, immediate- early- and short-term complications, variation in creatinine levels and pathologic margins were similar between groups [330].

A multicentre French prospective database compared the outcomes of 1,800 patients who underwent open PN and robot-assisted PN. Although the follow-up was shorter, there was a decreased morbidity in the robot-assisted PN group with less overall complications, less major complications, less transfusions and a much shorter hospital stay [331].

A SR and meta-analysis comparing RAPN and OPN demonstrated similar short-term functional outcomes, however results are inconsistent [332].

OPERA, a prospective RCT comparing open (OPN) vs. robotic partial nephrectomy (RAPN) in intermediate/high complexity renal tumours (RENAL Score > = 7) prematurely closed due to poor accrual and data have not been fully published [333].

The single-centre, open-label feasibility ROBOCOP II RCT enrolled patients with suspected localised RCC referred for PN and randomised them at a 1:1 ratio to either RAPN or OPN [334]. The primary outcome was the feasibility of recruitment, assessed as the accrual rate. Secondary outcomes included perioperative and post-operative data. Overall, 50 patients underwent RAPN or OPN (accrual rate 65%). In comparison to OPN, RAPN had lower blood loss, less need for opioids, and fewer complications according to the mean Comprehensive Complication Index. OPN has a shorter operative time and warm ischemia time. There were no differences between RAPN and OPN regarding post-operative functional outcomes. Considering the limitations of both prospective trials, the clinical impact of robotic PN is still controversial.

7.1.3.2.3 Open versus hand-assisted approach

Hand-assisted laparoscopic PN (HALPN) is rarely performed. A comparative study of open vs. HALPN showed no difference in OS or RFS at intermediate-term follow-up. The authors observed a lower rate of intra-operative and all-grade post-operative 30-day complications in HALPN vs. open PN patients, but there was no significant difference in high Clavien grade complications. Three months after the operation, GFR was lower in the HALPN than in the open PN group [335].

7.1.3.2.4 Open versus laparoscopic versus robotic approaches

In a retrospective propensity-score-matched study, comparing open-, laparoscopic- and robot-assisted PN, after five years of median follow-up, similar rates of local recurrence, distant metastasis and cancer-related death rates were found [336].

7.1.3.2.5 Laparoscopic versus robotic approach

Another study included the 50 last patients having undergone laparoscopic and robotic PN for T1-T2 renal tumours by two different surgeons with an experience of over 200 procedures each in laparoscopic and robotic PN and RAPN, respectively, at the beginning of the study. Peri-operative and short-term oncological and functional outcomes appeared broadly comparable between RAPN and LPN when performed by highly experienced surgeons [337].

A meta-analysis, including a series of NSS with variable methodological quality compared the peri-operative outcomes of robot-assisted- and laparoscopic PN. The robotic group had a significantly lower rate of conversion to open surgery and to radical surgery, shorter warm ischaemia time, smaller change in estimated GFR after surgery and shorter length of hospital stay. No significant differences were observed between the two groups regarding complications, change of serum creatinine after surgery, operative time, estimated blood loss and positive surgical margins (PSMs) [338].

A multi-institutional prospective study of 105 patients with hilar tumours demonstrated a reduced warm ischaemia time (20.2 min vs. 27.7 min) and a comparable rate of 1.9% when compared with a historical laparoscopic control group which was defined by literature research and meta-analysis for warm ischaemia time and PSM, respectively [339].

7.1.3.2.6 Laparoscopic transperitoneal versus retroperitoneal approach

Data from the Italian RECORD 2 project, a multi-institutional prospective observational project, compared the transperitoneal vs. the retroperitoneal approach for laparoscopic PN. After propensity score matching (each group n = 413) no differences in post-operative complications (surgical and medical), PSMs, early and late eGFR levels were observed. Intra-operative and surgical complications were slightly higher and operative times lower in the transperitoneal vs. the retroperitoneal approach [340]. In terms of peri-operative complications, retroperitoneal and transperitoneal PN have similar outcomes [327].

A SR assessed the outcomes of retroperitoneal vs. transperitoneal RAPN. Seventeen studies, published between 2013 and 2021, were retrieved; none of which an RCT. Among the 6,266 patients included 2,261 (36.1%) and 4,005 (63.9%) underwent retroperitoneal vs. transperitoneal RAPN, respectively. Both retroperitoneal and transperitoneal RAPN offered similar surgical outcomes, while retroperitoneal RAPN was associated with shorter surgical time and length of hospital stay [341].

7.1.3.2.7 Tumour enucleation, standard partial nephrectomy and single-port approach

Simple tumour enucleation also had similar PFS and CSS rates compared to standard PN and RN in a large study [328]. The feasibility of laparo-endoscopic single-site PN has been shown in selected patients but larger studies are needed to confirm its safety and clinical role [329].

The only prospective multi-centre study available to date assessing the impact of resection technique (enucleation vs. enucleoresection vs. resection) during PN using a standardised reporting score to classify the resection technique after surgery found that the resection technique significantly impacts surgical complications, early functional outcomes and positive surgical margins after PN of localised renal masses [342].

A SR and pooled analysis found heterogeneity in the reporting of resection techniques across robotic PN series [343]. Out of 20 studies retrieved, nine compared “standard” resection versus enucleation. A pooled analysis did not reveal significant differences in terms of operative time, ischemia time, blood loss, transfusions, or positive margins. Significant differences favoring enucleation were found for clamping management (odds ratio [OR] for renal artery clamping 3.51, 95% confidence interval [CI] 1.13-10.88; p = 0.03), overall complications (OR for occurrence 0.55, 95% CI 0.34-0.87; p = 0.01) major complications (OR for occurrence 0.39, 95% CI 0.19-0.79; p = 0.009), length of stay (weighted mean difference [WMD] -0.72 d, 95% CI -0.99 to -0.45; p < 0.001), and decrease in estimated glomerular filtration rate (WMD -2.64 ml/min, 95% CI -5.15 to -0.12; p = 0.04).

7.1.3.2.8 Off-clamp versus On-clamp PN

The use of a off-clamp and selective-clamping approaches for PN has increased in recent years with the aim to minimise/avoid warm ischemia time and improve functional outcomes. One RCT (CLOCK study) showed a comparable safety profile of off-clamp vs. on-clamp PN in terms of intra- and peri-operative complications as well as comparable absolute eGFR variation and split renal function at 6 months from surgery in patients with regular baseline function and two kidneys. However, 40% of the patients randomised in the off-clamp group, were intraoperatively shifted to on-clamp (median ischemia time of 15 minutes) [344, 345]. Due to the selective

inclusion criteria of the RCT, off-clamp techniques may still be indicated in patients with chronic kidney disease, single kidney or multifocal disease [346, 347].

In a contemporary cohort of 1359 patients from the prospectively maintained database of the French national network of research on kidney cancer (UROCCR), PSM rate was not statistically different between the off-clamp group (5.6%) and the on-clamp group (11%) (p = 0.1). With short median follow-up, no statistical differences between the two groups were seen in OS, local RFS and metastasis-free survival (MFS) [348].

7.1.3.2.9 Surgical volume

In a analysis of 8,753 patients who underwent PN, an inverse non-linear relationship of hospital volume with morbidity of PN was observed, with a plateauing seen at 35-40 cases per year overall, and 18-20 cases for the robotic approach [349]. A retrospective study of a U.S. National Cancer Database looked at the prognostic impact of hospital volume and the outcomes of robot-assisted PN, including 18,724 cases. This study showed that undergoing RAPN at higher-volume hospitals may have better peri-operative outcomes (conversion to open and length of hospital stay) and lower PSM rates [350]. A French study, including 1,222 RAPN patients, has shown that hospital volume is the main predictive factor of Trifecta achievement (no complications, warm ischaemia time < 25 min, and negative surgical margins) after adjustment for other variables, including surgeon volume [351]. The prospective Registry of Conservative and Radical Surgery for cortical renal tumour Disease (RECORd-2) study including 2,076 patients showed that the hospital volume (> 60 PN/year) is an independent predictor for PSMs [352].

7.1.3.2.10 Pre-operative embolisation prior to partial nephrectomy

A SR and meta-analysis of 270 patients demonstrated significantly reduced blood loss in patients with selective renal artery embolisation (n = 222; 154 ± 22.6 mL vs. n = 48; 353.4 ± 69.6 mL) prior to PN [353].

7.1.3.3 Positive surgical margins on histopathological specimens

A PSM is encountered in about 2-8% of T1 PNs [354]. Studies comparing surgical margins with different surgical approaches (open, laparoscopic, robotic) are inconclusive [355-357]. Most trials showed that intra-operative frozen section analysis had no influence on the risk of definite PSMs [358]. A PSM status occurs more frequently in cases in which surgery is imperative (solitary kidneys and bilateral tumours) and in patients with adverse pathological features (pT2a, pT3a, grade III–IV) [359-362].

The majority of retrospective analyses reported so far indicated that PSMs do not translate into a higher risk of metastases or a decreased CSS [360, 361]. On the other hand, another retrospective study of a large single-institutional series showed that PSMs are an independent predictor of PFS due to a higher incidence of distant and local relapses [363]. Another retrospective study of 42,114 PN patients with 2,823 PSM patients (6.7%) showed an increased presence of PSM in upstaged pT3a tumours (14.1%), increased all-cause mortality in PSM patients and a decreased 5-year OS rate in pT3a tumours (PSM: 69% vs. NSM: 90.9 %) [364].

However, only a proportion of patients with an uncertain margin status actually harbour residual malignancy. Local tumour bed recurrences were found in 16% in patients with PSMs compared with 3% in those with negative margins [359], Therefore, RN or re-resection of margins can result in over-treatment in many cases. Patients with PSMs should be informed that they will need a more intense surveillance (imaging) follow-up and that they are at increased risk of secondary local therapies [360, 365]. On the other hand, protection from recurrence is not ensured by negative surgical margins [366] as it is reported in up to 1.5% of cases in this category of patients [354].

7.1.3.4 Summary of evidence and recommendations for radical and partial nephrectomy techniques

Summary of evidence	**LE**
Laparoscopic RN has lower morbidity than open nephrectomy.	1b
Short-term oncological outcomes for T1-T2a tumours are equivalent for laparoscopic- and open RN.	2a
Partial nephrectomy can be performed, either by open-, pure laparoscopic- or robot-assisted approach, based on surgeon's expertise and skills.	2b
Robot-assisted and laparoscopic PN are associated with shorter length of hospital stay and lower blood loss compared to open PN.	2b

Transperitoneal and retroperitoneal laparoscopic PN do not differ in post-operative surgical and medical complications, PSMs, and kidney function.	2a
Hospital volume for PN might impact on surgical complications, warm ischaemia time and surgical margins.	3
Immediate completion nephrectomy for PSMs can result in over-treatment in many cases.	3
Off-clamp partial nephrectomy does not improve renal function outcomes in patients with baseline normal renal function.	1b

Recommendations	**Strength rating**
Offer laparoscopic or robotic radical nephrectomy (RN) to patients with T2 tumours and localised masses not treatable by partial nephrectomy (PN).	Strong
Do not perform minimally invasive RN in patients with T1 tumours for whom a PN is feasible by any approach, including open.	Strong
Do not perform minimally invasive surgery if this approach may compromise oncological-functional- and peri-operative outcomes.	Strong
Intensify follow-up in patients with a positive surgical margin, especially in upstaged pT3a patients.	Weak
Do not attempt off-clamp partial nephrectomy unless indicated.	Weak

*7.1.4 **Therapeutic approaches as alternatives to surgery***

7.1.4.1 Active surveillance and watchful waiting

Elderly and comorbid patients with incidental SRMs have a low RCC-specific mortality and significant competing-cause mortality [367, 368].

In this regard, beyond age and comorbidities, frailty has been increasingly recognised as a major risk factor for adverse perioperative and oncological outcomes in patients with genitourinary malignancies. Frailty is a geriatric syndrome characterised by a decline in individuals' resilience and physiological functional reserve across multiple body systems, resulting in increased vulnerability to external stressors [369]. The Comprehensive Geriatric Assessment is considered the gold standard of care for older patients in several settings, given its ability to identify frailty and risk of geriatric syndromes and the positive impact on patients' outcomes.

A SR evaluatig the impact of frailty on perioperative and oncologic outcomes in patients undergoing surgery or ablation for RCC found low-quality evidence pointing to frailty and sarcopenia as potential independent risk factors for worse perioperative and oncological outcomes across different RCC stages.

Active surveillance is defined as the initial monitoring of tumour size by serial abdominal imaging (US, CT, or MRI) with delayed intervention reserved for tumours showing clinical progression during follow-up [370]. The concept of AS differs from the concept of 'Watchful Waiting'; Watchful Waiting is reserved for patients whose comorbidities contra-indicate any subsequent active treatment and who do not require follow-up imaging, unless clinically indicated.

Population-based studies compared the oncological outcomes of surgery (RN or PN) and non-surgical management for tumours < 4 cm. The analyses showed a significantly lower CSM in patients treated with surgery [281, 371, 372]. However, the patients assigned to the surveillance arm were older and likely to be frailer and less suitable for surgery. Other-cause mortality rates in the non-surgical group significantly exceeded that of the surgical group [371]. Analyses of older patients (> 75 years) failed to show the same benefit in CSM for surgical treatment [280, 373, 374].

Growth rate and metastasis

In the largest reported series of AS the growth of renal tumours was low and progression to metastatic disease was reported in only a limited number of patients [375, 376]. A SR of eighteen AS cohorts comprising 2,066 patients (cT1-2 N0M0) with a pooled mean follow-up of 53 months, showed that 2.1% (95% CI: 1.0-3.6) of patients developed metastatic disease during follow-up [377]. For patients with SRMs (nine studies, n = 987), the pooled metastasis rate was 1.8% (95% CI: 0.5-3.7).

In 136 biopsy-proven SRMs managed by AS, median follow-up of patients who remained on AS was 5.8 years (interquartile range 3.4-7.5 years). Clear-cell RCC grew faster than papillary type 1 SRMs (0.25 and 0.02 cm/year on average, respectively, p = 0.0003). Overall, 60 (44.1 %) of the malignant SRMs progressed; 49 (82%) by rapid growth (volume doubling), seven (12%) increasing to ≥ 4 cm, and four (6.7%) by both criteria. Six patients developed metastases, and all were of ccRCC histology [378].

Overall- and cancer-specific survival

A single-institutional comparative study evaluating patients aged > 75 years showed decreased OS for those who underwent surveillance and nephrectomy relative to NSS for clinically T1 renal tumours. However, at multivariate analysis, management type was not associated with OS after adjusting for age, comorbidities, and other variables [367]. No statistically significant differences in OS and CSS were observed in another study of RN vs. PN vs. AS for T1a renal masses with a follow-up of 34 months [379].

The prospective non-randomised multi-institutional Delayed Intervention and Surveillance for Small Renal Masses (DISSRM) study enrolled 497 patients with solid renal masses < 4 cm who selected either AS or primary active intervention. Patients who selected AS were older, had worse ECOG scores, more comorbidities, smaller tumours, and more often had multiple and bilateral lesions. In patients who elected AS in this study the overall median SRM growth rate was 0.09 cm/year with a median follow-up of 1.83 years. The growth rate and variability decreased with longer follow-up. No patients developed metastatic disease or died of RCC [380, 381].

Overall survival for primary intervention and AS was 98% and 96% at two years, and 92% and 75% at five years, respectively (p = 0.06). At five years, CSS was 99% and 100%, respectively (p = 0.3). Active surveillance was not predictive of OS or CSS in regression modelling with relatively short follow-up [380]. In the previously mentioned large SR of eighteen AS cohorts 1.0% (95% CI: 0.3-2.1) died from RCC and 22.6% (95% CI: 15.8-30.2) died from any cause. For patients with SRMs RCC-specific mortality was 0.6% (95% CI: 0-2.1), and all-cause mortality was 28.5% (95% CI: 17.4-41.4) [377].

A study using data from the DISSRM Registry investigated the outcomes of active surveillance in a cohort of patients aged 60 or younger at diagnosis [382]. Of 224 patients with median follow-up of 4.9 years, 30.4% chose surveillance. There were 20 (29.4%) surveillance progression events, including four elective crossovers, and 13 (19.1%) patients underwent delayed intervention. Among patients with initial tumour size ≤ 2 cm, 15.1% crossed over, compared to 33.3% with initial tumour size 2-4 cm. Overall survival was similar in primary intervention and surveillance at 7 years (94.0% vs 90.8%, log-rank p = 0.2). Cancer-specific survival remained at 100% for both groups. Recurrence-free survival at five years was 96.0% and 100% for primary and delayed intervention, respectively (log-rank p = 0.6).

Overall, both short- and intermediate-term oncological outcomes indicate that in selected patients with advanced age and/or comorbidities, AS is appropriate for initially monitoring of SRMs, followed, if required, by treatment for progression [370, 375, 376, 383-386].

Quality of life

A multicentre study assessed QoL of patients undergoing immediate intervention vs. AS. Patients undergoing immediate intervention had higher QoL scores at baseline, specifically for physical health. The perceived benefit in physical health persisted for at least one year following intervention. Mental health, which includes domains of depression and anxiety, was not adversely affected while on AS [387].

7.1.4.2 Role of renal tumour biopsy before active surveillance

Histological characterisation of SRMs by renal tumour biopsy is useful to select tumours at lower risk of progression based on grade and histotype, which can be safely managed with AS. Pathology can also help to tailor surveillance imaging schedules. In the largest cohort of biopsy-proven, small, sporadic RCCs followed with AS, a significant difference in growth and progression among different RCC subtypes was observed. Clear-cell RCC SRMs grew faster than papillary type 1 SRMs (0.25 and 0.02 cm/year on average, respectively, p = 0.0003) [378].

7.1.4.3 Tumour ablation

7.1.4.3.1 Role of renal mass biopsy

A RMB is required prior to tumour ablation (see Sections 5.3 - Renal tumour biopsy and 5.4 - Summary of evidence and recommendations for the diagnostic assessment of RCC). Historically, up to 45% of patients underwent tumour ablation of a benign or non-diagnostic mass [388, 389]. An analysis of the European multi-national prospective EuRECA registry (871 patients undergoing cryoablation) showed that the use of pre-cryoablation biopsy has significantly increased from 42% (65/156) in 2015 to 72% (88/122) in 2019 (p < 0.001), making treatment for a benign or an unknown histology significantly less likely (OR: 0.64, p < 0.001 and OR 0.31, p = 0.044, respectively) [390]. A RMB in a separate session reduces over-treatment significantly, with 80% of patients with benign lesions opting not to proceed with TA [389]. Additionally, there is some evidence that the oncological outcome following TA differs according to RCC subtype which should therefore be factored into the decision-making process. In a series of 229 patients with cT1a tumours (mean size 2.5 cm) treated with RFA, the 5-year DFS rate was 90% for ccRCC and 100% for pRCC (80 months: 100% vs. 87%, p = 0.04) [391]. In another series, the total tumour ablation effectiveness rate was 90.9% for ccRCC and 100% for pRCC [392].

A study comparing RFA with surgery suggested worse outcomes of RFA vs. PN in cT1b ccRCC, while no difference was seen in those with non-ccRCC [393]. Furthermore, patients with high-grade RCC or metastasis may choose different treatments over tumour ablation. Finally, patients without biopsy or a non-diagnostic biopsy are often assumed to have RCC and will undergo potentially unnecessary radiological follow-up or further treatment.

7.1.4.3.2 Cryoablation

Cryoablation is performed using either a percutaneous- or a laparoscopic-assisted approach, with technical success rates of > 95% [394]. In comparative studies, there was no significant difference in the overall complication rates between laparoscopic- and percutaneous cryoablation [395-397]. One comparative study reported similar OS, CSS, and RFS in 145 laparoscopic patients with a longer follow-up vs. 118 patients treated percutaneously with a shorter follow-up [396]. A shorter average length of hospital stay was found with the percutaneous technique [396-398]. A SR including 82 articles reported complication rates ranging between 8-20% with most complications being minor [399]. Although a precise definition of tumour recurrence is lacking, the athors reported a lower RFS as compared to that of PN.

Oncological outcomes after cryoablation have generally been favourable for cT1a tumours. In a recently published series of 308 patients with cT1a and cT1b tumours undergoing percutaneous cryoablation, local recurrence was seen in 7.7% of cT1a tumours vs. 34.5% of cT1b tumours. On multivariable regression, the risk of disease progression increased by 32% with each 1 cm increase in tumour size (HR: 1.32, $p < 0.001$). Mean decline in eGFR was 11.7 mL/min/1.73 m2 [400]. In another large series of 220 patients with biopsy-proven cT1 RCC, five-year local RFS was 93.9%, while metastasis-free survival approached 94.4% [394]. A series of 134 patients with T1 RCC (median tumour size 2.8 cm) submitted to percutaneous cryoablation yielded a ten-year DSF of 94% [401].

For cT1b tumours, local tumour control rates drop significantly. One study showed local tumour control in only 60.3% at three years [402]. In another series, the PFS rate was 66.7% at twelve months [403]. Furthermore, recent analyses demonstrated five-year cancer-specific mortality rates of 7.6-9% [404, 405]. On multivariable analysis, cryoablation of cT1b tumours was associated a 2.5-fold increased risk of death from RCC compared with PN [404]

Recurrence after initial cryoablation is often managed with re-cryoablation, but only 45% of patients remain disease-free at two years [406].

7.1.4.3.3 Radiofrequency ablation

Radiofrequency ablation is performed laparoscopically or percutaneously. Several studies compared patients with cT1a tumours treated by laparoscopic or percutaneous RFA [407-410]. Complications occurred in up to 29% of patients but were mostly minor. Complication rates, recurrence rates and CSS were similar in patients treated laparoscopically and percutaneously.

The initial technical success rate on early (i.e., one month) imaging after one session of RFA is 94% for cT1a and 81% for cT1b tumours [411]. This is generally managed by re-RFA, approaching overall total technical success rates > 95% with one or more sessions [412].

Long-term outcomes with over five years of follow-up following RFA have been reported. In recent studies, the five-year OS rate was 73–79% [411, 412], due to patient selection. While oncological outcomes have been favourable for cT1a tumours, it's important to note that within the T1a 3-4cm subpopulation, these outcomes are less encouraging [413]. A study involving 106 patients treated with radiofrequency ablation, and with a median follow-up of 79 months, the ten-year DFS rate was 82%, but a notable decline was observed to 68% for tumours larger than 3 cm [412]. In series focusing on clinical T1b tumours (4.1–7.0 cm), the five-year DFS rate was 74.5% to 81% [411, 414]. Oncological outcomes appear to be worse than after surgery, but comparative data are severely biased (see Section 7.1.4.3.4). In general, most disease recurrences occur locally and recurrences beyond five years are rare [412, 414].

7.1.4.3.4 Microwave ablation

The best evidence base for these techniques exists for percutaneous microwave ablation. In a study of 185 patients with a median follow-up of 40 months, the five-year local progression rate was 3.2%, while 4.3% developed distant metastases [415]. Results appear to be favourable for cT1b tumours as well [416]. Overall, current data on cryoablation, RFA and microwave ablation of cT1a renal tumours indicate short-term equivalence with regards to complications, oncological and renal functional outcomes [417, 418].

7.1.4.3.5 Tumour ablation versus surgery

The Guideline Panel performed a protocol-driven SR of comparative studies (including > 50 patients) of TA with PN for T1N0M0 renal masses [419]. Twenty-six non-randomised comparative studies published between 2000 and 2019 were included, recruiting a total of 16,780 patients. Four studies compared laparoscopic TA vs.

laparoscopic/robotic PN; sixteen studies compared laparoscopic or percutaneous TA vs. open-, laparoscopic- or robotic PN; two studies compared different techniques of TA and four studies compared TA vs. PN vs. RN. In this SR, TA as treatment for T1 renal masses was found to be safe in terms of complications and adverse events (AEs), but its long-term oncological effectiveness compared with PN remained unclear. The primary reason for the persisting uncertainty was related to the nature of the available data; most studies were retrospective observational studies with poorly matched controls, or single- arm case series with short follow-up. Many studies were poorly described and lacked a clear comparator.

There was also considerable methodological heterogeneity. Another major limitation was the absence of clearly defined primary outcome measures. Even when a clear endpoint such as OS was reported, data were difficult to interpret because of the varying length and type of follow-up amongst studies. The Panel also appraised the published SRs based on the AMSTAR 2 tool which showed "Critically Low" or "Low" ratings [419].

Tumour ablation has been demonstrated to be associated with good long-term survival in several single-arm non-comparative studies [420, 421]. Due to the lack of controls, this apparent benefit is subject to significant uncertainties. Whether such benefit is due to the favourable natural history of such tumours or due to the therapeutic efficacy of TA, as compared to PN, remains unknown. In addition, there are data from comparative studies suggesting TA may be associated with worse oncological outcomes in terms of local recurrence and metastatic progression and CSM [279, 404, 405, 422-424]. However, there appears to be no clinically significant difference in five-year CSM between TA and AS [372]. A retrosepctive multicentre study, including 86 partial nephrectomies and 104 TA, matched for complexities, has shown that PN and cryoablation are comparable regarding complications within 90 days after treatment [425].

The Panel concluded that the current data are inadequate to reach conclusions regarding the clinical effectiveness of TA as compared with PN. Given these uncertainties in the presence of only low-quality evidence, TA can only be recommended to frail and/or comorbid patients with SRMs.

7.1.4.3.6 Stereotactic ablative radiotherapy

Stereotactic ablative radiotherapy (SABR) has been emerging as a treatment option for medically inoperable patients with localised cT1a and cT1b tumours [426, 427].

A variety of dose-fractionation schedules have been reported (26-60Gy; single, three and five fractions) [427]. Published single-arm studies, mainly including cT1 RCC, with a median follow-up range of 16.4-34.3 months, reported local control rates of 90-97.2% [427-434]. However, viable tumour cells are often seen in post-SABR biopsies, although their clinical significance remains unclear [430]. Grade 3 or 4 toxicities were reported in 0-9.1% of the patients across studies [427]. Even though early reported results of SABR look encouraging, more evidence from well conducted prospective studies with longer follow-up is needed.

7.1.4.3.7 Other ablative techniques

Some studies have shown the feasibility of other ablative techniques, such as high-intensity focused US ablation and non-thermal irreversible electroporation. However, these techniques are still considered experimental.

7.1.4.3.8 Summary of evidence and recommendations for therapeutic approaches as alternative to surgery

Summary of evidence	**LE**
Most population-based analyses show a significantly lower CSM for patients treated with surgery compared to non-surgical management.	3
In AS cohorts, the growth of SRMs is low in most cases and progression to metastatic disease is rare (1–2%).	3
Low quality studies suggest higher disease recurrence rates after RFA of tumours > 3 cm and after cryoablation of tumours > 4 cm.	3
Low quality studies suggest a higher local recurrence rate for TA therapies compared to PN, but quality of data does not allow definitive conclusions.	3

Recommendations	Strength rating
Offer active surveillance (AS) or tumour ablation (TA) to frail and/or comorbid patients with small renal masses.	Weak
Perform a percutaneous renal mass biopsy prior to, and not concomitantly with, TA.	Strong
When TA or AS are offered, discuss with patients about the harms/benefits with regards to oncological outcomes and complications.	Strong
Do not routinely offer TA for tumours > 3 cm and cryoablation for tumours > 4 cm.	Weak

7.2 Treatment of locally advanced RCC

*7.2.1 **Introduction***

In addition to the summary of evidence and recommendations outlined in Section 7.1 for localised RCC, certain therapeutic strategies arise in specific situations for locally-advanced disease.

*7.2.2 **Role of lymph node dissection in locally-advanced RCC***

In locally-advanced RCC, the role of LND is still controversial. The only available RCT demonstrated no survival benefit for patients undergoing LND but this trial mainly included organ-confined disease cases [293]. In the setting of locally-advanced disease, several retrospective papers and SRs addressed the topic with contradictory results. A SR and meta-analyses could not confirm any survival benefit in patients at high risk of progression treated with LND [435]. A More recent SR and meta-analyses showing a survival benefit in patients with locally-advanced disease treated with LND [436]. More specifically, thirteen studies on patients with LND and non-LND were identified and included in the analysis. In the subgroup of locally-advanced RCC (cT3-T4NxM0), LND showed a significantly better OS rate in patients who had undergone LND compared to those without LND (HR: 0.73, 95% CI: 0.60-0.90, p = 0.003).

7.2.2.1 Management of clinically negative lymph nodes (cN-) in locally-advanced RCC

In case of cN-, the probability of finding pathologically-confirmed LN metastases ranges between 0-25%, depending mainly on primary tumour size and the presence of distant metastases [437]. In case of clinically-negative LNs (cN-) at imaging, removal of LNs is justified only if visible or palpable during surgery [438], at least for staging, prognosis, adjuvant therapy and follow-up implications, although a benefit in terms of cancer control has not yet been demonstrated [295, 435].

7.2.2.2 Management of clinically positive lymph nodes (cN+) in locally-advanced RCC

In case of cN+, the probability to identify pathologically-confirmed LN metastases ranges between 10.3% (cT1 tumours) and up to 54.5% in case of locally-advanced disease. In cN+, removal of visible and palpable nodes during LND is justified [438], at least for staging, prognosis, adjuvant therapy and follow-up implications, although a benefit in terms of cancer control has not yet been demonstrated [295, 435]. Whether to extend the LND in case of lymphadenopathy (cN1) remains controversial. In addition retrospective data showed for resected isolated macrospcopical lympnode metastises (pN1) that the time to systemic progression was a median of 4.2 months [439].

*7.2.3 **Management of RCC with venous tumour thrombus***

Tumour thrombus formation in RCC patients is a significant adverse prognostic factor. Traditionally, patients with venous tumour thrombus undergo surgery to remove the kidney and tumour thrombus. Aggressive surgical resection is widely accepted as the default management option for patients with venous tumour thrombus [440-448].

The role of neoadjuvant treatment with targeted agents has also been investigated in downstaging of tumour thrombus within the inferior vena cava (IVC) with limited and controversial results [449, 450]. Further investigations are needed to better identifying which patients with RCC and tumour venous might benefit from neoadjuvant therapy (See also section 7.2.5).

Several scores and tools have been proposed to estimate surgical complexity and the risk of complications, although an external validation is needed [451, 452].

In two of the largest published studies a higher OS was different in patients with a level of thrombus in the renal vein and inferior caval vein and survival was also not associated with tumour size, grade, perinephric fat extension, sarcomatoid features, Eastern Cooperative Oncology Group PS and regional- and distant metastases in multivariate analysis [453, 454]. Therefore, all patients with non-metastatic disease and venous tumour thrombus, and an acceptable PS, should be considered for surgical intervention, irrespective of the extent of tumour thrombus at presentation.

The surgical technique (open vs. laparoscopic vs. robotic) and approach for each case should be selected based on patients' characteristics, surgeon and hospital volumes and the extent of tumour thrombus and the grade of occlusion of the IVC [449, 455, 456]. Minimally invasive techniques (laparoscopic and robotic) are still under investigation [457, 458].
A SR and metaanalyses regarding surgical approach included 1,375 patients, out of which 329 patients were in single-arm studies and 1,046 patients were in comparative studies [459]. Of the 329 patients who underwent robotic, 14.7% were level I, 60.9% level II, 20.4% level III and 2.5% level IV thrombus. Compared with open thrombectomy, robotic approach was associated with a lower blood transfusion rate and fewer overall complications. Major complication and 30-day mortality rates were similar in both groups. In experienced hands with carefully selected patients, robotic thrombectomy can be considered; however, an emphasised selection bias limits definitive inference of these results, and optimal patient selection criteria remain to be elucidated.

In case of venous thrombus, referral to a tertiary care centre is recommended to guarantee a multidisciplinary evaluation and treatment, especially in case of caval thrombus.

*7.2.4 **Management of locally-advanced unresectable RCC***

The management of locally-advanced unresectable RCC should be based around systemic therapy [460]. A multidisciplinary evaluation, including urologists, medical oncologists and radiation therapists is suggested to maximise cancer control, pain control and the best supportive care. In patients with non-resectable disease, embolisation can control symptoms, including visible haematuria or flank pain [309, 461-463].

7.2.4.1 Summary of evidence and recommendations for lymph node dissection, the management of RCC with venous tumour thrombus and unresectable tumours

Summary of evidence	**LE**
In patients with locally-advanced disease, the survival benefit of LN dissection is unproven but LN dissection has significant staging, prognosis, adjuvant therapy and follow-up implications.	3
Low quality data suggest that tumour thrombus excision in non-metastatic disease may be beneficial.	3

Recommendations	**Strength rating**
During nephrectomy, remove clinically enlarged lymph nodes for staging, prognosis and follow-up implications.	Weak
Remove the renal tumour and thrombus in case of venous involvement in non-metastatic disease.	Strong
Discuss treatment options in patients with locally-advanced unresectable RCC (biopsy and/or systemic therapy/deferred resection, or palliative management) within a multidisciplinary team to determine treatment goal.	Strong

*7.2.5 **Neoadjuvant and adjuvant therapy***

Neoadjuvant therapy is currently under investigation and available in clinical trials. In the pre-surgical setting neoadjuvant TKI and immune checkpoint therapy demonstrated varying response rates between 7-59% in retrospective series and some phase II trials [449, 464, 465].

In a presurgical phase II trial in patients with vascular thrombus treatment with axitinib demonstrated a reduction in the level of tumour thrombus in 35% of patients (7/20) [464]. There is currently no evidence of a prolonged OS by neoadjuvant treatment and at present, the data do not support its use outside clinical trials.

There is currently no evidence from a SR (including ten retrospective studies and two RCTs) that adjuvant radiation therapy increases survival [466]. The impact on OS of adjuvant tumour vaccination in selected patients undergoing nephrectomy for T3 renal carcinomas remains unconfirmed [467-471] (LE: 1b). A similar observation was made in an adjuvant trial of girentuximab, a monoclonal antibody against carbonic anhydrase IX (CAIX) (ARISER Study) [472].

At present, there is no OS data supporting the use of adjuvant VEGFR or mTOR inhibitors. Thus far, several RCTs comparing VEGFR-TKI or mTOR vs. placebo have been published [473-481]. Only S-TRAC, a trial of adjuvant sunitinib vs. placebo demonstrated a DFS benefit which was not reproduced in ASSURE, a trial of sunitinib and sorafenib vs. placebo. Due to an unfavourable AE profile and no survival advantage, none of these drugs are recommended [482].

7.2.5.1 PD-1 Inhibition: Keynote-564

The Keynote-564 trial is the first trial to report positive primary endpoint data on DFS [483, 484]. Keynote-564 evaluated pembrolizumab (17 cycles of 3-weekly therapy) vs. placebo as adjuvant therapy in 994 patients with intermediate (pT2, grade 4 or sarcomatoid, N0, M0; or pT3, any grade, N0, M0) or high risk (pT4, any grade, N0, M0; or pT any stage, and grade, or N+, M0), or M1 (no evidence of disease [NED] after primary tumour plus soft tissue metastases completely resected < one year from nephrectomy) disease. The median follow-up, defined as time from randomisation to data cut-off, was 24.1 months. The primary endpoint of DFS per investigator assessment was significantly improved in the pembrolizumab group vs. placebo (HR: 0.68, 95% CI: 0.53–0.87, p = 0.001). The estimated 24-month DFS rate was 77% vs. 68% for pembrolizumab and placebo, respectively. Benefit occurred across broad subgroups of patients including those with M1/NED disease post-surgery (n = 58 [6%]). Investigator assessed DFS was considered preferable to DFS by central review due to its clinical applicability. Overall survival showed a non-statistically significant trend towards a benefit in the pembrolizumab arm (HR: 0.54, 95% CI: 0.30-0.96, p = 0.0164). Follow-up was short and few OS events occurred (2-year OS rate of 97% [pembrolizumab] vs. 94% [placebo]). Grade III-V all-cause AEs occurred in 32% vs. 18% of patients for pembrolizumab and placebo, respectively. Quality of life assessment by FKSI-DRS and QLQ30 did not show a statistically significant or clinically meaningful deterioration in health-related QoL or symptom scores for either adjuvant pembrolizumab or placebo.

7.2.5.2 PD-L1 inhibition: IMmotion010

The IMmotion010 phase III trial was the first adjuvant ICI trial to be developed in RCC to investigate the effect of a PD-L1 inhibitor on DFS [485]. IMmotion010 evaluated atezolizumab 1200 mg (once every 3 weeks for 16 cycles or one year) vs. placebo as adjuvant therapy in 778 patients with increased risk of recurrence defined as: pT2, grade 4 or sarcomatoid, N0, M0; or pT3, grade 3–4, N0, M0; or pT3b/c/T4, any grade, N0, M0; or pT any stage and grade, pN1, M0, or M1 no NED after primary tumour plus soft tissue metastases completely resected either synchronous or if metachronous, > 12 months from nephrectomy.

The minimum follow-up, defined as time from randomisation to data cut-off, was 38.6 months. The primary endpoint of DFS per investigator assessment was not met in the atezolizumab group vs. placebo (HR: 0.93, 95% CI: 0.75-1.15, p = 0.4950) with a median DFS of 57.2 months (95% CI: 44.6, NE) for atezolizumab vs. 49.5 months for placebo (47.4, NE). None of the exploratory subgroups suggested a DFS benefit with atezolizumab, most notably the M1 NED subgroup (n = 108/13.9%) which was larger than in Keynote-564 (5.8%), the sarcomatoid subgroup and the subgroup expressing > 1% PD-L1 had a HR of 0.93 (0.58–1.49), 0.77 (0.44–1.36) and 0.83 (0.63-1.10), respectively.

There were no OS differences. Grade 3-4 all-cause and treatment-related AEs occurred in 27.2% and 14.1% vs. 21.1% and 4.7% of patients for atezolizumab and placebo, respectively. There were no treatment-related grade 5 AEs.

7.2.5.3 PD-1 and CTLA-4 inhibition: CheckMate 914

CheckMate 914 was the first phase III trial to investigate a combination of nivolumab plus ipilimumab vs. placebo as adjuvant treatment in RCC (part A) [486]. Subsequently, a nivolumab monotherapy arm was also added to the trial (part B). The following results relate to part A which evaluated nivolumab 240 mg every two weeks (Q2W) for 12 cycles or 6 months plus ipilimumab 1 mg/kg Q6W for 4 cycles vs. placebo in 816 patients with recurrence risk defined as pT2a, grade 3 or 4, N0, M0; pT2b/T3/T4, any grade, N0, M0, or pT any stage, any grade, pN1, M0. The median time of follow-up, defined as time from randomisation to data cut-off, was 37 months. The primary endpoint of DFS per investigator assessment was not met in the nivolumab plus ipilimumab group vs. placebo (HR 0.92 [0.71-1.19], p = 0.5347). Of the exploratory subgroups, patients with sarcomatoid tumours (n = 40) and those with > 1% PD-L1 expression (n = 107) had a HR of 0.29 (0.09-0.91) and 0.46 (0.23-0.94) in favour of the ICI combination, respectively.

All-cause treatment discontinuation due to study drug occurred in 43% and 33% in the nivolumab plus ipilimumab group vs. 11% and 1% in the placebo group. Treatment-related AE grade > III were 29% in the nivolumab plus ipilimumab group and 2% in the placebo group with four deaths (1%) considered related to combination therapy. The high AE profile may have contributed to the lack of efficacy and patient retention. The results of the nivolumab arm are awaited.

7.2.5.4 Perioperative PD-1 inhibition: PROSPER

PROSPER is a peri-operative trial of neoadjuvant nivolumab (one cycle) followed by radical or partial nephrectomy and adjuvant nivolumab (480 mg IV q4 weeks) for nine doses compared to surgery followed by surveillance without a placebo [487]. Patients with clinical stage > T2 or T any N+ RCC or patients with selected oligometastatic disease were included if they had no evidence of disease within 12-weeks post- surgery. A total of 819 patients with clear cell (87%) and non-ccRCC were included, a biopsy in the nivolumab arm was mandatory. The primary endpoint of RFS was similar between the arms (HR: 0.97; 95% CI: 0.74-1.28; p = 0.43)

and the trial was stopped by DSMC. The OS was not statistically different (HR: 1.48; 95% CI: 0.89-2.48; p = 0.93), although not mature. Grade III-IV AEs occurred in 20% (nivolumab arm) and 6% (control arm) of patients, respectively. Fifteen (4%) patients died in the nivolumab arm and eighteen (4%) in the surgery alone arm.

Following the application of the EAU Guidelines metodology, the Panel reached consensus and issued a weak recommendation for adjuvant pembrolizumab for patients with high-risk (defined as per study) operable ccRCC until final OS data are available [488]. This decision was taken as immune checkpoint inhibitor therapy has a different mode of action than VEGFR-TKI resulting in complete responses in up to 16% of patients in PD-1 unselected populations in metastatic disease [489]. Despite immature OS data with the early OS signal potentially driven by the M1 population the Panel cannot exclude that a survival benefit will emerge. This was not the case in the adjuvant sunitinib trial (STRAC) [486, 490]. The Panel took the following evidence limitations into account when deciding to make to a weak recommendation for adjuvant pembrolizumab:

- A high proportion of patients, cured by surgery, are receiving unnecessary, and potentially harmful treatment.
- The tolerability profile is acceptable but grade III-V AEs were higher with 14.7% in the pembrolizumab arm vs. the placebo arm (occurring in approximately one-third of patients, all cause). Approximately 18% of patients required treatment discontinuation early for AEs which gives a broad indicator of tolerability. There is a significant risk of life-changing toxicity.
- Other ICI trials have not shown consistent results.
- Biomarker analysis to predict outcome and AEs are not available.
- Final OS data are not yet available.

The results of IMmotion010, CheckMate 914 and PROSPER need to be discussed with patients [485-487]. Meta-analysis with these data sets is not recommended due to heterogeneity across the ICI studies. It is likely that there are several reasons behind these inconsistent results, including study population with potential heterogeneity independent of TNM risk groups, selection criteria and trial design. To date pembrolizumab is the only positive trial [490].

While the results of IMmotion010 may reflect the non-significant OS results seen in the metastatic setting with PD-L1 inhibitors (IMmotion151, Javelin 101), the results of CheckMate 914 and PROSPER are more difficult to interpret. Nivolumab and ipilimumab leads to durable remission and long-term OS in metastatic disease and nivolumab has a similar mode of action as pembrolizumab (anti PD-1).

The high treatment discontinuation rate of 33% in CheckMate 914 is of concern and may have had an impact on the trial effectivity (20% in Keynote-564). The Panel strongly feels that biomarker work on all of these trials should occur to identify patients that do respond to therapy and to give a better explanation for the inconsistent results. Treatment of unselected patients in the adjuvant setting based on the Keynote-564 criteria will result in a large proportion of patients receiving unnecessary therapy. In the absence of OS data or appropriate biomarkers, the patient preference should be leading in a shared decision-making process. Patients considering adjuvant therapy should be aware of all trials and not be presented with only one data set.

Table 7.1: Overview phase III trials of PD-1 immune checkpoint inhibitors in adjuvant RCC

Phase III trial of PD-1 immune checkpoint inhibitors in adjuvant RCC						
Study	**N**	**Experimental arm**	**Primary endpoint**	**Risk groups**	**DFS (mo) Median (95% CI) HR**	**OS (mo.) Median (95% CI) HR**
Keynote-564 NCT03142334 Median follow-up of 30.1 mo. ATEZO = atezolizumab; BICR = blinded independent central review; CI = confidence interval; DFS = disease-free survival; HR = hazard ratio; IPI = ipilimumab; IR = investigator review; ITT = intention-to-treat; IV = intravenous; mo = months; NE = non-estimable; NED = no evidence of disease; NIVO = nivolumab; NR = not reached; OS = overall survival; PD-1 = programmed death-receptor 1; PEMBRO = pembrolizumab; PFS = progressionfree survival; Q2W = every 2 weeks; Q3W = every 3 weeks.

7.2.5.5 Summary of evidence and recommendations for neoadjuvant and adjuvant therapy

Summary of evidence	**LE**
Neoadjuvant systemic therapy can reduce vascular thrombus and tumour size in the presurgical setting.	2a
Adjuvant sorafenib, pazopanib, everolimus, girentuximab, or axitinib does not improve DFS or OS after nephrectomy.	1b
In one single RCT, in selected high-risk patients, adjuvant sunitinib improved DFS but not OS.	1b
Adjuvant pembrolizumab defined by the inclusion criteria of the trial* after nephrectomy improves DFS.	1b
Adjuvant PD-L1 inhibition with atezolizumab did not improve DFS or OS.	1b
Adjuvant dual PD-1 and CTLA-4 inhibition with nivolumab and ipilimumab did not improve DFS.	1b
Peri-operative treatment with nivolumab did not improve RFS.	1b
The lack of biomarker data is hindering progress in this field. Adjuvant RCTs are ongoing to evaluate the benefit of adjuvant immunotherapy after nephrectomy in high-risk patients.	4

** pT2 G4 or pT3 any G; pT4 any G; pN+ any G; M1, NED after resection of metastases.*

Recommendations	Strength rating
Do not use neoadjuvant therapy outside a clinical trial setting.	Weak
Discuss the contradictory results of the available adjuvant ICI trials with patients to facilitate shared decision making.	Strong
Inform patients about the potential risk of overtreatment and immune related side effects if adjuvant therapy is considered.	Strong
Do not offer adjuvant therapy with sorafenib, pazopanib, everolimus, girentuximab, or axitinib.	Strong
Do not offer adjuvant sunitinib following surgically resected high-risk clear-cell renal cell carcinoma (ccRCC).	Weak

Offer adjuvant pembrolizumab to ccRCC patients, preferably within 12-16 weeks post-nephrectomy, with a recurrence risk as defined in the Keynote-564 trial:
• Intermediate-high risk:
  • pT2, grade 4 or sarcomatoid, N0 M0
  • pT3, any grade, N0, M0
• High risk:
  • pT4, any grade, N0, M0
  • any pT, any grade, N+, M0
• M1 no evidence of disease (NED):
  • NED after resection of oligometastatic sites ≤ 1 year from nephrectomy
	Weak

7.3 Advanced/metastatic RCC

*7.3.1 **Local therapy of advanced/metastatic RCC***

7.3.1.1 Cytoreductive nephrectomy

Tumour resection is potentially curative only if all tumour deposits are excised. This includes patients with the primary tumour in place and single- or oligometastatic resectable disease. For most patients with metastatic disease, cytoreductive nephrectomy (CN) is palliative and systemic treatments are necessary. In a combined analysis of two RCTs comparing CN+ IFN-based immunotherapy vs. IFN-based immunotherapy only, increased long-term survival was found in patients treated with CN [491]. However, IFN-based immunotherapy is no longer relevant in contemporary clinical practice.

Two RCTs [438, 492] and a narrative SR were identified [493]. The narrative SR included both RCTs and 10 non-RCTs. CARMENA, a phase III non-inferiority RCT investigating immediate CN followed by sunitinib vs. sunitinib alone, showed that sunitinib alone was not inferior to CN followed by sunitinib with regard to OS [494]. The trial included 450 patients with metastatic ccRCC of intermediate- and MSKCC poor risk of whom 226 were randomised to immediate CN followed by sunitinib and 224 to sunitinib alone. Patients in both arms had a median of two metastatic sites. Patients in both arms had a tumour burden of a median/mean of 140 mL of measurable disease by Response Evaluation Criteria In Solid Tumours (RECIST) 1.1, of which 80 mL accounted for the primary tumour. The study did not reach the full accrual of 576 patients and the Independent Data Monitoring Commission (IDMC) advised the trial steering committee to close the study. In an ITT analysis after a median follow-up of 50.9 months, median OS with CN was 13.9 months vs. 18.4 months with sunitinib alone (HR: 0.89, 95% CI: 0.71-1.10). This was found in both risk groups. For MSKCC intermediate-risk patients (n = 256) median OS was 19.0 months with CN and 23.4 months with sunitinib alone (HR: 0.92, 95% CI: 0.60-1.24) and for MSKCC poor risk (n = 193) 10.2 months and 13.3 months, respectively (HR: 0.86, 95% CI: 0.62-1.17). Non-inferiority was also found in two per-protocol analyses accounting for patients in the CN arm who either did not undergo surgery (n = 16) or did not receive sunitinib (n = 40), and patients in the sunitinib-only arm who did not receive the study drug (n = 11). Median PFS in the ITT population was 7.2 months with CN and 8.3 months with sunitinib alone (HR: 0.82, 95% CI: 0.67-1.00). The clinical benefit rate, defined as disease control beyond twelve weeks was 36.6% with CN and 47.9% with sunitinib alone (p = 0.022). Of note, 38 patients in the sunitinib-only arm required secondary CN due to acute symptoms or for complete or near-complete response. The median time from randomisation to secondary CN was 11.1 months.

The randomised EORTC SURTIME study revealed that the sequence of CN and sunitinib did not affect PFS (HR: 0.88, 95% CI: 0.59-1.37, p = 0.569). The trial accrued poorly and therefore results are mainly exploratory. However, in secondary endpoint analysis a strong OS benefit was observed in favour of the deferred CN approach in the ITT population with a median OS of 32.4 (range 14.5-65.3) months in the deferred CN arm vs. 15.0 (9.3-29.5) months in the immediate CN arm (HR: 0.57, 95% CI: 0.34-0.95, p = 0.032). The deferred CN approach appears to select patients with inherent resistance to systemic therapy [495]. This confirms

previous findings from single-arm phase II studies [493, 496]. Moreover, deferred CN and surgery appear safe after sunitinib which supports the findings, with some caution, of the only available RCT. In patients with poor PS or IMDC poor risk, small primaries, and high metastatic volume and/or a sarcomatoid tumour, CN is not recommended [497]. These data are confirmed by CARMENA [448] and upfront pre-surgical VEGFR-targeted therapy followed by CN seems to be beneficial [489].

Meanwhile first-line therapy recommendations for patients with their primary tumour in place have changed to ICI combination therapy (see Section 7.4.2.4) with sunitinib and other VEGFR-TKI monotherapies reserved for those who cannot tolerate ICI combination or have no access to these drugs. High-level evidence regarding CN is not available for ICI combinations but up to 30% of patients with primary metastatic disease, treated with their tumour in place, were included in the pivotal ICI combination trials (Table 7.2). The subgroup HRs, where available, suggest better outcomes for the ICI combination compared to sunitinib monotherapy. In mRCC patients without a need for immediate drug treatment, a SR evaluating effects of CN demonstrated an OS advantage of CN [493]. These data were supported by a nation-wide registry study showing that patients selected for primary CN had a significant OS advantage across all age groups [498].

Table 7.2: Key trials on immune checkpoint inhibitor combinations for primary metastatic disease

Trial	Drug combination	Number and % of patients treated with primary tumour in place	Number of patients treated with the primary tumour in place (ICI combination vs. sunitinib)		Subgroup analyses (HR with 95% CIs)	
			ICI combination	sunitinib	PFS	OS
CheckMate 214 [499]	ipilimumab + nivolumab	187/847 (22%)	84	103	NA	0.63 (0.42-0.94)
CheckMate 9ER [500]	cabozantinib + nivolumab	196/651 (30.1%)	101	95	0.63 (0.43-0.92)	0.79 (0.48-1.29)
Javelin 101 [501]	axitinib + avelumab	179/886 (20.2%)	90	89	0.75 (0.48-1.65)	NA
KEYNOTE-426 [502]	axitinib + pembrolizumab	143/861 (16.6%)	73	70	0.68 (0.45-1.03)	0.57 (0.36-0.89)
CLEAR [503]	lenvatinib + pembrolizumab	179/714 (25.1%)	97	82	0.38 (0.31-0.48)	0.52 (0.31-0.86)

CI = confidence interval; HR = hazard ratio; ICI = immune checkpoint inhibitor; NA = not available; PFS = progression-free survival; OS = overall survival.

The results of CARMENA and SURTIME demonstrated that patients who require systemic therapy benefit from immediate drug treatment. While randomised trials to investigate deferred vs. no cytoreductive nephrectomy with ICI and ICI combinations are ongoing, the exploratory results from the ICI combination trials demonstrate that the respective Immune-Oncology (IO) + IO or TKI + IO combinations have a superior effect on the primary tumour and metastatic sites when compared to sunitinib alone (Table 7.2). In accordance with the CARMENA and SURTIME data this suggests that mRCC patients and IMDC intermediate- and poor-risk groups with their primary tumour in place should be treated with upfront IO-based combinations. In patients with a clinical response to IO-based combinations, a subsequent CN may be considered. Real-world data have demonstrated durable response and surgical safety with this strategy, however long-term surveillance is lacking [504-506].

7.3.1.1.1 Embolisation of the primary tumour

In patients unfit for surgery or with non-resectable disease, embolisation can control symptoms including visible haematuria or flank pain [309, 462] (see recommendations Section 7.1.2.2.4).

7.3.1.1.2 Summary of evidence and recommendations for local therapy of advanced/metastatic RCC

Summary of evidence	LE
Deferred CN with pre-surgical sunitinib in intermediate-risk patients with clear cell metastatic renal cell carcinoma shows a survival benefit in secondary endpoint analyses and selects out patients with inherent resistance to systemic therapy.	2b
Sunitinib alone is non-inferior compared to immediate CN followed by sunitinib in patients with MSKCC intermediate and poor risk who require systemic therapy with VEGFR-TKI.	1a
Cytoreductive nephrectomy in patients with simultaneous complete resection of a single metastasis or oligometastases may improve survival and delay systemic therapy.	3
Patients with MSKCC or IMDC poor risk do not benefit from CN.	1a
Patients with their primary tumour in place treated with IO-based combination therapy have better PFS and OS in exploratory subgroup analyses compared to treatment with sunitinib.	2b

Recommendations	Strength rating
Do not perform cytoreductive nephrectomy (CN) in MSKCC poor-risk patients.	Strong
Do not perform immediate CN in intermediate-risk patients who have an asymptomatic synchronous primary tumour and require systemic therapy.	Weak
Start systemic therapy without CN in intermediate-risk patients who have an asymptomatic synchronous primary tumour and require systemic therapy.	Weak
Discuss delayed CN with patients who derive clinical benefit from systemic therapy.	Weak
Perform immediate CN in patients with a good performance status who do not require systemic therapy.	Weak
Perform immediate CN in patients with oligometastases when complete local treatment of the metastases can be achieved.	Weak

*7.3.2 **Local therapy of metastases in metastatic RCC***

A SR of the local treatment of metastases from RCC in any organ was undertaken [507]. Interventions included metastasectomy, various radiotherapy modalities, and no local treatment. The outcomes assessed were OS, CSS and PFS, local symptom control and AEs. A risk-of-bias assessment was conducted [508]. Of the 2,235 studies identified only sixteen non-randomised comparative studies were included. Data were too heterogeneous to meta-analyse. There was considerable variation in the type and distribution of systemic therapies (cytokines and VEGF-inhibitors) and in reporting the results. A subsequent SR did not change the quality of evidence [509].

7.3.2.1 Complete versus no/incomplete metastasectomy

A SR, including only eight studies, compared complete vs. no and/or incomplete metastasectomy of RCC metastases in various organs [510-517]. In one study complete resection was achieved in only 45% of the metastasectomy cohort, which was compared with no metastasectomy [517]. Non-surgical modalities were not applied. Six studies [511-513, 515-517] reported a significantly longer median OS or CSS following complete metastasectomy (the median value for OS or CSS was 40.75 months, range 23-122 months) compared with incomplete and/or no metastasectomy (the median value for OS or CSS was 14.8 months, range 8.4-55.5 months). Of the two remaining studies, one [510] showed no significant difference in CSS between complete and no metastasectomy, and one [514] reported a longer median OS for metastasectomy albeit no p-value was provided.

7.3.2.2 Local therapies for RCC bone metastases

Of the three studies identified, one compared single-dose image-guided radiotherapy (IGRT) with hypofractionated IGRT in patients with RCC bone metastases [518]. Single-dose IGRT (> 24 Gy) had a significantly better 3-year actuarial local PFS rate, also shown by Cox regression analysis. Another study compared metastasectomy/curettage and local stabilisation with no surgery of solitary RCC bone metastases in various locations [519]. A significantly higher five-year CSS rate was observed in the intervention group. After adjusting for prior nephrectomy, gender and age, multivariable analysis still favoured metastasectomy/curettage and stabilisation. A third study compared the efficacy and durability of pain relief between single-dose stereotactic body radiotherapy (SBRT) and conventional radiotherapy in patients with RCC bone metastases to the spine [520]. Pain, ORR, time-to-pain relief and duration of pain relief were similar.

7.3.2.3 Local therapies for RCC brain metastases

Two studies on RCC brain metastases were included. A three-arm study compared stereotactic radiosurgery (SRS) vs. whole brain radiotherapy (WBRT) vs. SRS and WBRT [521]. Each group was further subdivided into recursive partitioning analysis (RPA) classes I to III (I favourable, II moderate and III poor patient status). Two-year OS and intra-cerebral control were equivalent in patients treated with SRS alone and SRS plus WBRT.

Both treatments were superior to WBRT alone in the general study population and in the RPA subgroup analyses. A comparison of SRS vs. SRS and WBRT in a subgroup analysis of RPA class I showed significantly better 2-year OS and intra-cerebral control for SRS plus WBRT based on only three participants. The other study compared fractionated stereotactic radiotherapy (FSRT) with metastasectomy and conventional radiotherapy or conventional radiotherapy alone [522]. Several patients in all groups underwent alternative surgical and non-surgical treatments after initial treatment. One-, two- and three-year survival rates were higher but not significantly so for FSRT as for metastasectomy and conventional radiotherapy, or conventional radiotherapy alone. Fractionated stereotactic radiotherapy did not result in a significantly better two-year local control rate compared with metastasectomy plus conventional radiotherapy.

Stereotactic radiotherapy (SRT) with a median physical dose of 20 (18-30) Gy and a biologically effective dose (DED10) of 63.3 (45-125) Gy in a median (range) of 1 (1-6) fractions for 1-5 brain metastases were safe also during ICI and targeted therapy [479]. Targeted therapy was paused only in one-third of patients for 2-21 days. Local control at all sites, including extracranial, was 75% at one year. After one year, 62% of patients remained on the same systemic therapy as at the time of SRT, which was more frequent for ICI therapy as compared to targeted therapy (83% vs. 36%; p = 0.035). No grade IV or V toxicity was observed.

7.3.2.4 Embolisation of metastases

Embolisation prior to resection of hypervascular bone or spinal metastases can reduce intra-operative blood loss [174]. In selected patients with painful bone or paravertebral metastases, embolisation can relieve symptoms [175] (see recommendation Section 7.1.2.2.4).

7.3.2.5 Stereotactic radiotherapy in oligo-recurrent and oligo-progressive metastases

Sterotatic radiotherapy has been used in oligoprogression (i.e. limited number of metastasis in progression, while other sites are controlled under systemic therapy) and in oligonmetastatic recurrences. Two SRs of single arm studies have been conducted [523, 524]. The non comparative nature of the studies included in both SR does not allow to definate conclusions.

A retrospective analysis of 207 patients with oligo-recurrent and oligo-progressive lesions in mainly bones and lungs with or without systemic therapy (mainly targeted therapy) demonstrated two-year local control rate of 78.3% (95% CI: 72.5-83.0). One, two and three-year local control rates were 89.4%, 80.1% and 76.6% in oligo-recurrent patients, and 82.7%, 76.9% and 64.3% in those with oligo-progressive disease, respectively. Median applied biologically effective dose (BED) 10 was 60 Gy. Median time to subsequent systemic therapy was 13.9 months and median PFS was 37.9 months. No grade III or higher toxicities were reported [525].

Similar results in oligo-progressive mRCC has been reported in a single-arm prospective study including 37 patients with IMDC favourable- and intermediate risk where one-year local control of the irradiated lesions was 93% (95% CI: 71-98%) and median time to change in systemic TKI therapy was 12.6 months (95% CI: 9.6-17.4 months). Median therapy prior to study entry was 18.6 months and therapy was discontinued during SRT. The median BED10 was 72 Gy, corresponding to a SRT dose of 40 Gy in 5 fractions. Median PFS was 9.3 months and there were no reported grade III acute or late toxicities [526]. Several RCTs with SBRT in oligometastatic setting are ongoing.

7.3.2.6 Adjuvant treatment in cM0 patients after metastasectomy

Patients after metastasectomy and no evidence of disease (cM0) have a high risk of relapse. Recent attempts to reduce RFS in randomised prospective phase II trials of sorafonib and pazopanib after metastasectomy did not demonstrate an improvement in RFS [176, 177].

KEYNOTE-564 included a small percentage of patients who were treated by nephrectomy and complete metastasectomy within one year after primary diagnosis (6% in the experimental arm and 6% in the placebo arm) [483, 484]. A metachronous interval of < 1 year for recurrences following surgery with curative intent is a poor prognostic factor by IMDC classification [[267, 527]. Systemic therapy based on immune combinations has stronger levels of evidence than surgery in this intermediate/advanced disease setting [528]. Also, TKI- driven adjuvant trials after metastasectomy have shown no DFS or OS benefit [176, 177].

Results for single-agent pembrolizumab post-surgery for metastatic disease are therefore difficult to interpret due to the small subgroup. Nevertheless, the DFS HR of 0.29 (95% CI: 0.12-0.69) in favour of resection of M1 to NED plus pembrolizumab shows that patients with subclinical, but progressive, disease who were subjected to metastasectomy had a benefit of adjuvant systemic therapy with pembrolizumab. Based on the current data it cannot be concluded that for patients with oligo-progressive disease, metastasectomy within the first year of initial diagnosis of the primary and subsequent adjuvant pembrolizumab is superior to a period of observation and dual IO-based combination first-line therapy upon progression. Data from the TKI era suggest that patients with oligometastatic disease recurrence can be observed for up to a median of sixteen months before systemic therapy is required and that this practice is common in real-world settings (30%) [529, 530].

In addition, it is possible that metastasectomy may lead to poorer outcomes compared to systemic therapy approaches as a relapse within the first twelve months and presentation with synchronous (oligo-metastatic disease is attributed to the IMDC intermediate risk-group. The Panel therefore does not encourage metastasectomy and adjuvant pembrolizumab in this population with recurrent disease within one year after primary surgery. A careful reassessment of disease status to rule out rapid progressive disease should be performed. Data from another adjuvant ICI study with the PD-L1 inhibitor atezolizumab (IMmotion010) also included an M1 NED subgroup which showed no DFS advantage [485]. This result underscores the need for caution in the treatment of the M1 NED subgroup.

7.3.2.7 Summary of evidence and recommendations for local therapy of metastases in metastatic RCC

Summary of evidence	LE
Retrospective comparative studies point towards a benefit of complete metastasectomy in mRCC patients in terms of OS, CSS and delay of systemic therapy.	3
A single-arm prospective and retrospective study support that oligometastases can be observed for up to 16 months before systemic therapy is required due to progression.	2a
Radiotherapy to bone and brain metastases from RCC can induce significant relief from local symptoms (e.g. pain).	3
Tyrosine kinase inhibitors treatment after metastasectomy in patients with no evidence of disease did not improve RFS when compared to placebo or observation.	1b

Recommendations	Strength rating
To control local symptoms, offer ablative therapy, including metastasectomy, to patients with metastatic disease and favourable disease factors and in whom complete resection is achievable.	Weak
Offer stereotactic radiotherapy for clinically relevant bone- or brain metastases for local control and symptom relief.	Weak
Do not offer tyrosine kinase inhibitor treatment to mRCC patients after metastasectomy and no evidence of disease.	Strong
Perform a confirmatory axial scan of disease status prior to metastasectomy to rule out rapid progressive metastatic disease which requires systemic treatment.	Weak
Before initiating systemic therapy for oligometastases that cannot be resected, discuss with your patient a period of observation until progression is confirmed.	Weak

7.4 Systemic therapy for advanced/metastatic RCC

*7.4.1 **Chemotherapy***

Chemotherapy has proven to be generally ineffective in the treatment of RCC but can be offered to patients with collecting duct or medullary carcinoma [178].

7.4.1.1 Recommendation for systemic therapy in advanced/metastatic RCC

Recommendation	Strength rating
Do not offer chemotherapy to patients with metastatic renal cell carcinoma.	Strong

*7.4.2 **Targeted therapies***

In sporadic ccRCC, HIF accumulation due to VHL-inactivation results in overexpression of VEGF and platelet-derived growth factor (PDGF), which promote neo-angiogenesis [531-533]. This process substantially contributes to the development and progression of RCC. Several targeting drugs for the treatment of mRCC are approved in both the USA and Europe.

Most published trials have selected for clear-cell carcinoma subtypes, thus no robust evidencebased recommendations can be given for non-ccRCC subtypes.

In major trials leading to registration of the approved targeted agents, patients were stratified according to the IMDC risk model (see chapter 6.6 on prognostic models) [269].

7.4.2.1 Tyrosine kinase inhibitors

7.4.2.1.1 Sunitinib

Sunitinib is an oral TKI inhibitor and has anti-tumour and anti-angiogenic activity. First-line monotherapy with sunitinib demonstrated significantly longer PFS compared with IFN-α. Overall survival was greater in patients treated with sunitinib (26.4 months) vs. IFN-α (21.8 months) despite crossover [534].

In the EFFECT trial, sunitinib 50 mg/day (four weeks on/two weeks off) was compared with continuous uninterrupted sunitinib 37.5 mg/day in patients with clear cell metastatic renal cell carcinoma (cc-mRCC) [535]. No significant differences in OS were seen (23.1 vs. 23.5 months, p = 0.615). Toxicity was comparable in both arms. Because of the non-significant, but numerically longer time to progression with the standard 50 mg dosage, the authors recommended using this regimen. Alternate scheduling of sunitinib (two weeks on/one week off) is being used to manage toxicity, but robust data to support its use is lacking [536, 537].

7.4.2.1.2 Pazopanib

Pazopanib is an oral angiogenesis inhibitor. In a trial of pazopanib vs. placebo in treatment-naive mRCC patients and cytokine-treated patients, a significant improvement in PFS and tumour response was observed [538].

A non-inferiority trial comparing pazopanib with sunitinib (COMPARZ) established pazopanib as an alternative to sunitinib. It showed that pazopanib was not associated with significantly worse PFS or OS compared to sunitinib. The two drugs had different toxicity profiles, and QoL was better with pazopanib pazopanib [539]. In another patient-preference study (PISCES), patients preferred pazopanib to sunitinib (70% vs. 22%, p < 0.05) due to symptomatic toxicity [540]. Both studies were limited in that intermittent therapy (sunitinib) was compared with continuous therapy (pazopanib).

7.4.2.1.3 Axitinib

Axitinib is an oral selective second-generation inhibitor of VEGFR-1, -2, and -3. Axitinib was first evaluated as second-line treatment. In the AXIS trial, axitinib was compared to sorafenib in patients who had previously failed cytokine treatment or targeted agents (mainly sunitinib) [541].

The overall median PFS was greater for axitinib than sorafenib. Axitinib was associated with a greater PFS than sorafenib (4.8 vs. 3.4 months) after progression on sunitinib. Axitinib showed grade 3 diarrhoea in 11%, hypertension in 16%, and fatigue in 11% of patients. Final analysis of OS showed no significant differences between axitinib or sorafenib [542]. In a randomised phase III trial of axitinib vs. sorafenib in first-line treatment-naive cc-mRCC, a significant difference in median PFS between the treatment groups was not demonstrated, although the study was underpowered, raising the possibility of a type II error [543]. As a result of this study, axitinib is not approved for first-line therapy.

7.4.2.1.4 Cabozantinib

Cabozantinib is an oral inhibitor of tyrosine kinase, including MET, VEGF and AXL. Cabozantinib was investigated in a phase I study in patients resistant to VEGFR and mTOR inhibitors demonstrating objective responses and disease control [232]. Based on these results an RCT investigated cabozantinib vs. everolimus in patients with ccRCC failing one or more VEGF-targeted therapies (METEOR) [544, 545]. Cabozantinib delayed PFS compared to everolimus in VEGF-targeted therapy refractory disease (HR: 0.58, 95% CI: 0.45-0.75) [544] (LE: 1b). The median OS was 21.4 months (95% CI: 18.7 to not estimable) with cabozantinib and 16.5 months (95% CI: 14.7-18.8) with everolimus in VEGF-resistant RCC. The HR for death was 0.66 (95% CI: 0.53-0.83, p = 0.0003) [500]. Grade III or IV adverse events were reported in 74% with cabozantinib and 65% with everolimus. Adverse events were managed with dose reductions; doses were reduced in 60% of the patients who received cabozantinib.

The Alliance A031203 CABOSUN randomised phase II trial comparing cabozantinib and sunitinib in first-line in 157 intermediate- and poor-risk patients favoured cabozantinib for RR and PFS, but not OS [546, 547]. Cabozantinib significantly increased median PFS (8.2 vs. 5.6 months, adjusted HR: 0.66, 95% CI: 0.46 to 0.95; one-sided p = 0.012). Objective response rate was 46% (95% CI: 34-57) for cabozantinib vs. 18% (95% CI: 10-28) for sunitinib. All-causality grade III or IV adverse events were similar for cabozantinib and sunitinib. No difference

in OS was seen. Due to limitations of the statistical analyses within this trial, the evidence is inferior over existing choices.

7.4.2.1.5 Lenvatinib

Lenvatinib is an oral multi-target TKI of VEGFR1, VEGFR2, and VEGFR3, with inhibitory activity against fibroblast growth factor receptors (FGFR1, FGFR2, FGFR3, and FGFR4), platelet growth factor receptor (PDGFRα), re-arranged during transfection (RET) and receptor for stem cell factor (KIT). It has recently been investigated in a randomised phase II study in combination with everolimus vs. lenvatinib or everolimus alone (see Section 7.4.4.1.1 for discussion of results) [548].

7.4.2.1.6 Tivozanib

Tivozanib is a potent and selective TKI of VEGFR1, VEGFR2, and VEGFR3 and was compared in two phase III trials with sorafenib in patients with mRCC [549, 550]. Tivozanib was approved by the EMA in front-line mRCC. While it was associated with a PFS advantage in both studies, no OS advantage was seen. In view of the choice of sorafenib as the control arm in the front-line trial, the Panel considers there is too much uncertainty, and too many attractive alternatives, to support its use in this front-line setting.

7.4.2.2 Monoclonal VEGF antibody

Bevacizumab is a humanised monoclonal antibody. Initial first-line treatment in combination with IFN-α has been superseded by more effective therapies [551-553]. Bevacizumab in combination with atezolizumab has not been approved for treatment of mRCC (see Section 7.4.3.2) [554].

7.4.2.3 mTOR inhibitors

7.4.2.3.1 Temsirolimus

Temsirolimus is a specific inhibitor of mTOR [555]. Its use has been superseded as front-line treatment option.

7.4.2.3.2 Everolimus

Everolimus is an oral mTOR inhibitor, which is established in the treatment of VEGF-refractory disease. The RECORD-1 study compared everolimus plus best supportive care (BSC) vs. placebo plus BSC in patients with previously failed anti-VEGFR treatment (or previously intolerant of VEGF-targeted therapy) [556]. The data showed a median PFS of 4 vs. 1.9 months for everolimus and placebo, respectively [556].

The Panel consider, even in the absence of conclusive data, that everolimus may present a therapeutic option in patients who were intolerant to, or previously failed, immune- and VEGFR-targeted therapies (LE: 4). Recent phase II data suggest adding lenvatinib is attractive.

7.4.2.4 Small molucule inhibitor.

7.4.2.4.1 Belzutifan

Belzutifan is an inhibitor of the HIF2a transcription factor with single agent activity ccRCC. Initial Phase I/II trials in 55 patients confirmed objective response rate was 25% (all partial responses), and the median progression-free survival was 14.5 months. The most common grade ≥3 adverse events were anemia (27%) and hypoxia (16%) [59]. In the randomised phase III LITESPARK 005, it shows a progression free survival advantage over everolimus in heavily pretreated ccRCC. It has a favorable adverse event profile. It should be considered as an attractive alternative to everolimus in this setting. Overall survival is awaited as are the results of a number of combination studies [557].

7.4.2.5 Vascular endothelial growth factor (VEGF) targeted therapy

Intermittent VEGF targeted therapy is attractive for patients on long term therapy, due to the chronic toxicity associated with long term therapy such as fatigue. It has been tested with sunitinib or pazopainib in a phase III study and found to be safe [558]. Patients in the study had stable disease (or better) for at least six months after staring therapy. They were closely followed for progression with cross sectional imaging. Cessation of therapy was associated with higher rates of progression but no detrimental effect was seen on OS [558]. Intermittent therapy has not been tested with VEFG/PD-1 combinations, therefore its application in the modern 1st line setting is unknown, but extrapolation suggests it should be safe.

7.4.2.6 Summary of evidence and recommendations for single-agent targeted therapy in metastatic clear-cell RCC

Summary of evidence	LE
Single-agent VEGF-targeted therapy has been superseded by immune checkpoint-based combination therapy.	1b
Intermittent VEGF therapy can be considered in patients on long term VEGF targeted therapy	2
IO-VEGFR TKI combination estblished RR and PFS benefot over single agent VEGFR TKI but no OS benefit in subgroup analysis.	1a
Pazopanib is non-inferior to sunitinib as first-line management option in mRCC.	1b
Cabozantinib in intermediate- and poor-risk treatment-naive ccRCC leads to better response rates and PFS but not OS when compared to sunitinib.	2b
Tivozanib has been EMA approved in first-line setting.	3
Single-agent VEGF-targeted therapies are preferentially recommended after first-line PD-L1-based combinations. Re-challenge with treatments already used should be avoided.	3
Single-agent cabozantinib or nivolumab are superior to everolimus after one or more lines of VEGF-targeted therapy.	1b
Everolimus prolongs PFS after VEGF-targeted therapy when compared to placebo. This is no longer widely recommended before third-line therapy.	1b
Belzutifan has a progression free survial advantage over everolimus in second and more lines pretreated clear cell renal cancer.	1b
Lenvatinib in combination with everolimus improved PFS over everolimus alone in VEGF-refractory disease. Its role after ICIs is uncertain. There is a lack of robust data on this combination making its recommendation challenging.	2a

Recommendations	Strength rating
Offer nivolumab or cabozantinib for immune checkpoint inhibitor-naive vascular endothelial growth factor receptor (VEGFR)-refractory clear-cell metastatic renal cell carcinoma (cc-mRCC) after one or two lines of therapy.	Strong
Sequencing the agent not used as second-line therapy (nivolumab or cabozantinib) for third-line therapy is recommended.	Weak
Offer VEGF-tyrosine kinase inhibitors as second-line therapy to patients refractory to nivolumab plus ipilimumab or axitinib plus pembrolizumab or cabozantinib plus nivolumab or lenvatinib plus pembrolizumab.	Weak
Offer cabozantinib after VEGF-targeted therapy in cc-mRCC.	Strong
Sequence systemic therapy in treating mRCC.	Strong
Offer immune checkpoint inhibitor combination therapy for advanced cc-mRCC with sarcomatoid features.	Weak
Offer belzutifan as an alternative to everolimus in patients previously treated with second to fourth line therapy for clear cell renal carcinoma.	Weak
Intermittent single agent VEGFR tyrosine kinase inhibitor can be offered in case of partial response or stable disease > 6 months	Weak

7.4.3 ***Immunotherapy***

7.4.3.1 Immune checkpoint inhibitors

7.4.3.1.1 Immuno-oncology monotherapy

Immune checkpoint inhibitor with monoclonal antibodies targets and blocks the inhibitory T-cell receptor PD-1 or cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4)-signalling to restore tumour-specific T-cell immunity [559]. Immune checkpoint inhibitor monotherapy has been investigated as second- and third-line therapy. A phase III trial of nivolumab vs. everolimus after one or two lines of VEGF-targeted therapy for mRCC with a clear cell component (CheckMate 025, NCT01668784) reported a longer OS, better QoL and fewer grade 3 or 4 AEs with nivolumab than with everolimus [560]. Nivolumab has superior OS to everolimus (HR: 0.73, 95% CI: 0.57-0.93, $p < 0.002$) in VEGF-refractory RCC with a median OS of 25 months for nivolumab and 19.6 months for

everolimus with a 5-year OS probability of 26% vs. 18% [561] (LE: 1b). Patients who had failed multiple lines of VEGF-targeted therapy were included in this trial making the results broadly applicable. The trial included 15% MSKCC poor-risk patients. There was no PFS advantage with nivolumab despite the OS advantage. Progression-free survival does not appear to be a reliable surrogate of outcome for PD-1 therapy in RCC. Currently PD-L1 biomarkers are not used to select patients for this therapy.

There are no RCTs supporting the use of single-agent ICI in treatment-naive patients. Randomised phase II data for atezolizumab vs. sunitinib showed a HR of 1.19 (95% CI: 0.82-1.71) which did not justify further assessment of atezolizumab as single agent as first-line treatment option in this group of patients, despite high complete response rates in the biomarker-positive population [562]. Single-arm phase II data for pembrolizumab from the KEYNOTE-427 trial show high response rates of 38% (up to 50% in PD-L1+ patients), but a PFS of 8.7 months (95% CI: 6.7-12.2) [562]. Based on these results and in the absence of randomised phase III data, single-agent checkpoint inhibitor therapy is not recommended as an alternative in a first-line therapy setting.

In addition, several trials explored the strategy of nivolumab monotherapy in first-line ccRCC followed by a salvage strategy with nivolumab plus ipilimumab upon progression or if stable disease was the best response. Trial results do not support such a strategy which was frequently not feasible and of limited benefit [563, 564].

7.4.3.2 Immunotherapy/combination therapy

The phase III trial CheckMate 214 (NCT 02231749) showed a superiority of nivolumab and ipilimumab over sunitinib. The primary endpoint population focused on the IMDC intermediate- and poor-risk population where the combination demonstrated an OS benefit (HR: 0.63, 95% CI: 0.44-0.89) which led to regulatory approval [499] and a paradigm shift in the treatment of mRCC [565]. Results from CheckMate 214 further established that the combination of ipilimumab and nivolumab was associated with higher response rates (RR) (39% in the ITT population), complete RR (8% in the ITT population [central radiology review]) and duration of response compared to sunitinib. Progression-free survival did not achieve the pre-defined endpoint. The exploratory analysis of OS data in the PD-L1-positive population was 0.45 (95% CI: 0.29-0.41).

A recent update with 60-month data shows ongoing benefits for the immune combination with independently assessed complete response rates of 11% and a HR for OS in the IMDC intermediate- and poor-risk group of 0.68 (0.58-0.81) [520]. However, this complete response rate has not been consistent across trials for this combination (the Cosmic313 study showed complete response rates of 3% [566]).

In CheckMate 214 the 60-months OS probability was 43% for ipilimumab plus nivolumab vs. 31% for sunitinib, respectively [567]. In this update the IMDC good-risk group did not continue to perform better with sunitinib although this effect occurs due to a late overlap of the Kaplan-Meier curves (HR for OS: 0.94 [95% CI: 0.65-1.37]) [567]. Nivolumab plus ipilimumab was associated with 46% grade III-IV toxicity and 1.5% treatment-related deaths. It should therefore be administered in centres with experience of immune combination therapy and appropriate supportive care within the context of a multidisciplinary team (LE: 4). PD-L1 biomarker is currently not used to select patients for therapy.

The frequency of steroid use has generated controversy and further analysis, as well as real world data, are required. For these reasons the Panel continues to recommend ipilimumab and nivolumab in the intermediate- and poor-risk population.

The KEYNOTE-426 trial (NCT02853331 reported results for the combination of axitinib plus pembrolizumab vs. sunitinib in 861 treatment-naive cc-mRCC patients [568]. Overall survival and PFS assessed by central independent review in the ITT population were the co-primary endpoints. Response rates and assessment in the PD-L1-positive patient population were secondary endpoints. With a minimum follow-up of 35.6 months (median 42.8 months) this trial demonstrated an ongoing OS benefit for axitinib plus pembrolizumab in the ITT population (HR: 0.73, 95% CI: 0.60-0.88, $p < 0.001$). Median OS for axitinib plus pembrolizumab was 45.7 months (95% CI: 43.6 - NR) vs. 40.1 month (95% CI: 34.3 - 44.2) for sunitinib with a PFS benefit (HR: 0.68, 95% CI: 0.58-0.80, $p < 0.0001$) which was shown across all IMDC subgroups for PFS, while OS was similar between axitinib plus pembrolizumab vs. sunitinib in the favourable subgroup with an OS benefit in the IMDC intermediate- and poor-risk groups. The complete response rate by independent review was 10% in the pembrolizumab plus axitinib arm and 4% in the sunitinib arm [569]. With an extended median follow-up of 67 months median OS was 47.2 months (43.6-54.8) vs. 40.8 months (34.3-47.5; HR 0.84 95%CI: 0.71-0.99)) for sunitib, median PFS was 15.7 (13.6-20.2) vs. 11.1 (8.9-12.5) HR 0.69 (95% CI: 0.59-0.81) and ORR was 60.6% (CR 11.6%) vs. 39.6% (CR 4.0%) [570]. Treatment-related adverse events (≥ grade III) occurred in 63% of patients receiving axitinib and pembrolizumab vs. 58% of patients receiving sunitinib. Treatment- related deaths occurred in approximately 1% in both arms [568].

The phase III CheckMate 9ER trial randomised 651 patients to nivolumab plus cabozantinib (n = 323) or vs. sunitinib (n = 328) in treatment-naive cc-mRCC patients [456]. The primary endpoint of PFS assessed by central independent review in the ITT population was significantly prolonged for nivolumab plus cabozantinib (16.6 months) vs. sunitinib (8.3 months, HR: 0.51, 95% CI: 0.41-0.64, p < 0.0001). The nivolumab/cabozantinib combination also demonstrated a significant OS benefit in the secondary endpoint compared with sunitinib (HR: 0.60, CI: 0.40-0.89, p = 0.0010) after a median follow-up of 18.1 months in the initial report [571]. The independently assessed ORR was 55.7% vs. 27.1% with a complete response rate of 8% for nivolumab plus cabozantinib vs. 4.6% with sunitinib. The efficacy was observed independent of IMDC group and PD-L1 status. Treatment-related adverse events (> grade III) occurred in 61% of patients receiving cabozantinib and nivolumab vs. 51% of patients receiving sunitinib. Treatment-related deaths occurred in one patient in the nivolumab/cabozantinib arm and in two patients in the sunitinib arm. With an extended follow-up with median 44 months the median OS was 49.5 months (40.3-not estimable) in the nivolumab plus cabozantinib patients vs. 35.5 months (29.2-42.3) in the sunitinib treated patients (HR: 0.70 [95% CI: 0.56-0.87, p = 0.0043). The updated median PFS was 16.6 months (12.8-19.5) vs. 8.4 months (7.0-9.7; HR 0.59 [95% CI: 0.49-0.71], p < 0·0001 [572].

The randomised phase III trial CLEAR (Lenvatinib/Everolimus or Lenvatinib/Pembrolizumab vs. Sunitinib Alone as Treatment of Advanced RCC) was published [573]. CLEAR randomised a total of 1,069 patients (in a 1:1:1 ratio) to lenvatinib plus pembrolizumab (n = 355) vs. lenvatinib plus everolimus (n = 357) vs. sunitinib (n = 357). The trial reached its primary endpoint of independently assessed PFS at a median of 23.9 vs. 9.2 months, for lenvatinib plus pembrolizumab vs. sunitinib, respectively (HR: 0.39, 95% CI: 0.32-0.49, p < 0.001). Overall survival significantly improved with lenvatinib plus pembrolizumab vs. sunitinib (HR: 0.66, 95% CI: 0.49-0.88, p = 0.005). Objective response for lenvatinib plus pembrolizumab was 71% with 16% of the patients having a complete remission. In the final analyis with a median follow-up of 49.8 months median OS was 53.7 months (48.7-not estimable) for lenvatinib plus pembrolizumab vs. 54.3 (40.9-not estimable; HR 0.79 95% CI: 0.63-0.99) for sunitinib [574]. Efficacy was observed across all IMDC risk groups, independently of PD-L1 status. Treatment-related adverse events (> grade III) with lenvatinib plus pembrolizumab were 72%. Treatment-related death occurred in four patients in the lenvatinib plus pembrolizumab arm and in one patient in the sunitinib arm.

The JAVELIN trial investigated 886 patients in a phase III RCT of avelumab plus axitinib vs. sunitinib [501]. The trial met one of its co-primary endpoints (PFS in the PD-L1-positive population at first interim analysis [median follow up 11.5 months]). Hazard ratios for PFS and OS in the ITT population were 0.69 (95% CI: 0.56-0.84) and 0.78 (95% CI: 0.55-1.08), respectively, but with a missing significant OS improvement also with longer follow-up [575] and in the third interim analyis with a median follow-up of 34.1 months [576]. The same applies to the atezolizumab/bevacizumab combination (IMmotion151) which also achieved a PFS advantage over sunitinib in the PD-L1-positive population at interim analysis and ITT (HR: 0.74, 95% CI: 0.57-0.96), but has not shown a significant OS advantage at final analysis (HR: 0.91 [95% CI: 0.76-1.08], p = 0.27) [554, 577]. Therefore, these combinations cannot currently be recommended.

In IMDC favourable patients the treatment with axitinib+pembrolizumab (Keynote-426), cabozantinib+nivolumab (CheckMate-9ER) and lenvatinib+pembrolizumab (CLEAR) improved PFS and objective response rate, but not OS [570, 572, 574]. Given the long-term follow-up with no OS improvement by the respective TKI+IO combination vs sunitinib, TKI monotherapy becomes a standard of care as an additiional choice in IMDC favourable patients. Although sunitinib was the TKI monotherapy used in theses trials, pazopanib is a valid alternative based on the non-inferiority data of the phase III trial COMPARZ [539].

The COSMIC-313 trial is the first RCT to evaluate a triple combination of cabozantinib (40 mg) plus nivolumab plus ipilimumab vs. nivolumab plus ipilimumab, a current standard of care, in 855 patients with IMDC intermediate- and poor-risk [578]. The primary endpoint of PFS improvement, measured in a PFS ITT of 550 patient was met after 249 events occurred with a HR 0.73 (95% CI: 0.57-0.94, p = 0.013) favouring the triplet therapy. Median PFS was not reached (14.0-NE) vs. 11.3 months (7.7-18.2) in the control arm with a median follow-up of 20.2 months. Overall survival has yet to be reported. Objective response was 43% vs. 36% in the triplet vs. the control arm with a complete response rate of 3% in both arms. Treatment-related adverse events (> grade III) with cabozantinib plus nivolumab plus ipilimumab were 73% vs. 41% in the nivolumab plus ipilimumab control arm. The use of high-dose steroids (> = 40 mg prednisolone or equivalent) was 58% (triplet) vs. 35%. (control). Treatment discontinuation rate of any agent was high in the triplet arm (45%) compared to the doublet (24%), whilst discontinuation of all treatments due to the same adverse events was 12% vs. 5% in the control arm.

Although the primary endpoint of PFS was met, objective response rates of the triplet combination are modest as known for TKI + IO doublets. Treatment-related adverse events are high with a high rate of treatment discontinuation. As the OS rate is currently unknown, the additional benefit of this triplet therapy compared to standard immune-based doublet therapy is still uncertain.

Table 7.4: First line immune checkpoint inhibitor combination trials for clear-cell RCC
Cross trial comparison is not recommended and should occur with caution

Study	N	Experimental arm	Primary endpoint	Risk groups	PFS (mo) Median (95% CI) HR	OS (mo) Median (95% CI) HR

ATEZO = atezolizumab; AVE = avelumab; AXI = axitinib; BEV = bevacizumab; BICR = blinded independent central review; BID = twice a day; CABO = cabozantinib; CI = confidence interval; FAV = favourable; HR = hazard ratio; IPI = ipilimumab; IMD = intermediate; IMDC = Metastatic Renal Cancer Database Consortium; IR = investigator review; ITT = intention-to-treat; IV = intravenous; LEN = lenvatinib; mo = months; MSKCC = Memorial Sloan Kettering Cancer Center; NE = non-estimable; NR = not reached; NIVO = nivolumab; OS = overall survival; PEMBRO = pembrolizumab; PFS = profession-free survival; PITT = PFS intention-to-treat; PO = by mouth; Pts = patients; QD = once a day; Q2W = every 2 weeks; Q3W = every 3 weeks; SUN = sunitinib; wk = weeks.

Patients who stop nivolumab plus ipilimumab because of toxicity require expert guidance and support from a multidisciplinary team before re-challenge can occur (LE: 1). Patients who do not receive the full four doses of ipilimumab due to toxicity should continue on single-agent nivolumab, where safe and feasible (LE: 4).
Treatment past progression with nivolumab plus ipilimumab can be justified but requires close scrutiny and the support of an expert multidisciplinary team [499, 581] (LE: 1).

Patients who stop TKI and IO due to immune-related toxicity can receive single-agent TKI once the adverse events has resolved (LE: 1). Adverse event management, including transaminitis and diarrhoea, require particular attention as both agents may be causative. Expert advice should be sought on re-challenge of ICIs after significant toxicity (LE: 4). Treatment past progression on axitinib plus pembrolizumab or nivolumab plus cabozantinib requires careful consideration as it is biologically distinct from treatment past progression on ipilimumab and nivolumab.

Based on Panel consensus, nivolumab plus ipilimumab, pembrolizumab plus axitinib and nivolumab plus cabozantinib and lenvatinib plus pembrolizumab should be administered in centres with experience of immune combination therapy and appropriate supportive care within the context of a multidisciplinary team (LE: 4).

*7.4.4 **Therapeutic strategies***

7.4.4.1 Treatment-naïve patients with clear-cell metastatic RCC

The combination of pembrolizumab plus axitinib as well as nivolumab plus cabozantinib and lenvatinib plus pembrolizumab is the standard of care in all IMDC-risk patients and ipilimumab plus nivolumab in IMDC intermediate- and poor-risk patients (Figure 7.1). Therefore, the role of VEGFR-TKIs alone in front-line mRCC has been superseded in IMDC intermidiate and poor risk. In IMDC Favorable group, in the absence of OS benefit both options are acceptable. Sunitinib, pazopanib, and cabozantinib (IMDC intermediate- and poor-risk disease), remain alternative treatment options for patients who cannot receive or tolerate immune checkpoint inhibition in this setting (Figure 7.1).

7.4.4.1.1 Sequencing systemic therapy in clear-cell metastatic RCC

The sequencing of targeted therapies is established in mRCC and maximises outcomes [548, 560]. Pembrolizumab plus axitinib, nivolumab plus cabozantinib, lenvatinib plus pembrolizumab and nivolumab plus ipilimumab are the new standard of care in front-line therapy in IMDC intermediate/poor. The impact of front-line immune checkpoint inhibition on subsequent therapies is unclear. Randomised data on patients with disease refractory to either nivolumab plus ipilimumab or TKI plus IO in a first-line setting are limited. Sequencing immune checkpoint inhibition with atezolizumab did not demonstrate ORR, PFS , OS benefit over single agent TKI in the CONTACT 03 [582, 583]. Prospective data on cabozantinib, tivozanib, and axitinib are available for patients progressing on immunotherapy, but these studies do not focus solely on the front-line setting, involve subset analyses, and are too small for definitive conclusions [560, 584].

The use of mTOR inhibitors can be considered in VEGF-targeted therapy refractory disease but has been outperformed by other VEGF-targeted therapies in mRCC and belzutifan [585]. Drug choice in the third-line setting, after immune checkpoint inhibitor combinations and subsequent VEGF-targeted therapy, is unknown. The Panel recommends a subsequent agent which is approved in VEGF-refractory disease, with the exception of re-challenge with immune checkpoint blockade. Cabozantinib is the only agent in VEGF-refractory disease with RCT data showing a survival advantage and should be used preferentially [518]. Axitinib has positive PFS data in VEGF- refractory disease. Both sorafenib and everolimus have been outperformed by other agents in VEGF-refractory disease and are therefore less attractive [585]. The lenvatinib plus everolimus combination appears superior to everolimus alone and has been granted EMA regulatory approval based on randomised phase II data. This is an alternative despite the availability of phase II data only [548]. As shown in a study which also included patients on ICIs, tivozanib provides PFS superiority over sorafenib in VEGF-refractory disease [586].

7.4.4.1.2 Summary of evidence and recommendations for immunotherapy in cc-mRCC

Summary of evidence	**LE**
Treatment-naïve patients	
Currently, PD-L1 expression is not used for patient selection.	2b
The combination of nivolumab and ipilimumab in treatment-naïve patients with cc-mRCC of IMDC intermediate- and poor risk demonstrated OS and ORR benefits compared to sunitinib alone.	1b
The combination of pembrolizumab plus axitinib, lenvatinib plus pembrolizumab and nivolumab plus cabozantinib in treatment-naïve patients with cc-mRCC demonstrated PFS, OS and ORR benefits compared to sunitinib in the ITT population.	1b
The combination of pembrolizumab plus axitinib, lenvatinib plus pembrolizumab and nivolumab plus cabozantinib in treatment-naïve patients with cc-mRCC in IMDC favorable subgroups demonstrated PFS and ORR benefits compared to sunitinib, without OS improvememt.	2b
Triplet CABO-NIVO-IPI demonsrated a PFS benefit over NIVO-IPI.	1b
Nivolumab plus ipilimumab, pembrolizumab plus axitinib, nivolumab plus cabozantinib and lenvatinib plus pembrolizumab should be administered in centres with experience of immune combination therapy and appropriate supportive care within the context of a multidisciplinary team.	4
Sequencing systemic therapy	
Nivolumab leads to superior OS compared to everolimus in disease progression after one or two lines of VEGF-targeted therapy.	1b
Axitinib, cabozantinib or lenvatinib can be continued if immune-related adverse events result in cessation of axitinib plus pembrolizumab, cabozantinib plus nivolumab or lenvatinib plus pembrolizumab. Re-challenge with immunotherapy requires expert support.	4

Patients who do not receive the full four doses of ipilimumab due to toxicity should continue on single-agent nivolumab, where safe and feasible. Re-challenge with combination therapy requires expert support.	4
Treatment past progression can be justified but requires close scrutiny and the support of an expert multidisciplinary team.	1b
Nivolumab plus ipilimumab was associated with 46% grade III-IV toxicity and 1.5% treatment-related deaths. Tyrosine kinase inhibitor-based IO combination therapies were associated with grade III-V toxicity ranging between 61-72% and 1% of treatment-related deaths.	1b
In the CONTACT 3 study atezolizomab plus cabozantinib offer no benefit compared to cabozantinib alone in patients who's cancers have previously progressed on immune checkpoint inhibition therapy.	1b
Cabozantinib as a single agent has the most robust data after first line PD1 based combination therapy.	3

Recommendations	**Strength rating**
First line Treatment for metastatic clear cell RCC patients	
Offer treatment with PD1 combinations in centres with experience.	Weak
Offer nivolumab plus ipilimumab, pembrolizumab plus axitinib, lenvatinib plus pembrolizumab or nivolumab and cabozantinib to patients with International Metastatic Renal Cell Carcinoma Database Consortium (IMDC) intermediate- or poor risk-disease.	Strong
Offer pembrolizumab plus axitinib, lenvatinib plus pembrolizumab or nivolumab and cabozantinib or sunitinib or pazopanib for IMDC favourable risk disease.	Weak
Offer sunitinib or pazopanib to patients with any IMDC risk who cannot receive or tolerate immune checkpoint inhibition.	Strong
Offer cabozantinib to patients with IMDC intermediate- and poor-risk clear cell metastatic renal carcinoma (cc-mRCC) who cannot receive or tolerate immune checkpoint inhibition.	Strong[a]
Patients who do not receive the full four doses of ipilimumab due to toxicity should continue on single-agent nivolumab, where safe and feasible. Re-challenge with combination therapy requires expert support after discontinuation for toxicity.	Weak
Sequencing systemic therapy for metastatic clear cell RCC	
Sequence systemic therapy in treating mRCC.	Strong
Offer carbozantinib or other vascular endothelial growth factor (VEGF)-tyrosine kinase inhibitors as second-line therapy to patients refractory to nivolumab plus ipilimumab or axitinib plus pembrolizumab or cabozantinib plus nivolumab or lenvatinib plus pembrolizumab.	Weak
Sequencing the agent not used as second-line therapy (nivolumab or cabozantinib) for third-line therapy is recommended.	Weak
Offer nivolumab or cabozantinib for those patients who received first line VEGF targeted therapy alone.	Strong
Treatment past progression can be justified but requires close scrutiny and the support of an expert multi-disciplinary team.	Weak
Do not re-challenge patients who stopped immune checkpoint inhibitors because of toxicity without expert guidance and support from a multi-disciplinary team.	Strong
Do not offer PD-L1 combination therapy after progression after immune checkpoint inhibition combination.	Weak

[a] *WWhile this is based on a randomised phase II trial, cabozantinib (weak) looks at least as good as sunitinib in this population. This justified the same recommendation under exceptional circumstances.*

7.4.4.1.3 Renal tumours with sarcomatoid features

Subset analyses have shown improved results for PD-L1 inhibitors combined with CTLA4 or VEGF-targeted therapy in renal tumours with sarcomatoid features. Ipilimumab/nivolumab, axitinib/pembrolizumab and lenvatinib/pembrolizumab avelumab/axitinib can all be recommended instead of VEFG-targeted therapy alone. These options have OS advantages over sunitinib and superseded VEGF-targeted therapy. Nivolumab/Ipilimumab provided *post hoc* analysis demonstrating ORR of 61%, including 23% CR rate, PFS and OS benefit over sunitinb (HR 0.50 and OS HR 0.46 respectively with median OS 48.6 vs 14.2 month [587].

Table 7.5: Subgroup analysis of first-line immune checkpoint inhibitor combinations in RCC patients with sarcomatoid histology
Cross trial comparison is not recommended and should occur with caution

Study	N (ITT)	Therapy	N (sRCC)	PFS (mo.) Median (95% CI) HR	OS (mo.) Median (95% CI) HR	ORR (%) (95% CI)

7.4.4.1.3.1 Summary of evidence and recommendation for targeted therapy in RCC with sarcomatoid features

Summary of evidence	LE
Immune checkpoint inhibitor combination therapy is superior to sunitinib in terms of PFS and OS in trial subset analysis of clear-cell RCC with sarcomatoid features.	2a

Recommendation	Strength rating
Offer immune checkpoint inhibitor combination therapy for advanced clear cell metastatic renal carcinoma with sarcomatoid features.	Weak

7.4.4.2 Treatment of patients with non-clear-cell metastatic RCC (general considerations)

For the sake of historical purposes, the Panel recognises the use of Non-cc-mRCC but will where possible refer to the distinct subtype. This is a heterogenous group including papillary, chromophobe and other rare tumours with a widely differing tumour biology. Patients with non-cc-mRCC should therefore be referred to a clinical trial, where appropriate.While no phase III trials of patients with non-cc-mRCC have been reported it is increasingly recognised to study specific subtypes which have a higher incidence than other non-ccRCC. As papillary RCC (pRCC) comprise the majority of tumours defined as non-ccRCC, most of the evidence is available for this subtype, either from trials specifically selecting pRCC or having included a high percentage.

7.4.4.2.1 Treatment of patients with papillary metastatic RCC

There are small single-arm trials for sunitinib and everolimus [593-597]. Both these agents have been widely given in pRCC, but more recent data suggests cabozantinib and other combinations may be preferable [598, 599].

For pRCC new evidence is available from the SWOG PAPMET randomised phase II trial which compared sunitinib to cabozantinib, crizotinib and savolitinib in 152 patients with papillary mRCC [598]. Progression- free survival was longer in patients in the cabozantinib group (median 9.0 months, 95% CI: 6-12) than in the sunitinib group (5.6 months, CI: 3-7; HR for progression or death 0.60 [0.37-0.97, one-sided p = 0.019]). Response rate for cabozantinib was 23% vs. 4% for sunitinib (two-sided p = 0.010). Savolitinib and crizotinib did not improve PFS compared with sunitinib. Grade III or IV adverse events occurred in 69% (31/45) of patients receiving sunitinib, 74% (32/43) of patients receiving cabozantinib, 37% (10/27) receiving crizotinib, and 39% (11/28) receiving savolitinib; one grade V thromboembolic event was recorded in the cabozantinib group. These results support adding cabozantinib as an option for patients with papillary mRCC based on superior PFS results compared to sunitinib.

In addition, savolitinib was investigated in the SAVOIR trial [599] as first-line treatment for MET-driven tumours defined as chromosome 7 gain, MET amplification, MET kinase domain variations or hepatocyte growth factor amplification by DNA alteration analysis (~30% of screened patients were MET positive). In a limited patient group, savolitinib (n = 27) was compared with sunitinib (n = 33). The trial was stopped early, largely due to poor accrual. The efficacy data appeared to favour savolitinib (median PFS 7.0 months, 95% CI: 2.8 months-NR vs. 5.6 months, 95% CI: 4.1-6.9 months, PFS HR: 0.71, 95% CI: 0.37-1.36, OS HR: 0.51,94% CI: 0.21-1.17, RR: 27% vs. 7%, for savolitinib and sunitinib, respectively). The median OS for savolitinib was not reported, Savolitinib was better tolerated compared with sunitinib with 42% grade > 3 AEs compared to 81% with sunitinib. There are ongoing trials to confirm these findings. The results on these trials are required before recommendations can be made.

Evidence for TKI + IO based combination is derived from two phase II studies of lenvatinib plus pembrolizumab and cabozantinib and nivolumab. The Keynote-B61 phase II trial investigated lenvatinib plus pembrolizumab administered to non-ccRCC patients of whom 93 patients (59%) with pRCC [600, 601]. The primary endpoint of objective response was 54% in pRCC patients, with a median follow-up of 14.9 months, providing some evidence of good efficacy for TKI + IO based combinations. The cabozantinib and nivolumab study enrolled 40 patients with papillary and unclassified RCC with a response rate of 47% and a PFS of 13 (7-16) months [602]. In this trial chromophobe RCC was excluded and the percentage of pRCC was 68%. Indirect comparisons suggest these data compare to an increased efficacy with those of VEGFR-TKI monotherapy alone.
Efficacy for pembrolizumab in the pRCC subset (118/165) was; RR: 29%, PFS: 5.5 months (95% CI: 3.9-6.1 months) and OS: 31.5 months (95% CI: 25.5 months-NR), but these results are based on a single-arm phase II study [603]. Pembrolizumab can be considered in this setting due to the high unmet need; although the VEGFR TKI + IO combination may be preferable.

7.4.4.2.2 Summary of evidence and recommendations for systemic therapy in papillary metastatic RCC

Summary of evidence	LE
Cabozantinib improved PFS over sunitinib in patients with advanced pRCC without additional molecular testing.	2a
Lenvatinib plus pembrolizumab and cabozantinib plus nivolumab demonstrated response rates of 47-54% with median PFS rates >12 months	2a
Pembrolizumab resulted in long-term median OS in a single-arm study in the pRCC subgroup.	2a

Recommendations	Strength rating
Offer cabozantinib to patients with papillary RCC (pRCC) based on a positive randomised controlled trial.	Weak
Offer lenvatinib plus pembrolizumab or nivolumab plus cabozantinib to patients with pRCC based on small single-arm trials.	Weak

7.4.4.2.3 Treatment of patients with metastatic non-ccRCC other than papillary RCC

The evidence surrounding systemic therapy for non-ccRCC tumours other than pRCC is especially weak and has relied on subset analysis of randomised phase II trials as well as expanded access programmes. Results consistently demonstrate that the outcome of these patients with targeted therapy is poorer than for ccRCC. Treatment in non-cc-mRCC has focused on temsirolimus, everolimus, sorafenib, sunitinib, cabozantinib and pembrolizumab in the past [593, 602, 604-606]. Recent data of single-arm phase II trials of lenvatinib plus pembrolizumab demonstrated clinical efficacy of this IO+TKI combinations in different non-ccRCC subgroups. [600, 601, 607]. Meadian ORR across the different non-ccRCC subgroups of 158 patiens was 49%, 12 months PFS and OS rates were 63% and 82%.

7.4.4.2.4 Summary of evidence and recommendation for systemic therapy in chromophobe and unclassified RCC

Summary of evidence	LE
Both mTOR inhibitors and VEGF-targeted therapies have limited activity in non-cc-mRCC. There is a non-significant trend for improved oncological outcomes for sunitinib over everolimus and for cabozantinib over sunitinib.	2a
In non-cc-mRCC, sunitinib improved PFS over everolimus in a SR of phase II trials and subgroups of patients.	1a
In non—cc-mRCC lenvatinib plus pemrolizumab demonstrated clinical efficacy in different non-ccRCC subgroups	2a
In non—cc-mRCC cabozantinib plus nivolumab demonstrated clinical efficacy in different non-ccRCC subgroups except for chromophobe RCC which were excluded from the study	2a

Recommendations	Strength rating
Offer sunitinib to patients with other non-clear cell renal cell carcinoma (cc-RCC) subtypes than papillary RCC.	Weak
Offer lenvatinib plus pembrolizumab to patients with non-ccRCC subtypes.	Weak
Offer cabozantinib and nivolumab to patients with non-ccRCC subtypes other than chromophobe RCC.	weak

7.4.4.3 Renal medullary carcinoma

SMARCB1-deficient renal medullary carcinoma is one of the most aggressive RCCs [68, 199] and most patients (~67%) will present with metastatic disease [29, 68]. Even patients who present with seemingly localised disease may develop macro metastases shortly thereafter, often within a few weeks.

Despite treatment, median OS is thirteen months in the most recent series [33]. Due to the infiltrative nature and medullary epicentre of RMC, RN is favoured over PN even in very early-stage disease. Retrospective data indicate that nephrectomy in localised disease results in superior OS (16.4 vs. 7 months) compared with systemic chemotherapy alone, but longer survival was noted in patients who achieved an objective response to first-line chemotherapy [33, 608]. There is currently no established role for distant metastasectomy or nephrectomy in the presence of metastases.

Palliative radiation therapy is an option and may achieve regression in the targeted areas, but it will not prevent progression outside the radiation field [609, 610]. Renal medullary carcinoma is refractory to monotherapies with targeted anti-angiogenic regimens including TKIs and mTOR inhibitors [33, 173]. The mainstay systemic treatments for RMC are cytotoxic combination regimens which produce partial or complete responses in ~29% of patients [173]. There are no prospective comparisons between different chemotherapy regimens, but most published series used various combinations of platinum agents, taxanes, gemcitabine, and/or anthracyclines [33, 34]. High-dose-intensity combination of MVAC has also shown efficacy against RMC [611] although a retrospective comparison did not show superiority of MVAC over cisplatin, paclitaxel, and gemcitabine [34]. Single-agent anti-PD-1 immune checkpoint therapy has produced responses in a few case reports, although, as yet insufficient data are available to determine the response rate to this approach [609, 610]. Whenever possible, patients should be enrolled in clinical trials of novel therapeutic approaches, particularly after failing first-line cytotoxic chemotherapy.

7.4.4.3.1 Other rare tumours

Knowledge about the systemic treatment of rare tumors is very limited, mostly based on a set of case reports. For some facts about therapy of renal tumours see chapter 3.5 and table 3.2.

Metastatic collecting duct carcinoma (CDC) has a lowest mortality in concomitant use of cytoreductive nephrectomy and systemic therapy [612]. Systemic therapy was investigated in BONSAI phase II trial. Nivolumab showed cilical benefit in 60 % as a second-line therapy after cabozantinib failure [613].

TFE3-rearranged RCC showed objective response rate 25 % with ICI and 0 % with TKI and more prolonged OS (62.4 months with ICI vs 10.3 with TKI). Cabozantinib may be an exeption with 16.6% objective response. There is discussed future role of ICI-TKI combination (such as nivolumab plus cabozantinib) and cabozantinib plus belzutifan [614].

TFEB-altered RCC:

TFEB-rearranged RCC: There is a general lack of information regarding the response to moderm systemic therapy. Combination of ICI and mTOR inhibitors are discussed. *TFEB*-amplified RCC (it occurs in elderly patients and displays more aggressive behaviour compared to *TFEB*-rearranged RCC) can be treated with VEGFR targeting agents or with VEGFR-TKI combination [614].

Some studies combine therapy *TFE3*- and *TFEB*-altered RCCs (because of former grouping ob both tumours to MiT family translocation RCCs). One retrospective study exhibit efficacy of ICI or ICI-TKI combination [615]. Other study provided evidence of the activity of cabozantinib in MiT TRCC, with more durable responses than those observed historically with other VEGFR-TKIs or ICIs [616].

In fumarate hydratase-deficient RCC with high metastatic potential, ICI monotherapies offer a better disease control rate than TKI monotherapies. In phase II trial, ORR of 51 % of combination of erlotinib and bevacizumab [614]. Other trial expressed a favorable response to ICI/TKI combinational therapy comparred to bevacizumab plus erlotinib [92].

Succinate dehydrogenase (SDH)-deficient RCC has a low risk of metastasis (12 %) with exception of high-grade with risk 70 %. Due to rarity of disease, no evidence for systemic therapy [614].

Anaplastic lymphoma kinase (ALK)-rearranged RCC, there are some reports of the efficacy of ALK inhibitors, e.g. entrectinib [614]. ELOC (formerly TCEB1)-mutated RCC doesn't exhibit cinically aggressive behaviour [614].

There is no data that indicates a recommendation for one treatment over another.

7.4.4.4 Treatment of hereditary RCC

7.4.4.4.1 von-Hippel-Lindau-disease-associated RCC

Patients with VHL disease often develop RCC and tumours and cysts in other organs including adrenal glands, CNS, retinal haemangioblastomas, and pancreas, and commonly undergo several surgical resections in their lifetime. In VHL disease, belzutifan, a HIF-2α inhibitor, has been approved by the US Food and Drug Administration (FDA, August 2021) for the treatment of ccRCC and other neoplasms associated with VHL for

the treatment of tumours that do not require immediate surgery. Approval was based on the results from a phase II, open-label, single-arm trial in 61 patients with tumours not larger than 3 cm [59]. Belzutifan induced partial responses with an RCC ORR of 49%, and a disease control rate of 98.4% after 21.8 months treatment. All patients with pancreatic lesions had an ORR of 77%, and those with CNS haemangioblastoma had a 30% response rate. In total, 33% of patients reported > grade III adverse events, and seven patients (11.5%) discontinued the treatment. In the treatment with pazopanib for VHL only 52% continued with the treatment after 24 weeks [617]. A longer follow-up at 37.8 months, ORR for RCC was increased to 64%, with a median time to response of 11.1 months (range, 2.7 to 30.5). Median duration of response per Kaplan-Meier estimate was not reached (range, 5.4+ to 35.8+ months). Thirty-four of 39 patients with a confirmed response (87%) remain in response as of the data cut-off date (September 2022) [557].

With favourable efficacy results and with relatively low-grade side effects, belzutifan seems to be a valuable contribution to the treatment of patients with the VHL disease. The EMA has not yet considered belzutifan for approval in VHL disease.

7.5 Locally-recurrent RCC after treatment of localised disease

Most studies reporting on local recurrent disease after removal of the kidney have not considered the true definition of local recurrence after RN, PN and thermal ablation, which are: local recurrence in the tumour-bearing kidney, tumour growth exclusively confined to the true renal fossa, recurrences within the renal vein, the ipsilateral adrenal gland or the regional LNs. In the existing literature the topic is weakly investigated and often regarded as local recurrent disease.

RECUR is a protocol-based multicentre European registry capturing patient and tumour characteristics, risk of recurrence (RoR), recurrence patterns, and survival of those curatively treated for nonmetastatic RCC from 2006 to 2011. Per-protocol resectable disease (RD) recurrence was defined as (1) solitary metastases, (2) oligometastases, or (3) renal fossa or renal recurrence after radical or partial nephrectomy, respectively. Within the RECUR consortium, the authors assessed the effectiveness of local treatment of resectable recurrent RCC after surgical treatment of the primary kidney tumour [618]. Of 3039 patients with localised RCC treated with curative intent, 505 presented with recurrence, including 176 with RD. Of these patients, 97 underwent local treatment of recurrence (LTR) and 79 no LTR. The median OS was 70.3 mo versus 27.4 in the LTR versus no-LTR group ($p < 0.001$). The LTR effect on survival was consistent across risk groups. OS HR for high, intermediate, and low risks were 0.36 (0.2-0.64), 0.27 (0.11-0.65), and 0.26 (0.08-0.8), respectively. Local treatment of recurrence was associated with longer survival across groups with a risk of recurrence [618]

7.5.1 Locally-recurrent RCC after nephron-sparing approaches

Locally-recurrent disease can affect the tumour-bearing kidney after PN or focal ablative therapy such as RFA and cryotherapy. Local relapse may be due to the incomplete resection of the primary tumour, in a minority of the cases to the local spread of the tumour by microvascular embolisation, or true multifocality [214, 619].

The prognosis of recurrent disease not due to multifocality is poor, despite salvage nephrectomy [619]. Recurrent tumour growth in the regional LNs or ipsilateral adrenal gland may reflect metachronous metastatic spread (see Section 7.3). After treatment solely for localised disease, systemic progression is common [620, 621].

There are reports that minimally invasive approaches (laparoscopic and robotic) show atypical reoccurence (e.g. peritoneal, port site, etc) [622, 623]. Therefore, specific maneuvers to prevent tumour-cell contamination should be implemented. Those include the use of extraction bags, minimising trocar CO2 leakage, avoiding tumour morcellation, cleansing of instruments before reuse, changing of gloves after tumour extraction, avoiding violation of the tumor's natural capsule, and cleansing of port sites [622, 623].

A retrospective study relying on inverse probability of treatment weighting (IPTW) and comparing percutaneous ablation (PCA) and surgical resection (SR) for an isolated local recurrence (LR) following PN [624]. A total of 81 patients with an isolated LR were included. Percutaneous ablation was associated with a lower risk of post-operative complications (odds ratio=0.22; $p = 0.006$) and a smaller change in eGFR. There were no significant differences in the risk of disease, new LR (HR = 1.51; $p = 0.59$), and distant metastasis (HR = 0.19; $p = 0.09$) [624].

Following thermal ablation or cryotherapy generally intra-renal, but also peri-renal, recurrences have been reported in up to 14% of cases [625]. Whereas repeat ablation is still recommended as the preferred therapeutic option after treatment failure, the most effective salvage procedure as an alternative to complete nephrectomy has not yet been defined.

*7.5.2 **Locally-recurrent RCC after radical nephrectomy***

Isolated local fossa recurrence is rare and occurs in about 1-3% after radical nephrectomy. More commonly in pT3-4 than pT1-2 and grade III-IV disease. Most patients with local recurrence of RCC are diagnosed by either CT/MRI scans as part of the post-operative follow-up [626]. The median time to recurrence after RN was 19-36 months in isolated local recurrence or 14.5 months in the group including metastatic cases as well [626-628].

Isolated local recurrence is associated with worse survival [214, 629]. Based on retrospective and non-comparative data only, several approaches such as surgical excision, radiotherapy, systemic treatment and observation have been suggested for the treatment of isolated local recurrence [630-632]. Among these alternatives, surgical resection with negative margins remains the only therapeutic option shown to be associated with improved survival [629]. Open surgery has been successfully reported in studies [633, 634]. One of the largest series including 2,945 patients treated with RN reported on 54 patients with recurrent disease localised in the renal fossa, the ipsilateral adrenal gland or the regional LNs as sole metastatic sites [630]. Another series identified 33 patients with isolated local recurrences and 30 local recurrences with synchronous metastases within a cohort of 2,502 surgically treated patients, confirming the efficacy of locally directed treatment vs. conservative approaches (observation, systemic therapy) [635]

The 5-year OS with isolated local recurrence was 60% (95% CI: 0.44-0.73) and 10-year OS was 32% (95% CI: 0.15-0.51). Overall survival differed significantly by the time period between primary surgery and occurrence of recurrence (< 2 years vs. > 2 years: 10-year OS rate 31% (95% CI: 10.2-55.0) vs. 45% (95% CI: 21.5-65.8; HR: 0.26; p = 0.0034) [626]. Metastatic progression was observed in 60 patients (58.8%) after surgery [627]. Patient survival can be linked to the type of treatment received, as shown in a cohort of 96 patients, 45.8% were metastatic at the time of recurrence; three-year CSS rates after local recurrence were 92.3% ± 7.4%) for those who were treated with surgery and systemic therapy, 63.2% ± 13.2%) for those who only underwent surgery, 22.7% ± 0.9%) for those who only received systemic therapy and 20.5% ± 10.4%) for those who received no treatment (p < 0.001) [628]. A retrospective multi-centre study of patients with Local Retroperitoneal Recurrence (RPR) after radical nephrectomy (RN) with or without surgical treatment from 2008 to 2020. Retroperitoneal Recurrence of RCC was defined as an ipsilateral recurrence confined to the renal fossa, adrenal gland or retroperitoneal lymph nodes after prior nephrectomy, which was diagnosed by cross-sectional imaging. Treatment with RPR surgery resulted in significantly longer CSS than targeted therapy alone (P < .001). In multivariable analysis, high Fuhrman grade, size of RPR tumour, mixed type of RPR, multiple recurrence lesions and the absence of RPR surgery were associated with a significantly increased risk of death from RCC, suggesting that an aggressive surgical resection of RPR after RN represents a potentially curative treatment for selected RCC patients without synchronous metastases, resulting in significantly longer CSS than targeted therapy alone [636].

Minimally-invasive approaches, including standard and hand-assisted laparoscopic- and robotic approaches for the resection of isolated RCC recurrences have been occasionally reported. A large surgical cohort published of robotic surgery in this setting (n = 35) providing a standardisation of the nomenclature, describing the surgical technique for each scenario and reporting on complications, renal function, and oncologic outcomes [637]. Ablative therapies including cryoablation, radiofrequency and microwave ablation, may also have a role in managing recurrent RCC patients, but further validation will be needed [638, 639].

In summary, the limited available evidence suggests that in selected patients surgical removal of locally-recurrent disease with negative margins can induce durable tumour control, although with expected high risk of complications. A retrospective review on 51 planned repeat PNs in 47 patients with locally-recurrent disease, reporting a total of 40 peri-operative complications, with temporary urinary extravasation being the most prevalent [640]. Since local recurrences develop early, with a median time interval of 10-20 months after treatment of the primary tumour [641], a guideline-adapted follow-up scheme for early detection is recommended (see Chapter 8 - Follow-up) even though benefit in terms of cancer control has not yet been demonstrated [642].

Adverse prognostic parameters are a short time interval since treatment of the primary tumour (< 3-12 months) [643], sarcomatoid differentiation of the recurrent lesion and incomplete surgical resection [630]. In case complete surgical removal is unlikely to be performed or when significant comorbidities are present (especially when combined with poor prognostic tumour features), palliative therapeutic approaches including radiation therapy aimed at symptom control and prevention of local complications should be considered (see Sections 7.3 and 7.4). Following metastasectomy of local recurrence after nephrectomy, adjuvant therapy can be considered (see Section 7.2.5. Neoadjuvant and adjuvant therapy). Local recurrence combined with other metastases is treated as a metastatic RCC.

7.5.3 Summary of evidence and recommendation on locally-recurrent RCC after treatment of localised disease

Summary of evidence	LE
Isolated recurrence after nephron sparing procedures or nephrectomy is a rare entity (< 2%).	3
Surgical or percutaneous treatment of local recurrences in absence of systemic progression should be considered, especially in absence of adverse prognostic parameters and favourable performance status.	3
The most optimal modality of local treatment for locally-recurrent RCC after nephron sparing procedures or nephrectomy is not defined.	3

Recommendation	Strength rating
Offer local treatment of locally-recurrent disease when technically possible and after balancing adverse prognostic features, comorbidities and life expectancy.	Weak

8. FOLLOW-UP IN RCC

8.1 Introduction

Surveillance after treatment for RCC allows the urologist to monitor or identify:

- post-operative complications;
- renal function;
- local recurrence;
- recurrence in the contralateral kidney;
- distant metastases;
- cardiovascular events.

There is no consensus on follow-up strategies after RCC treatment, with limited evidence suggesting that more frequent post-operative imaging intervals do not provide any improvement for early detection of recurrence that would lead to improved survival [642]. As such, intensive radiological surveillance may not be necessary for all patients. Follow-up is also important to assess functional outcomes and to limit long-term sequelae such as renal function impairment, ESRD and cardiovascular events [644].

Currently, the key question is whether any recurrence detection during follow-up and subsequent treatment will lead to any meaningful change in survival outcome for these patients.

In contrast to high-grade and/or locally-advanced disease, the outcome after surgery for T1a low-grade tumours is almost always excellent. It is therefore reasonable to stratify follow-up, taking into account the risk of each different RCC to develop a local or distant recurrence. Although there is no randomised evidence, large studies have examined prognostic factors with long follow-up [197, 645, 646] (LE: 4). One study has shown a survival benefit in patients who were followed within a structured surveillance protocol vs. patients who were not [647]; patients undergoing follow-up seem to have a longer OS when compared to patients not undergoing routine follow-up [647].

Furthermore, an individualised and risk-based approach to RCC follow-up has recently been proposed. The authors used competing risk models, incorporating patient age, pathologic stage, relapse location and comorbidities, to calculate when the risk of non-RCC death exceeds the risk of RCC recurrence [648]. For patients with low-stage disease but with a Charlson comorbidity index > 2, the risk of non-RCC death exceeded that of abdominal recurrence risk already one month after surgery, regardless of patient age. As for pshylogical factors, a SR including 15 studies revealed that psychological distress (defined as anxiety, depression, or psychological distress at any time during treatment or follow-up) is also prevalent among renal cell carcinoma (RCC) patients, reaching up to 77% in non-metastatic cases [649].

The RECUR consortium, initiated by this Panel, collects similar data with the aim to provide comparators for guideline recommendations. Recently published RECUR data support a risk-based approach; more specifically a competing-risk analysis showed that for low-risk patients, the risk of non-RCC related death exceeded the risk of RCC recurrence shortly after the initial surgery. For intermediate-risk patients, the corresponding time point was reached around four to five years after surgery. In high-risk patients, the risk of RCC recurrence continuously exceeded the risk of non-RCC related death [650]. In the near future, genetic profiling may refine the existing prognostic scores and external validation in datasets from adjuvant trials have been promising in improving stratification of patient's risk of recurrence [650, 651].

Recurrence after PN is rare, but early diagnosis is relevant, as the most effective treatment is surgery [633, 652]. Recurrence in the contralateral kidney is rare (1-2%) and can occur late (median 5-6 years) [653] (LE: 3). Follow-up can identify local recurrences or metastases at an early stage. At recurrence, extensive metastatic tumour growth can hinder the opportunity for surgical resection. In addition, early diagnosis of tumour recurrence may enhance the efficacy of systemic treatment if the tumour burden is low.

8.2 Which imaging investigations for which patients, and when?

- The sensitivity of chest radiography and US for detection of small RCC metastases is poor. The sensitivity of chest radiography is significantly lower than CT-scans, as proven in comparative studies including histological evaluation [654-656]. Therefore, follow-up for recurrence detection with chest radiography and US are less sensitive [657].
- Positron-emission tomography and PET-CT as well as bone scintigraphy should not be used routinely in RCC follow-up, due to their limited specificity and sensitivity [117, 131].
- Surveillance should also include evaluation of renal function and cardiovascular risk factors [644].
- Outside the scope of regular follow-up imaging of the chest and abdomen, targeted imaging should be considered in patients with organ-specific symptoms, e.g., CT or MRI imaging of the brain in patients experiencing neurological symptoms [658].

Controversy exists on the optimal duration of follow-up. Some authors argue that follow-up with imaging is not cost-effective after five years; however, late metastases are more likely to be solitary and justify more aggressive therapy with curative intent. In addition, patients with tumours that develop in the contralateral kidney can be treated with NSS if the tumours are detected early. Several authors have designed scoring systems and nomograms to quantify the likelihood of patients to develop tumour recurrences, metastases, and subsequent death [250, 252, 659, 660]. These models, of which the most utilised are summarised in Chapter 6 - Prognosis, have been compared and validated [661] (LE: 2). Using prognostic variables, several stage-based follow-up regimens have been proposed, although, none propose follow-up strategies after ablative therapies [662, 663]. A post-operative nomogram is available to estimate the likelihood of freedom from recurrence at five years [247]. Recently, a pre-operative prognostic model based on age, symptoms and TNM staging has been published and validated [664] (LE: 3). A follow-up algorithm for monitoring patients after treatment for RCC is needed, recognising not only the patient's risk of recurrence profile, but also the efficacy of the treatment given (Table 8.1). These prognostic systems can be used to adapt the follow-up schedule according to predicted risk of recurrence. Ancillary to the above, life-expectancy calculations based on comorbidity and age at diagnosis may be useful in counselling patients on duration of follow-up [665].

Table 8.1: Proposed follow-up schedule following treatment for localised RCC, taking into account patient risk of recurrence profile and treatment efficacy (based on expert opinion [LE: 4])

Risk profile (*)	Oncological follow-up after date of surgery								
	3 mo	**6 mo**	**12 mo**	**18 mo**	**24 mo**	**30 mo**	**36 mo**	**> 3 yr (**) (***)**	**> 5 yr (**) (***)**
Low risk of recurrence For ccRCC: Leibovich Score 0-2 For non-ccRCC: pT1a-T1b pNx-0 M0 and histological grade 1 or2.	-	CT	-	CT	-	CT	-	CT once every two yrs	-
Intermediate risk of recurrence For ccRCC: Leibovich Score 3-5 For non-ccRCC: pT1b pNx-0 and/or histological grade 3 or 4.	-	CT	CT	-	CT	-	CT	CT once yr	CT once every two yrs
High risk of recurrence For ccRCC: Leibovich Score ≥ 6 For non-ccRCC: pT2–pT4 with any histological grade or pT any, pN1 cM0 with any histological grade	CT	CT	CT	CT	CT	-	CT	CT once yr	CT once every two yrs

ccRCC = clear cell renal cell carcinoma; CT = computed tomography; mo = months; non-ccRCC = non clear cell renal cell carcinoma; yr = years.

The table above provides recommendations on follow-up strategies for low, intermediate and high risk of recurrence in patients curatively treated for localised RCC either with NSS or RN. Computed tomography in the table refers to imaging of both chest and abdomen. Alternatively, MRI of the abdomen can be performed instead of a CT-scan.

* *Risk of recurrence profiles should be based on validated prognostic models. The EAU RCC Guidelines Panel recommends the 2003 Leibovich model for ccRCC [250]. However, other validated models can be used by physicians based on their own national/regional recommendations. In a similar fashion, for curatively treated localised non-ccRCC, the Panel recommends the use of the University of California Los Angeles integrated staging system (UISS) to determine risk of recurrence [251].*

** *For all risk of recurrence profiles, functional follow-up, mainly monitoring renal and cardiovascular function, may continue according to specific clinical needs irrespective of the length of the oncological follow-up.*

*** *For low-risk profiles at > 3 years and intermediate-risk at > 5 years of follow-up respectively, consider counselling patients about terminating oncological follow-up imaging based on assessment of comorbidities, age, life expectancy and/or patient wishes.*

8.3 Summary of evidence and recommendations for surveillance following RN or PN or ablative therapies in RCC

Summary of evidence	LE
Functional follow-up after curative treatment for RCC is useful to prevent renal and cardiovascular deterioration.	4
Oncological follow-up can detect local recurrence or metastatic disease while the patient may still be surgically curable.	4
After NSS, there is an increased risk of recurrence for larger (> 7 cm) tumours, or when there is a PSM.	3
Patients undergoing follow-up have a better OS than patients not undergoing follow-up.	3
Prognostic models provide stratification of RCC risk of recurrence based on TNM and histological features.	3
In competing-risk models, risk of non-RCC-related death exceeds that of RCC recurrence or related death in low-risk patients.	3
Life expectancy estimation is feasible and may support counselling of patients on duration of follow-up.	4
Overall survival is reduced in metastatic RCC patients with symptoms of depression and distress.	2a

Recommendations	Strength rating
Base follow-up after treatment of localised RCC on the risk of recurrence.	Strong
Base risk of recurrence stratification on validated subtype-specific models such as the Leibovich Score for clear cell renal cell carcinoma (ccRCC), or the University of California Los Angeles integrated staging system for non-ccRCC.	Weak
Intensify follow-up in patients after nephron-sparing surgery for tumours > 7 cm or in patients with a positive surgical margin.	Weak
Consider curtailing follow-up when the risk of dying from other causes is double that of the RCC recurrence risk.	Weak
Offer psychological evaluation for all patients diagnosed with RCC to provide timely support for distress, depression, or anxiety.	Weak

8.4 Patient involvment in kidney cancer treatment

One RCT has indicated that patient involvement in reporting their symptoms during management of a variety of metastatic solid tumours, can improve clinical outcomes, including OS [666].

A large-scale global survey of patients with renal cell carcinoma (RCC), identified geographic variations in patient education, experience, awareness, access to care, best practices, quality of life, and unmet psychosocial needs [667]. A total of 1,983 patients from 43 countries revealed that at diagnosis, 43% of all respondents had no understanding of their RCC subtype, 29% of all patients reported no involvement in their treatment decision and 96% of respondents reported psychosocial impacts, with only 50% disclosing it to their health care team, with 90% indicated they would be interested in participating in clinical trails.

8.5 Recommendation on patient involvement and shared decision making

Recommendation	Strength rating
Employ a shared decision-making approach when deciding on appropriate treatment for RCC	Strong

10. CONFLICT OF INTEREST

All members of the Renal Cell Cancer Guidelines Panel have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publicly accessible through the European Association of Urology website: https://uroweb.org/guideline/renalcell-carcinoma/?type=panel/.

This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

11. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Paris 2024. ISBN 978-94-92671-23-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, The Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aim and scope

This overview represents the updated European Association of Urology (EAU) Guidelines for Non-muscle invasive Bladder Cancer (NMIBC), TaT1 and carcinoma *in situ* (CIS). The information presented is limited to urothelial carcinoma (UC), unless specified otherwise. The aim is to provide practical recommendations on the clinical management of NMIBC with a focus on clinical presentation. Separate EAU Guidelines are available addressing upper tract urothelial carcinoma (UTUC) [1], muscle-invasive and metastatic bladder cancer (MIBC) [2] and primary urethral carcinoma [3].

It must be emphasised that clinical guidelines present the best evidence available to the experts, but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and references/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Guidelines Panel on NMIBC consists of an international multidisciplinary group of clinicians, including urologists, uro-oncologists, a pathologist, and a patient representative. Members of this Panel have been selected based on their expertise and to represent the professionals treating patients suspected of suffering from bladder cancer. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website Uroweb: https://uroweb.org/guidelines/non-muscle-invasive-bladder-cancer/panel.

1.3 Available publications

A quick reference document, the Pocket guidelines), is available in print. This is an abridged version which may require consultation together with the full text version. Several scientific publications are available, the latest publication dating to 2022 [4]. All documents are accessible through the EAU website Uroweb: https://uroweb.org/guidelines/non-muscle-invasive-bladder-cancer.

1.4 Publication history and summary of changes

*1.4.1 **Publication history***

The EAU Guidelines on Bladder Cancer were first published in 2000. Standard procedure for EAU Guidelines includes an annual assessment of newly published literature in the field to guide future updates This 2024 NMIBC Guidelines present a limited update of the 2023 publication.

*1.4.2 **Summary of changes***

For the 2024 NMIBC Guidelines new and relevant evidence was identified, collated and appraised through a structured assessment of the literature for all sections of the Guidelines. This resulted in the inclusion of 36 updated studies across the Guidelines. Key changes include the addition of:

- a new category of high-grade recurrence during or after BCG (table 7.2): the BCG-exposed tumour category;
- updates on the proposed treatment options for late BCG relapses and low grade (LG) recurrence after bacillus Calmette-Guérin (BCG) for primary intermediate-risk bladder cancer in table 7.3;
- a proposed follow-up schedule based on patient's risk category in Table 8.2;
- a new section on patient reported outcome measures and quality indicators for NMIBC (section 9).

In addition, minor adaptions and updates to multiple recommendations have been made and users are advised to review all sections in full. A summary of key recommendation changes include:

- an update in the evidence and guidelines in section 4.10 on bladder cancer classification;
- new summary of evidence and recommendations updates in section 5.15 on the transurethral resection of the bladder, biopsies and pathology report;
- guidelines updates in section 7.10 on adjuvant therapy in TaT1 tumours and for therapy of carcinoma *in situ*;
- a new update to the very high risk EAU risk group, in section 7.11 on the guidelines for the treatment of TaT1 tumours and carcinoma *in situ* according to risk stratification;

- new updates in section 8.2 on the summary of evidence and recommendations for the follow-up of patients after transurethral resection of the bladder for non-muscle-invasive bladder cancer.

2. METHODS

2.1 Data Identification

For the 2024 NMIBC Guidelines, new and relevant evidence has been identified, collated, and appraised through a structured assessment of the literature. A broad and comprehensive scoping exercise covering all areas of the NMIBC Guidelines was performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between the 5th of May 2022 and 1st May 2023. A total of 788 unique records were identified, retrieved, and screened for relevance. A total of 36 new references were added to the 2024 NMIBC Guidelines. A detailed search strategy is available online: https://uroweb.org/guidelines/non-muscle-invasive-bladder-cancer/publications-appendices.

For Chapters 3 through 6 (Epidemiology, Aetiology and Pathology, Staging and Classification systems, Diagnosis, Predicting disease recurrence and progression) the references used in this text were assessed according to their level of evidence (LE) based on the 2009 Oxford Centre for Evidence-Based Medicine (CEBM) Levels of Evidence [5]. For chapters 7 and 8 (Disease Management and Follow-up) chapters a system modified from the 2009 CEBM levels of evidence was used [5].

Recommendations within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [5];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact and certainty of patient values and preferences on the intervention.

Strong recommendations typically indicate a high degree of evidence quality and/or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [6].

Additional methodology information and a list of associations endorsing the EAU Guidelines can be found in the online: https://uroweb.org/eau-guidelines/methodology-policies.

2.2 Review

The 2024 publication was peer reviewed prior to publication.

2.3 Future goals

The Panel are currently conducting two individual patient data (IPD) analyses to validate the definition of bacillus Calmette-Guérin (BCG) failure/BCG unresponsive in patients with non-muscle invasive urothelial carcinoma of the bladder and the impact of BCG on progression in the BCG treated subgroup of the original cohort that served to generate the 2021 risk stratification. The results of both analyses will be included in the future update of the NMIBC Guidelines.

3. EPIDEMIOLOGY AND AETIOLOGY

3.1 Epidemiology

Bladder cancer (BC) is the seventh most commonly diagnosed cancer in the male population worldwide, and it is the tenth when both genders are considered [7]. The worldwide age-standardised incidence rate (per 100,000 person/years) is 9.5 in men and 2.4 in women [7]. In the European Union, the age-standardised incidence rate is 20 in men and 4.6 in women [7].

Worldwide, the BC age-standardised mortality rate (per 100,000 person/years) is 3.3 for men vs. 0.86 for women [7]. Bladder cancer incidence and mortality rates vary across countries due to differences in risk factors, detection and diagnostic practices, and variations in access to, and delivery of, healthcare. Additionally, epidemiological variations have been attributed to differing methodologies and the quality of data from individual datasets [8]. The incidence and mortality of BC has decreased in some registries, possibly reflecting the decreased impact of causative factors [9].

Approximately 75% of patients with BC present with a disease confined to the mucosa (stage Ta, CIS) or submucosa (stage T1); in younger patients (< 40 years of age) this percentage is even higher [10]. Patients with TaT1 and CIS have a high disease prevalence due to long-term survival in many cases and lower risk of cancer-specific mortality compared to patients with T2-4 disease [7, 8].

3.2 Aetiology

*3.2.1 **Main risk factors***

3.2.1.1 Tobacco

Tobacco smoking is the most important risk factor for BC, accounting for approximately 50% of cases [8, 9, 11, 12]. The aromatic amines and polycyclic aromatic hydrocarbons within the tobacco smoke, which undergo renal excretion, are linked to the development of BC. The risk of BC increases with smoking duration and intensity [18]. Low-tar cigarettes are not associated with a lower risk of developing BC [13]. The risk associated with electronic cigarettes has not been adequately assessed; however, carcinogens have been identified in the urine with electronic cigarettes [14]. 'Second-hand' exposure to tobacco smoke is also associated with an increased risk of BC [8].

3.2.1.2 Occupational exposure

Occupational exposure to aromatic amines, polycyclic aromatic hydrocarbons and chlorinated hydrocarbons is the second most important risk factor for BC, accounting for about 10% of all cases. This type of occupational exposure occurs mainly in industrial plants which process paint, dye, metal, and petroleum products [8, 9, 15, 16]. In developed industrial settings these risks have been reduced by work-safety guidelines; therefore, chemical workers no longer have a higher incidence of BC compared to the general population [8, 15, 16]. Recently, greater occupational exposure to diesel exhaust has been suggested as a significant risk factor (odds ratio [OR]: 1.61; 95% confidence interval [CI]: 1.08–2.40) [17]. Additionally, a large registry-based study of over one million people, with a follow up of 21 years, found that residents in the Haifa Bay Area of Israel (which is a centre for petrochemical industry) had a significantly higher incidence of several cancers, including bladder cancer (hazard ratio [HR] 1.11; 95% CI: 1.01–1.23), compared with non-residents [18].

*3.2.2 **Genetic***

Family history seems to have little impact [19]. To date, no clinically relevant genetic alteration has been linked to BC. Genetic predisposition may lead to a higher susceptibility to other risk factors, and thereby explain the familiar clustering of BC in first- and second-degree relatives (HR: 1.69; 95% CI: 1.47–1.95) [8, 20-25] that has been confirmed more recently [26]. A recent study identified three single nucleotide polymorphisms related to the development of aggressive NMIBC [27]. Currently, there is insufficient evidence to support genetic screening for BC.

*3.2.3 **Dietary habits***

Dietary habits seem to have limited impact on the risk of developing BC. A protective impact of flavonoids has been suggested [28]. The Mediterranean diet, characterised by a high consumption of vegetables and non-saturated fat (olive oil) with moderate consumption of protein, has been linked to some reduction of BC risk (HR: 0.85; 95% CI: 0.77–0.93) [29-33]. Western diet (high in saturated fats) and organ meat has been shown to increase the risk of BC in a recent meta-analysis [34, 35]. The impact of an increased consumption of fruits has been suggested to reduce the risk of BC. This effect has been demonstrated to be significant in women only (HR: 0.92; 95% CI: 0.85–0.99) [36]. This gender discrepancy was also evident in the BLEND study which showed that in men moderate or high intake of vitamins B1, B2 and vitamins related to energy metabolism were found to be associated with an increased BC risk, whereas in women high intake of the same vitamins and vitamin combinations was shown to have a protective effect with the exception of the entire B group vitamin

complex [37]. One possible explanation for this gender discrepancies is the difference in the main source of vitamin intake among study participants, being meat in men and fruits/vegetables in women. In addition, higher consumption of tea has also been associated with a reduction in risk of BC in men but through an interaction with tobacco smoking; therefore, making the protective effect of this compound questionable [38].

*3.2.4 **Environmental exposure***

Although the impact of drinking habits remains uncertain, the chlorination of drinking water and subsequent levels of trihalomethanes are potentially carcinogenic. Additionally, exposure to arsenic in drinking water has been suggested to increase the risk of BC [8, 39]. Arsenic intake and smoking have a combined effect [40]. Conversely, chronic exposure to nitrate in drinking water does not seem to be associated with increased risk of BC [41].

The association between personal hair dye use and risk of BC remains uncertain; an increased risk has been suggested in users of permanent hair dyes with a slow NAT2 acetylation phenotype [8] but a large prospective cohort study could not identify an association between hair dye and risk of cancer and cancer-related mortality [42].

*3.2.5 **Pelvic radiation***

Exposure to pelvic ionizing radiation is associated with an increased risk of BC [43, 44]. In a retrospective analysis of patients with localised prostate cancer, external beam radiotherapy (EBRT) was independently associated with a risk of developing a second primary BC [43]. A single centre study of 583 prostate cancer patients treated with brachytherapy revealed that the risk of developing BC increased in those who received additional EBRT (n=255) (HR 3.29; 95% CI 1.03–10.52). The BC specific mortality was also higher when combination therapy was used [44].

*3.2.6 **Other***

The impact of metabolic factors (body mass index, blood pressure, plasma glucose, cholesterol, and triglycerides) remains uncertain [45]. However, data suggest that high circulating levels of vitamin D are associated with a reduction in the risk of BC [46]. Schistosomiasis, which is an infection caused by a parasitic trematode, can lead to BC [8]. A weak association was also suggested for cyclophosphamide and pioglitazone [8, 39, 47].

3.3 Summary of evidence for epidemiology and aetiology

Summary of evidence	**LE**
Worldwide, bladder cancer (BC) is the tenth most commonly diagnosed cancer.	2a
Several risk factors connected with the risk of BC diagnosis have been identified.	3
Tobacco smoking is the most important risk factor for BC.	3

4. PATHOLOGICAL STAGING, GRADING AND CLASSIFICATION SYSTEMS

4.1 Definition of non-muscle-invasive bladder cancer

Urothelial tumours confined to the mucosa and invading the lamina propria are classified as stage Ta and T1, respectively, according to the Tumour, Node, Metastasis (TNM) classification system [48]. Intra-epithelial, high-grade (HG) tumours confined to the mucosa are classified as CIS (Tis). All of these tumours can be treated by transurethral resection of the bladder (TURB), eventually in combination with intravesical instillations and are therefore grouped under the heading of NMIBC for therapeutic purposes. The term 'Non-muscle-invasive BC' represents a group definition and all tumours should be characterised according to their stage, grade, and further pathological characteristics (see Sections 4.5 and 4.7 and the International Collaboration on Cancer Reporting website: http://www.iccr-cancer.org/datasets/published-datasets/urinary-male-genital/bladder. The term 'superficial BC' should no longer be used as it is incorrect.

4.2 Tumour, Node, Metastasis Classification (TNM)

The latest TNM classification approved by the Union International Contre le Cancer (UICC) (8th Edn.) is referred to (Table 4.1) [48].

Table 4.1: 2017 TNM classification of urinary bladder cancer

T - Primary tumour		
TX	Primary tumour cannot be assessed	
T0	No evidence of primary tumour	
Ta	Non-invasive papillary carcinoma	
Tis	Carcinoma *in situ*: 'flat tumour'	
T1	Tumour invades subepithelial connective tissue	
T2	Tumour invades muscle	
	T2a	Tumour invades superficial muscle (inner half)
	T2b	Tumour invades deep muscle (outer half)
T3	Tumour invades perivesical tissue	
	T3a	Microscopically
	T3b	Macroscopically (extravesical mass)
T4	Tumour invades any of the following: prostate stroma, seminal vesicles, uterus, vagina pelvic wall, abdominal wall	
	T4a	Tumour invades prostate stroma, seminal vesicles, uterus or vagina
	T4b	Tumour invades pelvic wall or abdominal wall
N – Regional lymph nodes		
NX	Regional lymph nodes cannot be assessed	
N0	No regional lymph node metastasis	
N1	Metastasis in a single lymph node in the true pelvis (hypogastric, obturator, external iliac, or presacral)	
N2	Metastasis in multiple regional lymph nodes in the true pelvis (hypogastric, obturator, external iliac, or presacral)	
N3	Metastasis in common iliac lymph node(s)	
M - Distant metastasis		
M0	No distant metastasis	
	M1a	Non-regional lymph nodes
	M1b	Other distant metastases

4.3 T1 subclassification

The depth and extent of invasion into the lamina propria (T1 sub-staging) has been demonstrated to be of prognostic value in retrospective cohort studies [48, 49] (LE: 3). Its use is recommended by the most recent 2022 World Health Organization (WHO) classification [50, 51]. T1 sub-staging methods are based either on micrometric (T1e and T1m) or histo-anatomic (T1a and T1b) principles; the optimal classification system, however, remains to be defined [52, 53] .

4.4 Lymphovascular invasion

The presence of lymphovascular invasion (LVI) in TURB specimens is associated with an increased risk of pathological upstaging and worse prognosis [54-58] (LE: 3). Immunohistochemistry for confirmation is not mandatory [50].

4.5 Histological grading of non-muscle-invasive bladder urothelial carcinomas

4.5.1 Types of histological grading systems

In 2004 the WHO published a histological classification system for UCs including papillary urothelial neoplasm of low malignant potential (PUNLMP), non-invasive papillary carcinoma low grade (LG) and HG. This system was also taken into the updated 2016/2022 WHO classifications [50, 51]. It provides a different patient stratification between individual categories compared to the older 1973 WHO classification, which distinguished between grade 1 (G1), grade 2 (G2) and grade 3 (G3) categories [52, 59].

There is a significant shift of patients between the categories of the WHO 1973 and the WHO 2004/2022 systems (see Figure 4.1), for example an increase in the number of HG patients (WHO 2004/2022) due to inclusion of a subset of G2 patients with a more favourable prognosis compared to the G3 category (WHO 1973) [60, 61]. According to a multi-institutional individual patient data analysis, the proportion of tumours classified as PUNLMP (WHO 2004/2016) has decreased to very low levels in the last decade [62].

4.5.2 Prognostic value of histological grading

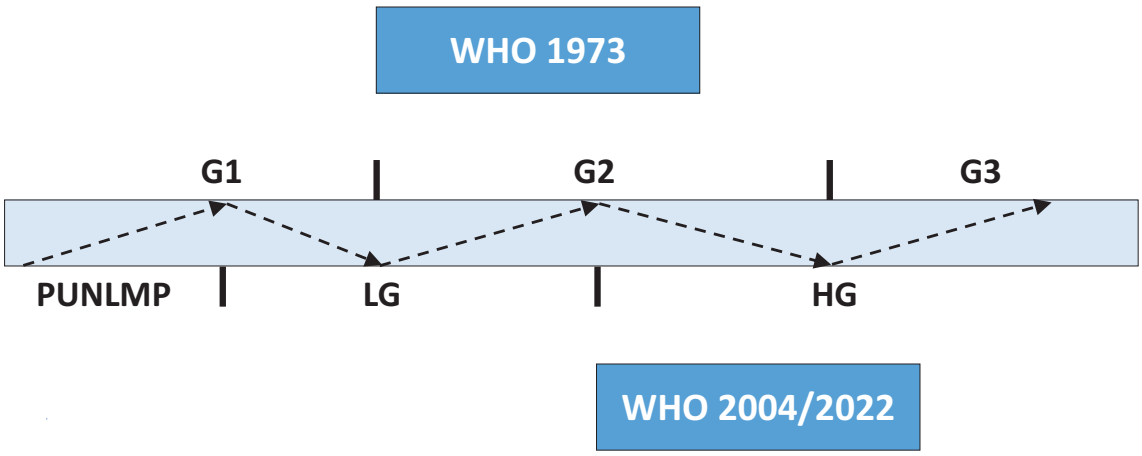
A systematic review and meta-analysis did not show that the 2004/2016 classification outperforms the 1973 classification in prediction of recurrence and progression [60].

To compare the prognostic value of both WHO classifications, an individual patient data analysis of 5,145 primary TaT1 NMIBC patients from sixteen centres throughout Europe and one in Canada was conducted. Patients had a transurethral resection of bladder tumour (TURBT) followed by intravesical instillations at the physician's discretion. In this large study, the WHO 1973 and the WHO 2004/2016 were both prognostic for progression but not for recurrence. When compared, the WHO 1973 was a stronger prognosticator of progression in TaT1 NMIBC than the WHO 2004/2016. However, a 3-tier (LG/G1-G2, HG/G2 & HG/G3) or a 4-tier hybrid combination LG/G1, LG/G2, HG/G2 and HG/G3) of both classification systems proved to be superior to either classification system alone, as it divides the large group of G2 patients into two subgroups (LG/HG) with different prognoses [63]. In a subgroup of 3,311 patients with primary Ta bladder tumours, a similar prognosis was found for PUNLMP and Ta LG carcinomas [62].

4.5.3 Clinical application of histological grading systems

- The WHO 2004/2022 classification system is currently supported by the WHO for clinical application. Nevertheless, the WHO 1973 is still being used.
- The most important parameters, which must be considered for clinical application of any grading system are its inter-observer reproducibility and prognostic value (see Sections 4.5.1 and 4.6).
- These guidelines provide recommendations for tumours classified by both classification systems.

Figure 4.1: Schematic representation of tumours according to grade in the WHO 1973 and 2004/2022 classifications [63]*



**Grade shifts from the WHO 1973 (G1–G3) to the WHO 2004/2022 (PUNLMP, LG and HG) classification for Ta/T1 bladder tumours are displayed with dotted lines and arrows. Along the dotted lines, both the degree of anaplasia and the 5-year progression rates increased in LG/G1, LG/G2, HG/G2, and HG/G3 patients.*

Note: the 2004/2022 WHO classification is the updated version of 2004/2016 WHO classification. According to a series of 5145 primary Ta-T1 patients, the distribution of G1, G2 and G3 in the WHO 1973 classification is 23.5, 49.3 and 27.2% respectively while the corresponding PUNLMP, LG and HG rates for the WHO 2004/2022 system are 1.5, 49.8 and 48,7% respectively [63]. Figure reproduced with permission from Elsevier from [63] .

4.6 Carcinoma *in situ*

Carcinoma *in situ* is an intra-epithelial, HG, non-invasive UC. It can be missed or misinterpreted as an inflammatory lesion during cystoscopy if not biopsied. Carcinoma *in situ* is often multifocal and can occur in the bladder, but also in the upper urinary tract (UUT), prostatic ducts and urethra [64].

From a clinical point of view, CIS may be classified as [65]:

- Primary: isolated CIS with no previous or concurrent papillary tumours and no previous CIS;
- Secondary: CIS detected during follow-up of patients with a previous tumour that was not CIS;
- Concurrent: CIS in the presence of any other urothelial tumour in the bladder.

4.7 Inter- and intra-observer variability in staging and grading

There is significant variability among pathologists for the diagnosis of CIS, for which agreement is achieved in only 70–78% of cases [66]. There is also inter-observer variability in the classification of stage T1 vs. Ta tumours and tumour grading in both the 1973 and 2022 classifications. The general conformity between pathologists in staging and grading is 50–60% [67-70]. The WHO 2004/2022 classification provides slightly better reproducibility than the 1973 classification [60].

4.8 Subtypes of urothelial carcinoma

Currently the following differentiations of urothelial carcinoma (UC) are used [71, 72]:

1. Pure UC (more than 90% of all cases);
2. UC with partial (squamous-glandular or trophoblastic) divergent differentiation;
3. UC with micropapillary divergent differentiation;
4. UC with nested/microcystic divergent differentiation;
5. UC with microtubular divergent differentiation;
6. UC with large nested divergent differentiation;
7. UC with plasmacytoid divergent differentiation;
8. UC with lymphoepithelioma-like divergent differentiation;
9. UC with giant cell, diffuse, undifferentiated divergent differentiation;
10. UC with sarcomatoid divergent differentiation;
11. some UCs with other rare differentiations;
12. UCs with partial NE (neuroendocrine differentiation, % to be given);
13. pure neuroendocrine carcinoma (including small and large cell neuroendocrine carcinomas.

In the new WHO 2022 all subtypes are considered HG [51]. The percentage of subtype in the specimen should be reported since it has been shown to be of prognostic value [73]. The WHO 2022 classification considers all subtypes UC (LG and HG) with more than 5% of HG as a HG tumour [2, 73-80].

4.9 Tumour markers and molecular classification

Tumour markers and their prognostic role have been investigated [81-85]. These methods, in particular complex approaches such as the stratification of patients based on molecular classification, are promising but have not yet been recommended by any pathological organisation and are therefore not suitable for routine application [53, 86, 87].

4.10 Summary of evidence and guidelines for bladder cancer classification

Summary of evidence	**LE**
The depth of invasion (staging) is classified according to the TNM classification.	2a
Tumours confined to the mucosa and invading the lamina propria are classified as stage Ta and T1, respectively. Flat, high-grade tumours that are confined to the mucosa are classified as CIS (Tis).	2a
Histological grading of urothelial NMIBC is classified according to the WHO 2004/2016/2022 (PUNLMP, LG/HG) systems and/or WHO 1973 (G1–G3).	2a
The WHO 2004/2016/2022 classification provides slightly better reproducibility than the 1973 classification.	2a

Both the WHO 1973 and the 2004/2016/2022 classification systems are prognostic for progression, but not for recurrence.	2a
The WHO 1973 is a stronger prognosticator of progression in TaT1 NMIBC than the WHO 2004/2016. However, a 3-tier hybrid (LG/G1-G2, HG/G2 & HG/G3) or a 4-tier hybrid LG/G1, LG/G2, HG/G2 and HG/G3) combination of both classification systems proved to be superior to either classification system alone.	2a

Recommendations	Strength rating
Use the 2017 TNM system for classification of the depth of tumour invasion (staging).	Strong
Provide T1 sub-stage if the lamina propria is adequately sampled using either micrometric (T1e and T1m) or histo-anatomic (T1a and T1b) principles.	Weak
Use both the 1973 and 2004/2022 WHO grading classification systems, or a hybrid system.	Weak
Do not use the term 'superficial' bladder cancer.	Strong

5. DIAGNOSIS

5.1 Patient history

A focused patient history is mandatory.

5.2 Signs and symptoms

Haematuria is the most common finding in NMIBC. Visible haematuria was found to be associated with higher stage at diagnosis disease compared to nonvisible haematuria [88]. Carcinoma *in situ* might be suspected in patients with lower urinary tract symptoms, especially irritative voiding symptoms.

5.3 Physical examination

A focused urological examination is mandatory although it does not reveal NMIBC.

5.4 Imaging

*5.4.1 **Computed tomography urography and intravenous urography***

Computed tomography (CT) urography is used to detect papillary tumours in the urinary tract, indicated by filling defects and/or hydronephrosis [89].

Intravenous urography (IVU) is an alternative if CT is not available [90], but CT urography provides more information particularly in muscle-invasive tumours of the bladder and in UTUCs (including status of lymph nodes and neighbouring organs).

The necessity to perform a baseline CT urography once a bladder tumour has been detected is questionable due to the low incidence of significant findings which can be obtained [91-93]. The incidence of UTUCs is low (1.8%), but increases to 7.5% in tumours located in the trigone [92]. The risk of UTUC during follow-up increases in patients with multiple and high-risk tumours [94].

*5.4.2 **Ultrasound***

Ultrasound (US) may be performed as an adjunct to physical examination as it has moderate sensitivity to a wide range of abnormalities in the upper- and lower urinary tract. It permits characterisation of renal masses, detection of hydronephrosis, and visualisation of intraluminal masses in the bladder, but cannot rule out all potential causes of haematuria [95, 96]. It cannot reliably exclude the presence of UTUC and cannot replace CT urography.

*5.4.3 **Multi-parametric magnetic resonance imaging***

The role of multi-parametric magnetic resonance imaging (mpMRI) has not yet been established in BC diagnosis and staging. A standardised methodology of MRI reporting (Vesical Imaging-Reporting and Data System [VI-RADS]) in patients with BC has recently been published and requires further validation [97]. A systematic review of 8 studies showed that the VI-RADS scoring system can accurately differentiate NMIBC from MIBC with high inter-observer agreement rates [98]. A diagnosis of CIS cannot be made with imaging methods alone (CT urography, IVU, US or MRI).

5.5 Urinary cytology

The examination of voided urine or bladder-washing specimens for exfoliated cancer cells has high sensitivity in HG and G3 tumours (84%), but low sensitivity in LG/G1 tumours (16%) [99]. The sensitivity in CIS detection is 28–100% [100]. A recent report applying the Paris system found a sensitivity of 46% for HG disease [101]. Cytology is useful, particularly as an adjunct to cystoscopy, in patients with HG/G3 tumours; it is not designed to detect LG tumours. Positive voided urinary cytology can indicate an UC anywhere in the urinary tract; negative cytology, however, does not exclude its presence.

Cytological interpretation is user-dependent [102, 103] and evaluation can be hampered by low cellular yield, urinary tract infections, stones, or intravesical instillations: although in experienced hands specificity exceeds 90% [104]. Artificial intelligence algorithms combined with digital image processing (VisioCyt test) improved the sensitivity of cytology for HG tumours up to 92% [105].

A standardised reporting system known as The Paris System published in 2022 (2nd Edn.) redefined urinary cytology diagnostic categories as follows [106]:

- No adequate diagnosis possible (No diagnosis);
- Negative for UC (Negative);
- Atypical urothelial cells (Atypia);
- Suspicious for HG UC (Suspicious);
- High-grade/G3 UC (Malignant).

The principle of the system and its terminology underlines the role of urinary cytology in detection of G3 and HG tumours. The Paris system for reporting urinary cytology has been validated in several retrospective studies [107, 108].

Urine collection should respect the recommendation provided in Section 5.9. One cytospin slide from the sample is usually sufficient [106]. In patients with suspicious cytology repeat investigation is advised as the underlying risk of a high grade lesion is between 24-53% [109].

5.6 Urinary molecular marker tests

Driven by the low sensitivity of urine cytology in LG/G1 tumours, numerous urinary tests have been developed [110]. None of these markers have been accepted as routine practice by any clinical guidelines for diagnosis or follow-up.

The following general statements can be drawn regarding the existing tests:

- Sensitivity is usually higher at the cost of lower specificity compared to urine cytology [106].
- Benign conditions and previous BCG instillations may influence the results of many urinary marker tests [111].
- Requirements for sensitivity and specificity of a urinary marker test largely depend on the clinical context of the patient (screening, primary detection, follow-up [high-risk, low/intermediate-risk]) [106].
- Several urinary biomarkers, assessing multiple targets, have been tested in prospective multicentre studies [112, 113]. Four of the commercially available urine biomarkers, Cx-Bladder [114, 115], ADX-BladderTM [116, 117], Xpert Bladder® [118-120] and EpiCheckTM [112], although not tested in RCTs, have such high sensitivities and negative predictive values in the referenced studies for HG disease that these biomarkers may approach the sensitivity of cystoscopy. These 4 tests might be used in the initial diagnostic workup to avoid/implement cystoscopy [114, 121, 122], or in follow-up to replace or postpone cystoscopy [116, 117, 120, 123]. See section 8 for more details on the use of urine markers in the follow up.
- In patients with negative cystoscopy and upper tract work-up, positive results of urine cytology or molecular urine tests such as UroVysion™ (FISH), Nuclear Matrix Protein (NMP)22®, Fibroblast Growth Factor Receptor (FGFR)3/Telomerase Reverse Transcriptase (TERT) and microsatellite analysis may identify patients more likely to experience disease recurrence and possibly progression [124-131].

5.7 Potential application of urinary cytology and markers

The following objectives of urinary cytology or molecular tests must be considered.

5.7.1 ***Screening of the population at risk of bladder cancer***

The application of haematuria dipstick, followed by FGFR3, or UroVysionTM tests if dipstick is positive has been reported in BC screening in high-risk populations [132, 133]. However, the low incidence of BC in the general population and the short lead-time impair feasibility and cost-effectiveness of BC screening [127, 133]. Thus, routine screening for BC is not recommended [127, 132, 133].

5.7.2 ***Investigation of patients after haematuria or other symptoms suggestive of bladder cancer (primary detection)***

It is generally accepted that none of the currently available tests can replace cystoscopy. However, urinary cytology or biomarkers can be used as an adjunct to cystoscopy to detect missed tumours, particularly CIS. In this setting, specificity is particularly important. Recently, CellDetect® and UroVysion™ have shown similar performance to detect BC and were both superior to cytology [134]. In addition, Xpert Bladder® had higher sensitivity and negative-predictive value than both cytology or UroVysion™ for the detection of BC in patients with haematuria [121].

5.7.3 ***Follow-up of non-muscle-invasive bladder cancer***

The current status of urine cytology and urinary molecular marker tests in follow-up for non-muscle-invasive bladder cancer is discussed in Section 8.

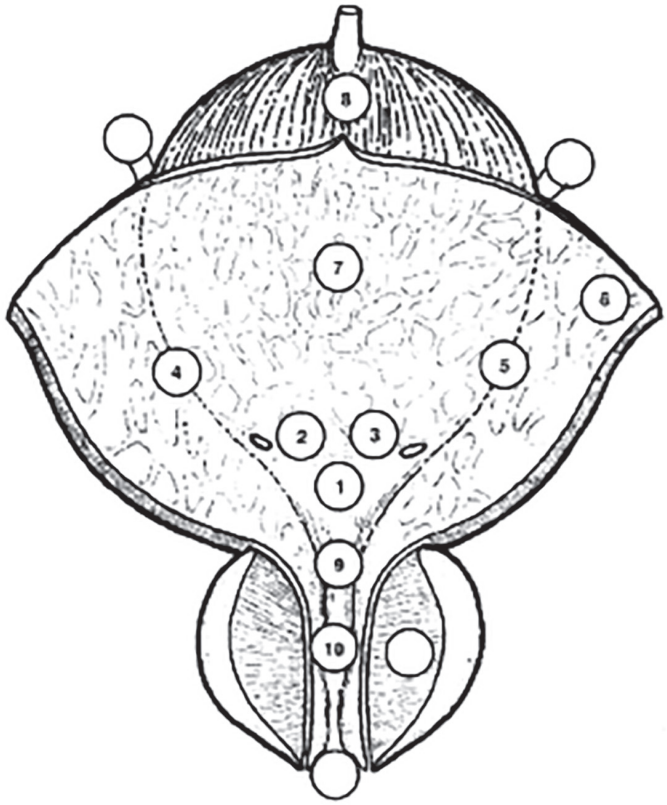
5.8 Cystoscopy

The diagnosis of papillary BC ultimately depends on cystoscopic examination of the bladder and histological evaluation of sampled tissue by either cold-cup biopsy or resection. Carcinoma *in situ* can be suspected through cystoscopy and urine cytology and confirmed by histological evaluation of multiple bladder biopsies [135].

Cystoscopy can be performed as an outpatient procedure. A flexible instrument with topical intraurethral anaesthetic lubricant instillation results in better compliance compared to a rigid instrument, especially in men [136, 137].

To temporary increase the urethral pressure by irrigation 'bag squeeze' when passing membranous and prostatic urethra with a flexible cystoscope in males also decreases pain during the procedure [138, 139].

Figure 5.1: Bladder diagram



5.9 Summary of evidence and recommendations for the primary assessment of non-muscle invasive bladder cancer

Summary of evidence	LE
Cystoscopy is necessary for the diagnosis of BC.	1
Urinary cytology has high sensitivity in high-grade tumours including carcinoma *in situ*.	2b

Recommendations	Strength rating
Take a patient history, focusing on urinary tract symptoms and haematuria.	Strong
Use renal and bladder ultrasound and/or computed tomography-intravenous urography (CT-IVU) during the initial work-up in patients with haematuria.	Strong
Once a bladder tumour has been detected, perform a CT urography in selected cases (e.g., tumours located in the trigone, multiple- or high-risk tumours).	Strong
Perform cystoscopy in patients with symptoms suggestive of bladder cancer or during surveillance. It cannot be replaced by cytology or by any other non-invasive test.	Strong
In men, use a flexible cystoscope, if available, and apply irrigation 'bag squeeze' to decrease procedural pain when passing the proximal urethra.	Strong
Describe all macroscopic features of the tumour (site, size, number, and appearance) and mucosal abnormalities during cystoscopy. Use a bladder diagram (Figure 5.1).	Strong
Use voided urine cytology as an adjunct to cystoscopy to detect high-grade tumour.	Strong
Perform cytology on at least 25 mL fresh urine or urine with adequate fixation. First morning urine is not suitable because of the frequent presence of cytolysis.	Strong
Use the Paris System 2nd Edn. for cytology reporting.	Strong

5.10 Transurethral resection of TaT1 bladder tumours

*5.10.1 **Strategy of the procedure***

The goals of TURB in TaT1 BC is to establish accurate pathological diagnosis/staging and completely remove all visible lesions. It is a crucial procedure in the management of BC. Transurethral resection of the bladder tumours should be performed systematically in individual steps [140, 141] (see Section 5.14).

The operative steps necessary to achieve a successful TURB include identifying the factors required to assign disease risk (number of tumours, size, architecture, location, concern for the presence of CIS, recurrent vs. primary tumour), clinical stage (bimanual examination under anaesthesia, assignment of clinical tumour stage), adequacy of the resection (visually complete resection, visualisation of muscle at the resection base), visualisation of tumour in the distal ureter and presence of complications (assessment for perforation) [140, 142]. Documentation of cystoscopic tumour characteristics and consequent clinically predicted tumour grade and stage can help assign patients to post-TURB single instillation of chemotherapy (low grade non-invasive) and muscle invasive cancers to be fast tracked to definitive treatment [143]. To measure the size of the largest tumour, one can use the end of the cutting loop, which is approximately 1 cm wide, as a reference. Tumour architecture can be sessile, nodular, papillary, mixed papillary/solid or flat.

*5.10.2 **Surgical and technical aspects of tumour resection***

5.10.2.1 Surgical strategy of resection (piecemeal/separate resection, en-bloc resection)

A complete resection, performed by either fractioned or *en-bloc* technique, is essential to achieve a good prognosis [141, 144].

- Piecemeal resection in fractions (separate resection of the exophytic part of the tumour, the underlying bladder wall and the edges of the resection area) provides good information about the vertical and horizontal extent of the tumour [145]. Whilst this technique is carried out using a loop with diathermy (monopolar or bipolar), the Thulium-YAG laser is potentially a feasible alternative [146].
- *En-bloc* resection using monopolar or bipolar current, Thulium-YAG or Holmium-YAG or KTP-Green Light lasers is feasible in selected exophytic tumours. It provides high-quality resected specimens with the presence of detrusor muscle in 96–100% of cases [141, 147-154]; however, its superiority over conventional TURB remains debatable [155, 156]. Detrusor muscle sampling rates were no different between these techniques in a systematic review of 1,142 patients [157], and in a single centre RCT showing similar detrusor muscle sampling rates of 95% between conventional TURB and *en-bloc* resection [155]. Conversely, another systematic review of 4,484 patients revealed higher detrusor muscle sampling

rates in favour of *en-bloc* resection [147], and a multicentre RCT found significantly higher detrusor muscle rates with *en-bloc* compared to conventional TURB (80.7 vs 71.1) [156]. Respect for tumour architecture increases the accuracy of T1 staging and the possibility of sub-staging while potentially reducing the risk of bladder perforation [147, 152-155]. With regards oncological outcomes, two RCTs did not reveal a difference in time to recurrence between *en-bloc* resection and conventional TURB [155, 156]. This has also been shown in two systematic reviews [147, 157].

The technique selected is dependent on the size and location of the tumour and experience of the surgeon. The tumour size feasible for retrieval *en-bloc* is limited by the currently available endoscopic equipment and it has been shown that technical success declines with tumours larger than three cm [158]. With better detection of tumours and abnormal margins, methods of optical enhancement are expected to improve complete resection rates (see Section 5.11).

5.10.2.2 Evaluation of resection quality

The absence of detrusor muscle in the specimen is associated with a significantly higher risk of residual disease, early recurrence, and tumour under-staging [159] (LE: 1b). The presence of detrusor muscle in the specimen is considered as a surrogate criterion of the resection quality [159] and is required (except in Ta LG/ G1 tumours). Surgical checklists and quality performance indicator programmes have been shown to increase surgical quality (accurate documentation of factors required to assign risk and sample detrusor muscle) and decrease recurrence rates [140, 142, 160-162]. The Panel have included a sample TURB checklist in Table 5.1 and reported quality indicators for the procedure in Table 9.1.

It has been shown that surgical experience can improve TURB results, which supports the role of teaching programmes [159, 163]. Virtual training on simulators is an emerging approach [164]. Its role in the teaching process still needs to be established [140]. Surgical experience and/or volume has been associated with risk of complications [165], recurrence [166] and survival [167] in retrospective studies. Despite a relatively low overall rate of detrusor muscle (DM) sampling, a collaborative study of 503 patients demonstrated that higher utilisation of surgical checklists by residents was associated with a higher rate of detrusor muscle sampling (62.9%) vs. 'experts' (50.6%) who's utilisation of checklists was lower [140, 162].

5.10.2.3 Monopolar and bipolar resection

Compared to monopolar resection, bipolar resection has been introduced to reduce the risk of complications (e.g., bladder perforation due to obturator nerve stimulation) and to produce better specimens. Currently, the results remain controversial [168-170], with significant inherent limitations due to selection bias, heterogeneity of surgical approach or inability to qualify surgeon experience. A systematic review of 13 RCTs (2,379 patients) showed no benefit of bipolar vs. monopolar TURB for efficacy and safety [170] while one meta-analysis of RCTs (n = 2,099) suggests a lower fall in haemoglobin and shorter hospital stay with bipolar resections [168] and another systematic review of RCTs and observational studies (n = 19,927) suggests lesser thermal artifacts in the specimen [169].

5.10.2.4 Resection of small papillary bladder tumours at the time of transurethral resection of the prostate (TURP)

It is not uncommon to incidentally detect bladder tumours during TURP in men with benign prostatic hyperplasia. Provided these tumours are papillary, rather small and not extensively multifocal, it seems feasible to resect these tumours and continue with the resection of the prostate [171, 172]. Simultaneous TURB and TURP does not appear to lead to any increased risk of tumour recurrence or progression [173]. Whilst most reports have suggested surgeons prefer to undertake saline irrigation following the combined TURBT and TURP, post-operative single instillation of chemotherapy also appears to be feasible and safe provided there is no capsular or bladder perforation [174].

5.11 Endoscopic biopsies

*5.11.1 **Bladder biopsies***

Carcinoma *in situ* can present as a velvet-like, reddish area, indistinguishable from inflammation, or it may not be visible at all. For this reason, biopsies from suspicious urothelium should be taken. In patients with positive urine cytology (see Section 5.5), and normal-looking mucosa at cystoscopy, mapping biopsies are recommended [175, 176]. To obtain representative mapping of the bladder mucosa, biopsies should be taken from the trigone, bladder dome, right, left, anterior and posterior bladder wall [175, 176]. If the equipment is available, photodynamic diagnosis (PDD) is a useful tool to target the biopsy (see section 5.12.1).

*5.11.2 **Prostatic urethral biopsies***

Involvement of the prostatic urethra and ducts in men with NMIBC has been reported. Palou *et al.*, showed that in 128 men with T1G3 UC, the incidence of CIS in the prostatic urethra was 11.7% [177]. The risk of prostatic urethra or duct involvement is higher if the tumour is located at the trigone or bladder neck, in the presence of bladder CIS and multiple tumours [178]. Based on this observation, a biopsy from the prostatic urethra is necessary in some cases [177, 179, 180]. Biopsies should preferably be from the pre-collicular area (between 5 and 7 o'clock position next to the veru montanum) using a resection loop.

5.12 New methods of tumour visualisation

As a standard procedure, cystoscopy and TURB are performed using white light (WL). However, the use of WL alone can lead to missing lesions that are present but not visible, which is why new technologies are being developed.

*5.12.1 **Photodynamic diagnosis (fluorescence cystoscopy or blue light cystoscopy)***

Photodynamic diagnosis is performed using blue light after intravesical instillation of 5-aminolaevulinic acid (ALA) or hexaminolaevulinic acid (HAL).

5.12.1.1 Impact on bladder cancer detection

It has been confirmed that fluorescence-guided biopsy and resection are more sensitive than conventional procedures for the detection of malignant tumours, particularly CIS [181, 182] (LE: 1a). In a systematic review and meta-analysis, PDD had higher sensitivity than WL endoscopy in the pooled estimates for analyses at both the patient-level (92% vs. 71%) and biopsy-level (93% vs. 65%) [182]. A prospective RCT did not confirm a higher detection rate in patients with known positive cytology before TURB [183].

Photodynamic diagnosis had lower specificity than WL endoscopy (63% vs. 81%) and it does not help to rule out prostatic involvement [182]. False- positivity can be induced by inflammation or recent TURB and during the first 3 months after BCG instillation [184, 185].

5.12.1.2 Impact on bladder cancer recurrence

The beneficial effect of ALA or HAL fluorescence cystoscopy on recurrence rate in patients with TURB was evaluated. A systematic review and analysis of 14 RCTs including 2,906 patients, 6 using 5-ALA and 9 HAL, demonstrated a decreased risk of BC recurrence in the short and long term. There were, however, no differences in progression and mortality rates. The analysis demonstrated inconsistency between trials and potential susceptibility to performance and publication bias [186]. While a recent systematic review and meta-analysis of 12 RCTs (n = 2,288) revealed lower risk of recurrence and improved time to recurrence (at least in the first 2 years and possibly up to 5 years) with PDD [187], the most recent Cochrane systematic review and meta-analysis of 16 RCTs (n = 4,325) demonstrated that PDD-assisted TURBT may prolong not only recurrence over time but also risk of progression, albeit supported only by low certainty evidence [188]. This finding has been corroborated in a systematic review and meta-analysis of 12 RCTs involving 2,775 patients [189].

Contrary to previous evidence, a multicenter RCT from UK showed that PDD-guided TURBT did not reduce recurrence rates, nor was it cost-effective compared with WL cystoscopy at three years [190] .

*5.12.2 **Narrow-band imaging***

In narrow-band imaging (NBI), the contrast between normal urothelium and hyper-vascular cancer tissue is enhanced. Improved cancer detection has been demonstrated by NBI flexible cystoscopy and NBI-guided biopsies and resection [191-194] (LE: 3b). Two RCTs assessed the reduction of recurrence rates if NBI is used during TURB [194, 195]. Although the overall results were negative, a benefit after three and twelve months was observed for low-risk tumours (pTa LG, < 30 mm, no CIS) [195].

A systematic review and meta-analysis by Russo *et al.*, (17 RCTs and non-RCTs) demonstrated improved detection (diagnostic accuracy) of bladder tumours with either PDD or NBI over WL cystoscopy [196], while another one (including 5,217 patients) showed improved RFS with either enhancement technique [197]. Conversely, a systematic review and network meta-analysis that took into account the use of single post-operative instillation of chemotherapy, concluded that there was a lower likelihood of recurrence at one year only following PDD-guided TURB (with or without single instillation) but not with NBI-guided surgery [198].

5.12.3 IMAGE1 S™, and other technologies

IMAGE1 S™ (formerly named SPIES) is an image enhancement system based on a computerized processing of different colour components that uses specific light filters. Limited evidence has been produced so far in an attempt to validate the 4 different light spectra modalities, suggesting an improvement in the diagnostic accuracy of WL [199, 200]. Early (18 months) follow-up data of an RCT failed to show an advantage in recurrence rate in the IMAGE1 S™ arm over WL, except in a subgroup of primary low intermediate-risk NMIBCs [201].

Confocal laser micro-endoscopy is a high-resolution imaging probe designed to provide endoscopic histological grading in real time but requires further validation [202].

5.13 Second resection (second TURB)

5.13.1 Detection of residual disease and tumour upstaging

The significant risk of residual tumour after initial TURB of TaT1 lesions has been demonstrated [144]. This residual cancer has the potential to worsen oncological outcomes and therefore further emphasises the importance of an effective initial TURB. As patients with an initial incomplete TURB (either from extensive tumour or intra-operative complications) will require a second completion resection, documentation of resection completeness at the time of the initial TURB is essential.

The main purposes of a second TURB are to: (1) clear any residual cancer; (2) re-resect the previous resection site to establish correct pathological staging; and (3) obtain any missing elements of the clinical information (e.g. extent of cancer, involvement of prostatic urethra).

A systematic review analysing data of 8,409 patients with Ta or T1 HG UC demonstrated a 51% risk of persistence and an 8% risk of under-staging in T1 tumours. The analysis also showed a high risk of residual disease in Ta tumours, but this observation was based only on a limited number of cases. Most of the residual lesions were detected at the original tumour location [203].

Another systematic review and meta-analysis of 3,556 patients with T1 tumours showed that the prevalence rate of residual tumours and upstaging to invasive disease after TURB remained high even in a subgroup with detrusor muscle sampled at the initial TURB. In the subgroup of 1,565 T1 tumours with detrusor muscle present, persistent tumour was found in 58% and under-staging occurred in 11% of cases [204].

Prospective trials suggest that post-operative positive urine cytology [205] and Xpert Bladder® (urine mRNA test) [206] are independently associated with residual disease at second resection and risk of future recurrences, respectively. These data, however, need to be confirmed in further studies.

5.13.2 The impact of second resection on treatment outcomes

A second TURB can increase recurrence-free survival (RFS) [207-209], improve outcomes after BCG treatment [210] and provide prognostic information [211-214].

In a retrospective evaluation of a large multi-institutional cohort of 2,451 patients with BCG-treated T1 G3/HG tumours (a second resection was performed in 935 patients), the second resection improved RFS, progression-free survival (PFS) and overall survival (OS) only in patients without detrusor muscle in the initial resection specimen [215]. In a retrospective analysis of 7,666 patients diagnosed with T1 cancer in Ontario, 2,162 underwent a second resection; after adjusting for the effects of confounding variables, only OS (and not CSS) was better in patients who underwent second resection [167]. This apparent improved survival could also be the result of selection bias with fitter patients undergoing second resections. Whilst a single centre retrospective review revealed survival benefit in 209 HGTa patients who underwent a second TURB [216], further evidence is required to identify specific sub-groups of patients with high-grade cancer who are most likely to benefit from a second resection.

5.13.3 Timing of second resection

Retrospective evaluation showed that a second resection performed 14–42 days after initial resection provides longer RFS and PFS compared to second resection performed after 43–90 days [217]. Based on this currently available evidence, a second TURB is recommended in selected cases 2 to 6 weeks after initial resection [217] (for recommendations on patient selection, see Section 5.14).

5.13.4 Recording of results

The results of the second resection (residual tumours and under-staging) reflect the quality and effectiveness of the initial TURB. As the goal is to improve the quality of the initial TURB, the results of the second resection should be recorded.

5.14 Pathology report

Pathological investigation of the specimen(s) obtained by TURB and biopsies is an essential step in the decision-making process for BC [218]. Close co-operation between urologists and pathologists is required. Clinical information and high quality of resected and submitted tissue is essential for correct pathological assessment. To obtain all relevant information, the specimen collection, handling and evaluation, should respect the recommendations provided below (see Section 5.14) [219]. In difficult cases, an additional review by an experienced genitourinary pathologist can be considered.

Table 5.1 TURBT checklist*

TURBT checklist - In the Operating Room	
Check the operating room setup	Instruments (sheath, resectoscope, loops, roller if needed, monopolar/ bipolar), camera, video, strainer, specimen container, catheter if needed
Decide irrigation fluid	Saline, Glycine, Water
Disease characteristics checklist	History of bladder cancer, tumour characteristics at cystoscopy if any, imaging results if any, first or second look, visual optimisation planned (PDD/NBI), risk classification
Cystoscopy/ TURBT	
Cystoscopy	Urethra/prostate (males)
	Ureteral orifices
	Diverticula
	Tumour location, number, size, appearance (papillary/sessile), CIS (yes/no)
	White light/PDD/NBI/IMAGE1 S™
	Urine for cytology/bladder wash
TURBT	Resection technique (standard/*en bloc*/cold cup/roller ball cautery)
	Depth of resection
	Complete/incomplete resection
	Prostatic urethra biopsy if performed
	Any additional procedure, i.e. retrograde contrast study
	Estimated blood loss
	Intra-operative complications, if any
	Intravesical therapy if given or planned in recovery setting

**Adapted from Mostafid et al., and Suarez-Ibarrola et al., [140, 220].*
NBI = narrow-band imaging; PDD = photodynamic diagnosis; TURBT = transurethral resection of bladder tumour.

5.15 Summary of evidence and guidelines for transurethral resection of the bladder, biopsies and pathology report

Summary of evidence	**LE**
Transurethral resection of the bladder tumour (TURB) followed by pathology investigation of the obtained specimen(s) is an essential step in the management of NMIBC.	1
The absence of detrusor muscle in the specimen is associated with a significantly higher risk of residual disease and tumour under-staging (with the exception of Ta LG/G1 tumours).	2b
A second TURB can detect residual tumours and tumour under-staging, increase recurrence-free survival, improve outcomes after BCG treatment and provide prognostic information.	2
Photodynamic diagnosis has been shown to improve the detection of bladder cancer, especially CIS.	1a

Recommendations	Strength rating
In patients suspected of having bladder cancer, perform a transurethral resection of the bladder tumour (TURB) followed by pathology investigation of the obtained specimen(s) as a diagnostic procedure and initial treatment step.	Strong
Perform TURB systematically in individual steps: • bimanual palpation under anaesthesia before starting the procedure and at the end; • insertion of the resectoscope, under visual control with inspection of the whole urethra; • inspection of the whole urothelial lining of the bladder; • biopsy from the prostatic urethra (if indicated); • cold-cup bladder biopsies (if indicated); • resection of the tumour; • recording of findings in the surgery report/record including visual impression of grade/stage; • precise description of the specimen(s) for pathology evaluation.	Strong
Performance of individual steps	
Perform *en-bloc* resection or resection in fractions (exophytic part of the tumour, the underlying bladder wall and the edges of the resection area).	Strong
Avoid cauterisation as much as possible during TURB to avoid tissue deterioration.	Strong
Take biopsies from abnormal-looking urothelium.	Strong
Take multiple biopsies (mapping biopsies from the trigone, bladder dome, right, left, anterior and posterior bladder wall) or perform photodynamic diagnosis (PDD) guided biopsies, in case of normal looking urothelium and positive urine cytology.	Strong
Take a sample of the prostatic urethra if there is positive urine cytology without evidence of tumour in the bladder, or if abnormalities of the prostatic urethra are visible (see section 5.11.2).	Strong
Take a sample biopsy of the prostatic urethra in cases of bladder neck tumour, suspicion of bladder CIS and/or T1 disease. If a sample was not taken during the initial procedure, it should be performed at the time of second resection, if the latter is needed (see section 5.11.2).	Weak
Use methods to improve tumour visualisation (fluorescence cystoscopy, narrow-band imaging) during TURB, if available.	Weak
Refer the specimens from different biopsies and resection fractions to the pathologist in separately labelled containers. Submit the tumour base separately especially in large and multifocal tumours or when *en-bloc* resection is not feasible.	Weak
The TURB record must describe tumour location, appearance, size and multifocality, all steps of the procedure, extent, macroscopic completeness of resection as well as any complications.	Strong
In patients with positive cytology, but negative cystoscopy, exclude an upper tract urothelial carcinoma, CIS in the bladder (by mapping biopsies or PDD-guided biopsies) and tumour in the prostatic urethra (by prostatic urethra biopsy).	Strong
Perform a second TURB in the following situations: • after incomplete initial TURB, or in case of doubt about completeness of a TURB; • if there is no detrusor muscle in the specimen after initial resection, with the exception of Ta LG/G1 tumours and primary CIS; • in T1 tumours.	Strong
If indicated, perform a second TURB within 2–6 weeks after the initial resection. This second TURB should include resection of the primary tumour site.	Weak
Record the pathology results of the second TURB as it reflects the quality of the initial resection.	Weak
Inform the pathologist of prior treatments (intravesical therapy, radiotherapy, etc.).	Strong
The pathological report should specify tumour location, tumour grade and stage, lymphovascular invasion, subtypes of urothelial carcinoma, presence of CIS and detrusor muscle.	Strong

6. PREDICTING DISEASE RECURRENCE AND PROGRESSION

6.1 TaT1 tumours

Treatment should take into account a patient's prognosis. In order to predict the risk of disease recurrence and/or progression, several prognostic models for specified patient populations have been introduced.

*6.1.1 **Scoring models using the WHO 1973 classification system***

6.1.1.1 The 2006 European Organisation for Research and Treatment of Cancer (EORTC) scoring model

To be able to predict both the short- and long-term risks of disease recurrence and progression in individual patients, the EORTC Genito-Urinary Cancer Group (GUCG) published a scoring system and risk tables based on the WHO 1973 classification in 2006 [221]. The scoring system is based on the 6 most significant clinical and pathological factors in patients mainly treated by intravesical chemotherapy:

- number of tumours;
- tumour diameter;
- prior recurrence rate;
- T category;
- concurrent CIS;
- WHO 1973 tumour grade.

Using the 2006 EORTC scoring model, individual probabilities of recurrence and progression at 1 and 5 years may be calculated (https://www.omnicalculator.com/health/eortc-bladder-cancer).

6.1.1.2 The model for patients with Ta G1/G2 (WHO 1973) tumours treated with chemotherapy

Patients with Ta G1/G2 tumours receiving chemotherapy were stratified into 3 risk groups for recurrence, taking into account the history of recurrences, history of intravesical treatment, tumour grade (WHO 1973), number of tumours and adjuvant chemotherapy [222].

6.1.1.3 Club Urologico Español de Tratamiento Oncologico (CUETO) scoring model for BCG-treated patients

A model that predicts the risk of recurrence and progression, based on 12 doses of intravesical BCG over a 5 to 6 months period following TURB, has been published by the CUETO (Spanish Urological Oncology Group). It is based on an analysis of 1,062 patients from 4 CUETO trials that compared different intravesical BCG treatments. No immediate post-operative instillation or second TURB was performed in these patients. The scoring system is based on the evaluation of seven prognostic factors:

- gender;
- age;
- prior recurrence status;
- number of tumours;
- T category;
- associated CIS;
- WHO 1973 tumour grade.

Using this model, the calculated risk of recurrence is lower than that obtained by the EORTC tables. For progression, probability is lower only in high-risk patients [223] (LE: 2a). The lower risks in the CUETO tables may be attributed to the use of BCG in this study. The prognostic value of the EORTC scoring system has been confirmed by data from the CUETO patients treated with BCG [224] and by long-term follow-up in another patient population [225].

6.1.1.4 The 2016 EORTC scoring model for patients treated with maintenance BCG

In 1,812 intermediate- and high-risk patients without CIS treated with 1 to 3 years of maintenance BCG, the EORTC found that the prior disease-recurrence rate and number of tumours were the most important prognostic factors for disease recurrence, stage and WHO 1973 grade for disease progression and disease- specific survival, while age and WHO 1973 grade were the most important prognostic factors for OS. T1 G3 patients did poorly, with 1- and 5-year disease-progression rates of 11.4% and 19.8%, respectively. Using these data, EORTC risk groups and nomograms for BCG-treated patients were developed [226].

*6.1.2 **Scoring model using the WHO 2004/2016 and WHO 1973 classification systems***

6.1.2.1 EAU NMIBC 2021 scoring model

To update the risk of disease progression and create new prognostic factor risk groups using both the WHO 1973 and WHO 2004/2016 classification systems (without central pathology review), individual patient data from 3,401 primary patients treated from 1990 to 2018 were used [227] (see Section 4.5). Only patients treated with TURB ± intravesical chemotherapy were included, those treated with adjuvant intravesical BCG were excluded because BCG may reduce the risk of disease progression. From the multivariate analyses, tumour stage, WHO 1973 grade, WHO 2004/2022 grade, concomitant CIS, number of tumours, tumour size and age were independent predictors of disease progression [227].

This is the only available model where the WHO 2004/2022 classification system is included as one of the parameters to calculate an individual patient's risk group and probability of progression. As the WHO 2004/2022 classification system is the main grading classification system used by pathologists, the Guidelines Panel recommends to use the 2021 EAU NMIBC scoring model for risk groups definition (see Section 6.3).

The 2021 EAU NMIBC scoring model determines the risk of tumour progression, but not recurrence; therefore any of the models mentioned in Section 6.1.1 may be used for calculation of an individual's risk of disease recurrence.

*6.1.3 **Further prognostic factors***

Further prognostic factors have been described in selected patient populations:

- In T1 HG/G3 tumours, important prognostic factors were female sex, CIS in the prostatic urethra in men treated with an induction course of BCG, and age, tumour size and concurrent CIS in BCG-treated patients (62% with an induction course only) [177, 228].
- Attention must be given to patients with T1 HG/G3 tumours in bladder diverticulum because of the absence of muscle layer in the diverticular wall [229].
- In patients with T1 tumours, the finding of residual T1 disease at second TURB is an unfavourable prognostic factor [212-214].
- In patients with T1G2 tumours treated with TURB, recurrence at 3 months was the most important predictor of progression [230].
- The prognostic value of pathological factors has been discussed elsewhere (see Section 4.6). More research is needed to determine the role of molecular markers in improving the predictive accuracy of currently available risk tables [225, 231].

6.2 Primary carcinoma *in situ*

Without any treatment, approximately 54% of patients with CIS progress to muscle-invasive disease [232] (LE: 3). There are no reliable prognostic factors, but some studies, however, have reported a worse prognosis in concurrent CIS and T1 tumours compared to primary CIS [233, 234], in extended CIS [235] and in CIS in the prostatic urethra [177]. The response to intravesical treatment with BCG or chemotherapy is an important prognostic factor for subsequent progression and death caused by BC [223, 224, 230]. Approximately 10 to 20% of complete responders eventually experience disease progression to muscle-invasive disease, compared with 66% of non- responders [236, 237].

6.3 Patient stratification into risk groups

To be able to facilitate treatment recommendations, the Guidelines Panel recommends the stratification of patients into risk groups based on their probability of progression to muscle-invasive disease. The new risk group definitions provided in these EAU Guidelines are based on an individual patient data analysis in primary patients and the calculation of their progression scores (2021 EAU NMIBC scoring model) as presented in Sections 4.5 and 6.1.2) [227].

For calculation of the risk group in individual patients, either one, or both, of the WHO 1973 and WHO 2004/2016 classification systems may be used. The probability of progression at 5 years varies from less than 1% to more than 40% between the risk groups.

For factors where individual patient data were not collected such as subtypes of UC, LVI, primary CIS and CIS in the prostatic urethra; literature data have been used to classify patients into risk groups.

The clinical compositions of the new EAU NMIBC prognostic factor risk groups based on the WHO 2004/2016 or WHO 1973 classification systems are provided in Table 6.1. Applications for the web (www.nmibc.net), iOS and Android have been developed to facilitate determining a patient's risk group in daily clinical practice. The individual probability of disease progression at 1, 5 and 10 years for the new EAU NMIBC risk groups is presented in Table 6.2. A single-centre study validated the EAU NMIBC 2021 scoring model in 529 patients who

received BCG [238]. The authors found that the progression risk for the EAU 2021 high- and very high-risk groups were significantly lower in BCG-treated patients than that in Table 6.2 [227]. These lower risks may be attributed to the use of BCG.

Table 6.1: Clinical composition of the new EAU NMIBC prognostic factor risk groups based on the WHO 2004/2016 or the WHO 1973 grading classification systems [227]

- Only one of the two classification systems (WHO 1973 or WHO 2004/2016) is required to use this table.
- If both classification systems are available in an individual patient, the Panel recommends using the risk group calculation based on the WHO 1973 as it has better prognostic value.
- The category of LG tumours (WHO 2004/2016) also includes patients with tumours classified as PUNLMP.
- Additional clinical risk factors are: age > 70; multiple papillary tumours; and tumour diameter > 3 cm.

Risk group	
Low Risk	• A primary, single, TaT1 LG/G1 tumour < 3 cm in diameter without CIS in a patient ≤ 70 years • A primary Ta LG/G1 tumour without CIS with at most ONE of the additional clinical risk factors
Intermediate Risk	• Patients without CIS who are not included in either the low-, high-, or very high-risk groups
High Risk	• All T1 HG/G3 without CIS, EXCEPT those included in the very high-risk group • All CIS patients, EXCEPT those included in the very high-risk group
	Stage, grade with additional clinical risk factors: • Ta LG/G2 or T1G1, no CIS with all 3 risk factors • Ta HG/G3 or T1 LG, no CIS with at least 2 risk factors • T1G2 no CIS with at least 1 risk factor
Very High Risk	**Stage, grade with additional clinical risk factors:** • Ta HG/G3 and CIS with all 3 risk factors • T1G2 and CIS with at least 2 risk factors • T1 HG/G3 and CIS with at least 1 risk factor • T1 HG/G3 no CIS with all 3 risk factors

The scoring model is based on individual patient data, but does not consider patients with primary CIS (high risk) or with recurrent tumours, as well as some pathologic parameters like subtypes of UC (see Section 4.7) and LVI. Nevertheless:

- Based on data from the literature, all patients with CIS in the prostatic urethra, with subtypes of UC (see Section 4.8) or with LVI should be included in the very high-risk group.
- Patients with recurrent tumours should be included in the intermediate-, high-, or very high-risk groups according to their other prognostic factors.

Table 6.2: Probabilities of disease progression in 1, 5 and 10 year(s) for the new EAU NMIBC risk groups [227]*

Risk group	*Probability of Progression and 95% Confidence Interval (CI)*		
	1 Year	5 Years	10 Years
New Risk Groups with WHO 2004/2016			
Low	0.06% (CI: 0.01%–0.43%)	0.93% (CI: 0.49%–1.7%)	3.7% (CI: 2.3%–5.9%)
Intermediate	1.0% (CI: 0.50%–2.0%)	4.9% (CI: 3.4%–7.0%)	8.5% (CI: 5.6%–13%)
High	3.5% (CI: 2.4%–5.2%)	9.6% (CI: 7.4%–12%)	14% (CI: 11%–18%)
Very High	16% (CI: 10%–26%)	40% (CI: 29%–54%)	53% (CI: 36%–73%)
New Risk Groups with WHO 1973			
Low	0.12% (CI: 0.02%–0.82%)	0.57% (CI: 0.21%–1.5%)	3.0% (CI: 1.5%–6.3%)
Intermediate	0.65% (CI: 0.36%–1.2%)	3.6% (CI: 2.7%–4.9%)	7.4% (CI: 5.5%–10%)
High	3.8% (CI: 2.6%–5.7%)	11% (CI: 8.1%–14%)	14% (CI: 10%–19%)
Very High	20% (CI: 12%–32%)	44% (CI: 30%–61%)	59% (CI: 39%–79%)

WHO = World Health Organization.

**Table 6.2 does not include patients with subtypes of urothelial carcinoma (variant histologies), LVI, CIS in the prostatic urethra, primary CIS or recurrent patients.*

**Please note that these percentages refer to patients who were not (immediately) treated with adjuvant BCG instillations after their primary TUR.*

6.4 Summary of evidence and guidelines for stratification of non-muscle-invasive bladder cancer

Summary of evidence	LE
The EAU NMIBC 2021 scoring model and risk tables predict the short- and long-term risks of disease progression in individual patients with primary NMIBC using either the WHO 1973 or the WHO 2022 classification system (see Section 6.1.2.1).	2b
The 2006 EORTC scoring model and risk tables predict the short- and long-term risks of disease recurrence and progression in individual patients with NMIBC using the WHO 1973 classification system (see Section 6.1.1.1).	1b
Patients with Ta G1/G2 tumours receiving chemotherapy have been further stratified into 3 risk groups for recurrence, taking into account the history of recurrences, history of intravesical treatment, tumour grade (WHO 1973), number of tumours and adjuvant chemotherapy (see Section 6.1.1.2).	2b
In patients treated with 5 to 6 months of BCG, the CUETO scoring model predicts the short- and long-term risks of disease recurrence and progression using the WHO 1973 classification system (see Section 6.1.1.3).	1b
In patients receiving at least 1 year of BCG maintenance; prior recurrence rate and number of tumours are the most important prognostic factors for disease recurrence. Stage and grade are the most important prognostic factors for disease progression and disease-specific survival; patient age and grade (WHO 1973) are the most important prognostic factors for OS (see Section 6.1.1.4).	1b

Recommendations	Strength rating
Stratify patients into 4 risk groups to predict progression, according to Table 6.1. A patient's risk group can be determined using the 2021 EAU risk group calculator available at www.nmibc.net.	Strong
For information about the risk of disease progression in a patient with primary TaT1 tumours, not treated with bacillus Calmette-Guérin (BCG), use the data from Table 6.2.	Strong
Use the 2006 EORTC scoring model to predict the risk of tumour recurrence in individual patients not treated with BCG.	Strong
Use the 2016 EORTC scoring model or the CUETO risk scoring model to predict the risk of tumour recurrence in individual patients treated with BCG intravesical immunotherapy (the 2016 EORTC model is calculated for 1 to 3 years of maintenance, the CUETO model for 5 to 6 months).	Strong

7. DISEASE MANAGEMENT

7.1 Counselling of smoking cessation

It has been confirmed that smoking increases the risk of tumour recurrence and progression in NMIBC patients [239-241] as well as mortality in all BC patients [242]. A subgroup analysis of 4,405 patients in a large systematic review revealed that current smokers had a significantly higher risk of recurrence compared with former smokers [241]. Patients should be counselled to stop smoking due to the general health risks associated with tobacco smoking [229, 243-245].

7.2 Office-based fulguration and laser vaporisation

In patients with a history of small Ta LG/G1 tumours, fulguration, or laser vaporisation of small papillary recurrences on an outpatient basis can reduce the therapeutic burden [246, 247]. In a prospective RCT, laser photocoagulation with intravesical lidocaine in an outpatient setting proved non inferior to standard TURB under general anaesthesia for the 4 months recurrence rate. Notably, the laser fulguration procedure resulted in only a modest pain score (2.4) and was preferred by 98% of patients [248].

7.3 Active Surveillance

With recurrence in LG(G1) Ta tumours being more likely low grade and non-invasive [249-251] the risk of progression to a higher grade or stage is infrequent to rare [252-254]. Expectant management or active surveillance (AS), offer an alternative to TURB and office-based fulguration. Observing no progression to MIBC, Soloway *et al.*, first recommended this approach in 2003 [255] and Miyake *et al.*, subsequently proposed an algorithm for AS using changes in size and multifocality as triggers for intervention [256]. However, from a review undertaken by the EAU Young Academic Urology group [257], it appears that the level of evidence in favour of AS is low, with observational studies having heterogenous selection criteria, triggers for intervention and surveillance tools. The multicentre prospective Bladder Cancer Italian Active Surveillance (BIAS) project, conversely, demonstrated that AS is feasible in selected patients [258, 259] and its success be predicted by prognostic variables associated to TaLG disease [260]. However, additional evidence from quality clinical trials is required.

7.4 Adjuvant intravesical treatment

Although TURB by itself can eradicate a TaT1 tumour completely, these tumours commonly recur and can progress to MIBC. The high variability in the 3-month recurrence rate indicates that the TURB was incomplete or provokes recurrences in a high percentage of patients [144]. It is therefore necessary to consider adjuvant therapy in all patients.

*7.4.1 **Post-operative irrigation***

Two systematic reviews [261, 262] and one meta-analysis [263] suggest efficacy of continuous irrigation in the prevention of early recurrences. In case intravesical chemotherapy is not feasible, irrigation of the bladder might be considered. Optimal volume infused and duration of irrigation remains unknown.

*7.4.2 **Intravesical chemotherapy***

7.4.2.1 A single, immediate, post-operative intravesical instillation of chemotherapy

Immediate single instillation (SI) has been shown to act by destroying circulating tumour cells after TURB, and by an ablative effect on residual tumour cells at the resection site and on small overlooked tumours [264-267]. Four large meta-analyses comprising 1,476 to 3,103 patients have consistently shown that after TURB, SI significantly reduces the recurrence rate compared to TURB alone [268-271]. In a systematic review and individual patient data meta-analysis of 2,278 eligible patients [268], SI reduced the 5-year recurrence rate by 14%, from 59% to 45%. Only patients with primary tumours or intermediate-risk recurrent tumours with a prior recurrence rate of < 1 recurrence/year and those with a 2006 EORTC recurrence score < 5 benefited from SI. In patients with a 2006 EORTC recurrence score > 5 and/or patients with a prior recurrence rate of > 1 recurrence per year, SI was not effective as a single adjuvant treatment. No randomised comparisons of individual drugs have been conducted [268-271].

Single instillation with mitomycin C (MMC), epirubicin or pirarubicin [268], as well as gemcitabine [271], have all shown to lower the intravesical recurrence rate. Single instillation with gemcitabine was superior to saline in a RCT with approximately 200 patients per arm with remarkably low toxicity rates [272]. These findings are in contrast with a previous study, which, however, used a shorter instillation time [273]. In the Böhle *et al.*, study, continuous saline irrigation was used for 24 hours post-operatively in both arms, which could explain the low recurrence rate in the control arm [273].

Prevention of tumour cell implantation should be initiated within the first few hours after TURB. After that, tumour cells are firmly implanted and are covered by the extracellular matrix [264, 274-276]. In all SI studies, the instillation was administered within 24 hours. Two RCTs found no overall impact of SI with apaziquone, a bio reductive prodrug similar to MMC; in contrast, a *post-hoc* analysis did find a reduction of recurrence risk in patients receiving apaziquone within 90 minutes following TURB [277].

To maximise the efficacy of SI, one should devise flexible practices that allow the instillation to be given as soon as possible after TURB, preferably within the first two hours in the recovery room or even in the operating theatre. As severe complications have been reported in patients with drug extravasation, safety measures should be maintained (see Section 7.7) [278, 279]. To allow for optimal compliance with this Level 1 evidence, clinical teams are encouraged to explore barriers and facilitators within their practice [280].

7.4.2.2 Additional adjuvant intravesical chemotherapy instillations

The need for further adjuvant intravesical therapy depends on prognosis. In low-risk patients (Tables 6.1 and 6.2), a SI reduces the risk of recurrence and is considered to be the standard and complete treatment [268, 269]. For other patients, however, a SI remains an incomplete treatment because of the considerable likelihood of recurrence and/or progression (Tables 6.1 and 6.2). Efficacy data for the following comparisons of application schemes were published.

Single installation only vs. SI and further repeat instillations

In one study, further chemotherapy instillations after SI improved RFS in intermediate-risk patients [281].

Repeat chemotherapy instillations vs. no adjuvant treatment

A large meta-analysis of 3,703 patients from 11 RCTs showed a highly significant (44%) reduction in the odds of recurrence at one year in favour of chemotherapy over TURB alone [282]. This corresponds to an absolute difference of 13–14% in the proportion of patients with recurrence. Contrary to these findings, two meta-analyses have demonstrated that BCG therapy may also reduce the risk of tumour progression [283, 284] (see Section 7.2.2.1). Moreover, BCG maintenance therapy appears to be significantly better in preventing recurrences than chemotherapy [285-287] (see Section 7.2.2.1). However, BCG causes significantly more side effects than chemotherapy [287].

Single instillation + further repeat instillations vs. later repeat instillations only

There is evidence from several studies in intermediate-risk patients that SI might have an impact on recurrence even when further adjuvant instillations are given [288-291]. A RCT including 2,243 NMIBC patients, which compared SI of MMC with an instillation of MMC delayed two weeks after TURB (followed by further repeat instillations in both treatment arms), showed a significant reduction of 9% in the risk of recurrence at 3 years in favour of SI, from 36% to 27%. The effect was significant in the intermediate- and high-risk groups of patients receiving additional adjuvant MMC instillations [288]. Since the author's definition of the risk groups differed significantly in the initial publication, they adapted their patient stratification in the second analysis and consistently showed improved efficacy of SI followed by repeat MMC instillations [292]. The results of this study should be considered with caution since some patients did not receive adequate therapy. Another RCT found no impact of SI with epirubicin followed by further chemotherapy or BCG instillations in a cohort of predominant HR BC patients [293].

The optimal schedule of intravesical chemotherapy instillations

The length and frequency of repeat chemotherapy instillations is still controversial; however, it should not exceed one year [291]. A systematic review of 16 comparative studies concluded that most of the available evidence does not support the use of maintenance chemotherapy over induction only in the treatment of NMIBC [294].

7.4.2.3 Measures to improve the efficacy of intravesical chemotherapy

7.4.2.3.1 Adjustment of pH, duration of instillation, and drug concentration

Two prospective RCTs showed that optimized intravesical administration of MMC reduced recurrence rates, either by a combination of measures (higher MMC-dose, peroral sodium bicarbonate, and refraining from drinking) [295] and by adding cytosine arabinoside [296], respectively. The value of these measures in addition to alternative maintenance schedules is not known however MMC admixtures ≥ 1 mg/ml do not achieve full solubilisation which might lead to decreased drug exposure to the bladder [297]. Another trial reported that duration of a one- hour instillation of MMC was more effective compared to a 30-minute instillation, but no efficacy comparisons are available for one- vs. two-hour durations of instillation [298]. Another RCT using epirubicin has documented that concentration is more important than treatment duration [299]. In view of these data, instructions are provided (see Section 7.7).

7.4.2.3.2 Device-assisted intravesical chemotherapy

Hyperthermic intravesical chemotherapy

Different technologies which increase the temperature of instilled MMC are available. A recent systematic review and meta-analysis including four RCTs suggests similar toxicity as for BCG with maintenance schedule [300].

Microwave-induced hyperthermia effect (RITE)

Promising data have been presented on enhancing the efficacy of MMC using microwave-induced hyperthermia in patients with high-risk tumours [301]. In one RCT comparing one year of BCG with one year MMC and microwave-induced hyperthermia in patients with intermediate- and high-risk BC, increased RFS at 24 months in the MMC group was demonstrated [302].

Conductive chemohyperthermia

In an open-label phase II RCT including 259 patients, HIVEC chemo-hyperthermia failed to demonstrate an improvement in DFS at 24 months over standard adjuvant intravesical chemotherapy in intermediate-risk NMIBC (61% vs. 60%), with a higher risk of treatment discontinuation (59% vs. 89% of completed planned treatments) [303]. These results are in line with the multicentre HIVEC 1 phase 3 open label RCT, including 212 intermediate-risk patients, showing that four-month adjuvant hyperthermic MMC using the COMBAT system in intermediate-risk NMIBC was well tolerated, but was not superior to normothermic MMC at 24 months [304].

In a pilot phase II RCT on 50 high-risk NMIBCs, HIVEC™ MMC showed early outcomes comparable to BCG (24 months RFS, 86.5% with HIVEC™ and 71.8% with BCG, p = 0.184) [305]. These data need to be corroborated by further studies.

Electromotive drug administration

The efficacy of MMC using electromotive drug administration (EMDA) sequentially combined with BCG in patients with high-risk tumours has been demonstrated in one small RCT [306]. The definitive conclusion, however, needs further confirmation. For application of device-assisted instillations in patients recurring after BCG treatment, see Section 7.9.3.

7.4.2.4 Summary of evidence - intravesical chemotherapy

Summary of evidence	**LE**
In patients with low-risk NMIBC and in those with a small Ta LG/G1 recurrence detected more than one year after previous TURB, a SI significantly reduces the recurrence rate compared to TURB alone.	1a
Single instillation might have an impact on recurrence even when further adjuvant chemotherapy instillations are given, but not in high-risk NMIBC treated with adjuvant BCG.	3
Repeat chemotherapy instillations (with or without previous SI) improve RFS in intermediate-risk patients.	2a

7.4.3 ***Intravesical bacillus Calmette-Guérin (BCG) immunotherapy***

7.4.3.1 Efficacy of BCG

7.4.3.1.1 Recurrence rate

Five meta-analyses have confirmed that BCG after TURB is superior to TURB alone or TURB plus chemotherapy for preventing the recurrence of NMIBC [285, 307-310]. Three RCTs of intermediate- and high-risk tumours have compared BCG with epirubicin and interferon (INF) [311], MMC [312], or epirubicin alone [286] and have confirmed the superiority of BCG for prevention of tumour recurrence (LE: 1a). The effect is long lasting [286, 312] and was also observed in a separate analysis of patients with intermediate-risk tumours [286]. One meta-analysis [285] has evaluated the individual data from 2,820 patients enrolled in 9 RCTs that have compared MMC vs. BCG. In the trials with BCG maintenance, there was a 32% reduction in the risk of recurrence for BCG compared to MMC, but a 28% increase in the risk of recurrence for patients treated with BCG in the trials without BCG maintenance. A Cochrane systematic review confirmed that BCG is more effective in reducing the recurrence rate over MMC [313].

7.4.3.1.2 Progression rate

Two meta-analyses have demonstrated that BCG therapy delays and potentially lowers the risk of tumour progression [283, 284, 310] (LE: 1a). A meta-analysis carried out by the EORTC GUCG has evaluated data from 4,863 patients enrolled in 24 RCTs. In 20 of the trials, some form of BCG maintenance was used. Based on a median follow-up of 2.5 years, tumours progressed in 9.8% of the patients treated with BCG compared to 13.8%

in the control groups (TURB alone, TURB and intravesical chemotherapy, or TURB with the addition of other immunotherapy). This shows a reduction of 27% in the odds of progression with BCG maintenance treatment. The size of the reduction was similar in patients with TaT1 papillary tumours and in those with CIS [284]. A RCT with long-term follow-up has demonstrated significantly fewer distant metastases and better overall- and disease-specific survival in patients treated with BCG compared to epirubicin [286] (LE: 1b). In contrast, an individual patient data meta-analysis and Cochrane review were not able to confirm any statistically significant difference between MMC and BCG for progression, survival, and cause of death [285, 313].

The conflicting results in the outcomes of these studies can be explained by different patient characteristics, duration of follow-up, methodology and statistical power. However, most studies showed a reduction in the risk of progression in high-and intermediate-risk tumours if a BCG maintenance schedule was applied.

7.4.3.1.3 Influence of further factors

Two other meta-analyses have suggested a possible bias in favour of BCG arising from the inclusion of patients previously treated with intravesical chemotherapy [314]. In the individual patient data meta-analysis, however, BCG maintenance was more effective than MMC in reduction of recurrence rate, both in patients previously treated and not previously treated with chemotherapy [285] (LE: 1a). It was demonstrated that BCG was less effective in patients > 70 years of age, but still more effective than epirubicin in a cohort of elderly patients [315] (LE: 1a). According to a cohort analysis, the risk of tumour recurrence after BCG was shown to be higher in patients with a previous history of UTUC [316].

7.4.3.2 BCG strain

Although smaller studies without maintenance demonstrated some differences between strains [316-318], a network meta-analysis identified ten different BCG strains used for intravesical treatment in the published literature but was not able to confirm superiority of any BCG strain over another [319].

Similarly, a meta-analysis of prospective RCTs [284], published data from a prospective registry [320] as well as from a *post-hoc* analysis of a large phase II prospective trial assessing BCG and INF-α in both BCG-naive and BCG-failure patients did not suggest any clear difference in efficacy between the different BCG strains [321]. The quality of data, however, does not allow definitive conclusions.

7.4.3.3 BCG toxicity

Bacillus Calmette-Guérin intravesical treatment is associated with more side effects compared to intravesical chemotherapy [284, 313]. However, serious side effects are encountered in < 5% of patients and can be treated effectively in almost all cases [322]. The incidence of BCG infections after BCG instillations was 1% in a registry-based cohort analysis [323]. It has been shown that a maintenance schedule is not associated with an increased risk of side effects compared to an induction course [322]. Side effects requiring treatment stoppage were seen more often in the first year of therapy [324]. Elderly patients do not seem to experience more side effects leading to treatment discontinuation [325]. No significant difference in toxicity between different BCG strains was demonstrated [320]. Symptoms may be the result of side effects of the BCG treatment or caused by bladder disease (widespread CIS) itself. Consequently, the burden of symptoms is reduced after completion of the treatment in a significant number of patients albeit delayed hypersensitivity to BCG may rarely present even years after completion of treatment [326].

Major complications can appear after systemic absorption of the drug. Thus, contraindications of BCG intravesical instillation should be respected (see Section 7.9). The presence of leukocyturia, nonvisible haematuria or asymptomatic bacteriuria is not a contraindication for BCG application, and antibiotic prophylaxis is not necessary in these cases [131, 327] (LE: 3). Three RCTs showed reduced side effects by administering different quinolones in conjunction with the BCG-instillations [328-330]. The latter, by using two doses of levofloxacin (at 6 and 12 hours after first voiding) in conjunction with each BCG-instillation, reduced the proportion of patients with high-grade side effects, both local (pollakisuria) and systemic (fever), without improving the completion rate of the maintenance regimen or the risk of severe BCG related adverse events [330].

Bacillus Calmette-Guérin should be used with caution in immunocompromised patients. Immunosuppression, for example human immunodeficiency virus (HIV) infection, poses relative contraindications [331], although some small studies have shown similar efficacy and no increase in complications compared to non-immunocompromised patients. The role of prophylactic anti-tuberculosis medication in these patients remains unclear [332-334]. Kidney transplant recipients can be safely treated with BCG [335].

The management of side effects after BCG should reflect their type and grade according to the recommendations provided by the International Bladder Cancer Group (IBCG) and by a Spanish group [336, 337] (Table 7.1).

Table 7.1: Management options for side effects associated with intravesical BCG [337-340]

Management options for local side effects (modified from International Bladder Cancer Group)	
Symptoms of cystitis	Phenazopyridine, propantheline bromide, or non-steroidal anti-inflammatory drugs (NSAIDs).
	If symptoms improve within a few days: continue instillations.
	If symptoms persist or worsen: a. Postpone the instillation. b. Perform a urine culture. c. Start empirical antibiotic treatment.
	If symptoms persist even with antibiotic treatment: a. With positive culture: adjust antibiotic treatment according to sensitivity. b. With negative culture: quinolones* and potentially analgesic anti-inflammatory instillations once daily for 5 days (repeat cycle if necessary) [338].
	If symptoms persist: anti-tuberculosis drugs + corticosteroids.
	If no response to treatment and/or contracted bladder: radical cystectomy.
Haematuria	Perform urine culture to exclude haemorrhagic cystitis if other symptoms present.
	If haematuria persists, perform cystoscopy to evaluate presence of bladder tumour.
Symptomatic granulomatous prostatitis	Symptoms rarely present: perform urine culture.
	Quinolones.
	If quinolones are not effective: isoniazid (300 mg/day) and rifampicin (600 mg/day) for 3 months.
	Cessation of intravesical therapy.
Epididymo-orchitis [339]	Perform urine culture and administer quinolones.
	Cessation of intravesical therapy.
	Orchidectomy if abscess or no response to treatment.
Management options for systemic side effects	
General malaise, fever	Generally resolve within 48 hours, with or without antipyretics.
Arthralgia and/or arthritis	Rare complication and considered autoimmune reaction.
	Arthralgia: treatment with NSAIDs.
	Reactive arthritis: NSAIDs.
	If no/partial response, proceed to corticosteroids, high-dose quinolones or antituberculosis drugs [340].
Persistent high-grade fever (> 38.5°C for > 48 h)	Permanent discontinuation of BCG instillations.
	Immediate evaluation: urine culture, blood tests, chest X-ray.
	Prompt treatment with more than two antimicrobial agents while diagnostic evaluation is conducted.
	Consultation with an infectious diseases specialist.
BCG sepsis	Prevention: initiate BCG at least 2 weeks post-transurethral resection of the bladder (if no signs and symptoms of haematuria).
	Cessation of BCG.
	For severe infection: • High-dose quinolones or isoniazid, rifampicin, and ethambutol 1.2 g daily for 6 months. • Early, high-dose corticosteroids as long as symptoms persist. • Consider an empirical non-specific antibiotic to cover Gram-negative bacteria and/or *Enterococcus.*

Allergic reactions	Antihistamines and anti-inflammatory agents.
	Consider high-dose quinolones or isoniazid and rifampicin for persistent symptoms.
	Delay therapy until reactions resolve.

** Persistent severe cystitis symptoms associated with BCG use have a high risk to underlie a complicated UTI (even in the absence of a positive culture) and thus no restriction applies to the empirical use of quinolones by the Pharmacovigilance Risk Assessment Committee of the EMA (see also Section 3.7 Complicated UTI and 3.7.4.1- Choice of antimicrobials of the EAU Guidelines on Urological Infection 2022) [341, 342].*

7.4.3.4 Optimal BCG schedule

Induction BCG instillations are given according to the empirical 6-weekly schedule introduced by Morales *et al.*, [343]. For optimal efficacy, BCG must be given in a maintenance schedule [283-285, 310]. Many different maintenance schedules have been used, ranging from a total of 10 instillations given in 18 to 27 weeks over 3 years [344]. The optimal 3-years maintenance schedule is outlined in recommendation table 7.10.

7.4.3.4.1 Optimal number of induction instillations and frequency of instillations during maintenance

The optimal number of induction instillations and frequency of maintenance instillations were evaluated by NIMBUS, a prospective phase III RCT. Safety analysis after 345 randomised patients demonstrated that a reduced number of instillations (3 instillations in induction and 2 instillations at 3, 6 and 12 months) proved inferior to the standard schedule (6 instillation in induction and 3 instillations at 3, 6 and 12 months) regarding the time to first recurrence [345]. In a RCT including 397 patients CUETO showed that in high-risk tumours a maintenance schedule with only one instillation every 3 months for 3 years was not superior to induction therapy only, which suggested that one instillation may be suboptimal to 3 instillations in each maintenance cycle [346].

7.4.3.4.2 Optimal length of maintenance

In their meta-analysis, Böhle *et al.*, concluded that at least one year of maintenance BCG is required to obtain superiority of BCG over MMC for prevention of recurrence or progression [283].

In a RCT of 1,355 patients, the EORTC has shown that when BCG is given at full dose, 3 years' maintenance (3-weekly instillations 3, 6, 12, 18, 24, 30 and 36 months) reduces the recurrence rate compared to one year in high- but not in intermediate-risk patients. There were no differences in progression or OS. In the 3-year arm, however, 36.1% of patients did not complete the 3-year schedule [347]. The main reason why these patients stopped treatment was treatment inefficacy, not toxicity.

7.4.3.5 Optimal dose of BCG

To reduce BCG toxicity, instillation of a reduced dose was proposed. However, it has been suggested that a full dose of BCG is more effective in multifocal tumours [348, 349]. The CUETO study compared one-third dose to full-dose BCG and found no overall difference in efficacy. One-third of the standard dose of BCG might be the minimum effective dose for intermediate-risk tumours. A further reduction to one-sixth dose resulted in a decrease in efficacy with no decrease in toxicity [350]. The EORTC did not find any difference in toxicity between one-third and full-dose BCG, but one-third dose BCG was associated with a higher recurrence rate, especially when it was given only for one year [324, 347]. In a recent meta-analysis of 9 RCTs, patients who received less than half of the standard BCG dose experienced less adverse events as compared to patients receiving the full dose, but faced more unfavourable outcomes such as higher rates of disease recurrences [351].

7.4.3.6 BCG shortage

A statement by the Panel on BCG shortage can be accessed online:
https://uroweb.org/guidelines/non-muscle-invasive-bladder-cancer/publications-appendices.

7.4.3.7 Summary of evidence - BCG treatment

Summary of evidence	**LE**
In patients with intermediate- and high-risk tumours, intravesical BCG after TURB reduces the risk of tumour recurrence; it is more effective than TURB alone or TURB and intravesical chemotherapy.	1a
For optimal efficacy, BCG must be given in a maintenance schedule. A complete BCG schedule comprises an induction phase of 6-weekly instillations, followed by a maintenance phase of three-weekly instillations at 3, 6, 12, 18, 24, 30 and 36 months, respectively.	1a
Three-year maintenance is more effective than one year to prevent recurrence in patients with high-risk tumours, but not in patients with intermediate-risk tumours.	1a

*7.4.4 **Combination therapy***

7.4.4.1 Intravesical BCG plus chemotherapy versus BCG alone

In one RCT, a combination of MMC and BCG was shown to be more effective in reducing the risk of disease recurrence while increasing toxicity compared to BCG monotherapy. Using similar BCG schedules in both groups, each BCG instillation in the combination group was preceded a day before by an added MMC instillation [352]. In a RCT using MMC with EMDA, a combination of BCG and MMC with EMDA showed an improved recurrence-free interval and reduced progression rate compared to BCG monotherapy [306, 353]. Two meta-analyses demonstrated improved disease-free survival (DFS), but no benefit in PFS in patients treated with combination treatment comparing to BCG monotherapy [353, 354].

7.4.4.2 Combination treatment using interferon

In a Cochrane meta-analysis of 4 RCTs, a combination of BCG and IFN-2α did not show a clear difference in recurrence and progression over BCG alone [355]. In one study, weekly MMC followed by monthly BCG alternating with IFN-2α showed a higher probability of recurrence compared to MMC followed by BCG alone [356]. Additionally, a RCT in a similar population of NMIBC comparing BCG monotherapy with a combination of epirubicin and INF for up to two years showed the latter was significantly inferior to BCG monotherapy in preventing recurrence [357].

7.4.4.3 Sequential chemotherapy instillations

Preclinical data suggest that the efficacy of intravesical chemotherapy instillations can be improved by combinations compared to the administration of single agents only [358]. Sequential (immediate) instillations of gemcitabine and docetaxel was initially reported in 2015 in the wake of BCG-shortage but also at times of limited access to mitomycin [359]. Subsequently other sequential chemotherapy combinations such as valrubicin and docetaxel have been suggested [360]. Over time, additional retrospective data have accumulated where sequential gemcitabine and docetaxel instillations were used in patients recurring after induction BCG and BCG-unresponsive disease [361]; in patients with recurrence after BCG-induction but not fulfilling the criteria for BCG-unresponsive disease [362]; and also in BCG-naïve high-risk patients [363]. Thus, in patients with BCG-unresponsive disease when the treatment standard (radical cystectomy) is not feasible due to age and/or comorbidity or when patients are unwilling to accept radical surgery, sequential instillations with gemcitabine and docetaxel is an emerging treatment concept awaiting further prospective scientific evaluation.

*7.4.5 **Specific aspects of treatment of carcinoma in situ***

7.4.5.1 Treatment strategy

The detection of concurrent CIS increases the risk of recurrence and progression of TaT1 tumours [221, 223]. In this case further treatment according to the criteria summarised in Sections 7.4.2, 7.4.3 and 7.9 is mandatory. Carcinoma *in situ* cannot be cured by an endoscopic procedure alone. Histological diagnosis of CIS must be followed by further treatment, either intravesical BCG instillations or RC. Tumour-specific survival rates after immediate RC for CIS are excellent, but a large proportion of patients might be over-treated [232].

7.4.5.2 Cohort studies on intravesical BCG or chemotherapy

In retrospective evaluations of patients with CIS, a complete response rate of 48% was achieved with intravesical chemotherapy and 72–93% with BCG [232-235, 356]. Up to 50% of complete responders might eventually show recurrence with a risk of invasion and/or extravesical recurrence [235, 276, 344, 364].

7.4.5.3 Prospective randomised trials on intravesical BCG or chemotherapy

Unfortunately, there have been few RCTs in patients with CIS only. A meta-analysis of clinical trials comparing intravesical BCG to intravesical chemotherapy in patients with CIS has shown a significantly increased response rate after BCG and a reduction of 59% in the odds of treatment failure with BCG [365].

In an EORTC-GUCG meta-analysis of tumour progression, in a subgroup of 403 patients with CIS, BCG reduced the risk of progression by 35% as compared to intravesical chemotherapy or immunotherapy [284]. The combination of BCG and MMC was not superior to BCG alone [366]. In summary, compared to chemotherapy, BCG treatment of CIS increases the complete response rate, the overall percentage of patients who remain disease free, and reduces the risk of tumour progression.

7.4.5.4 Treatment of CIS in the prostatic urethra and upper urinary tract

Patients with CIS are at high risk of extravesical involvement in the UUT and in the prostatic urethra. Solsona *et al.*, found that 63% of 138 patients with CIS developed extravesical involvement initially or during follow-up [367]. Patients with extravesical involvement had worse survival than those with bladder CIS alone [367]. In the prostate, CIS might be present only in the epithelial lining of the prostatic urethra or in the prostatic ducts [368]. These situations should be distinguished from tumour invasion into the prostatic stroma (stage T4a in bladder

tumours) and for which immediate radical cystoprostatectomy is mandatory. Patients with CIS in the epithelial lining of the prostatic urethra can be treated by intravesical instillation of BCG. Transurethral resection of the prostate can improve contact of BCG with the prostatic urethra [137, 369]. However, potential spread of CIS has to be considered; no suprapubic trocar-placed catheter should be used.

In patients with prostatic duct involvement there are promising results of BCG, but only from small series. The data are insufficient to provide clear treatment recommendations and radical surgery should be considered [369, 370].

7.4.5.5 Summary of evidence - treatment of carcinoma in situ

Summary of evidence	**LE**
Carcinoma *in situ* cannot be cured by an endoscopic procedure alone.	4
Compared to intravesical chemotherapy, intravesical BCG maintenance instillations increase the complete response rate, the overall percentage of patients who remain disease free, and reduce the risk of tumour progression.	1b

7.5 Intravesical chemoablation and neoadjuvant treatment

Two different modalities of administering chemotherapy as first-line approach for a presumed NMIBC have been reported: neoadjuvant intravesical chemotherapy before TURB or chemoresection of the tumour as a replacement of TURB.

Neoadjuvant

Hypothesis-generating findings from an older RCT comparing immediate pre-operative device-assisted (EMDA) MMC with post-operative SI with MMC and TURB only, showed improved long-term RFS among patients treated prior to TURB [371], and thus even suggest a long-term effect after neoadjuvant instillations. While this has not been reproduced by other groups, two recent small neoadjuvant RCTs have reported conflicting results on the ability of neoadjuvant administration of MMC to improve outcomes over the standard approach [372, 373].

Chemoablation

Older marker lesion studies have shown that chemoablation with a single intravesical chemotherapy instillation can achieve a complete response in a proportion of patients [374]; therefore, making it possible to avoid TURB. In recurrent low-grade [375] and recurrent Ta tumours [376], 4 and 6 intravesical MMC instillations achieved complete response in 37% and 57% of the patients, respectively. In an update of the DaBlaCa-13 RCT evaluating chemoablation with 40 mg/40 mL of intravesical MMC three times a week for 2 weeks without preceding biopsy to standard TURB, the 12-month RFS was 36% in the chemoablation group vs. 43% in the TURB group, with no statistical significant difference [376]. Despite the lack of long-term outcomes, chemoablation appears to be a promising treatment option for well-selected NMIBC patients and can potentially help avoid unnecessary TURB, specifically in some elderly patients with intermediate-risk NMIBC [377].

7.6 Radical cystectomy for non-muscle-invasive bladder cancer

There are several reasons to consider immediate RC for selected patients with NMIBC::

- The staging accuracy for T1 tumours by TURB is low with 27–51% of patients being upstaged to muscle-invasive tumour at RC [180, 378-382].
- Some patients with NMIBC experience disease progression to muscle-invasive disease (Table 6.2).
- Patients who experience disease progression to muscle-invasive stage have a worse prognosis than those who present with 'primary' muscle-invasive disease [383, 384].

The potential benefit of RC must be weighed against its risks, morbidity, and impact on quality of life (QoL) and discussed with patients, in a shared decision-making process. It is reasonable to propose immediate RC in those patients with NMIBC who are at very high risk of disease progression (see Section 6.3 and Tables 6.1 and 6.2) [73, 177, 221, 223, 385].

Early RC is strongly recommended in patients with BCG-unresponsive tumours and should be considered in BCG relapsing HG tumours as mentioned in Section 7.9 and Table 7.3. A delay in RC may lead to decreased disease-specific survival [386].

In patients in whom RC is performed before progression to MIBC, the 5-year DFS rate exceeds 80% [387-389].

7.7 Primary treatment by disease type

The type of further therapy after TURB should be based on the risk groups shown in Section 6.3 and Table 6.1. The stratification and treatment recommendations are primarily based on the risk of disease progression (Table 6.2). In some instances, mainly in intermediate-risk tumours, the 2006 EORTC scoring model is useful (Section 6.1.1.1) to determine a patient's individual risk of disease recurrence as the basis to decide further treatment on.

- Treatment of low-risk disease
  Patients in the low-risk group have a negligible risk of disease progression. The single post-operative instillation of chemotherapy reduces the risk of recurrence and is considered as sufficient treatment in these patients.

- Treatment of intermediate-risk disease
  Patients in the intermediate-risk group have a relatively low risk of disease progression (7.4 and 8.5% after 10 years according to the 2021 EAU NMIBC scoring model). In these patients induction chemotherapy with or without maintenance for a maximum of one year is a reasonable first-line option in the majority of patients. One-year full-dose BCG treatment (induction plus 3-weekly instillations at 3, 6 and 12 months), is an alternative option. The final choice should reflect the individual patient's risk of recurrence and progression as well as the efficacy and side effects of each treatment modality.

- Treatment of high-risk disease
  Patients in the high-risk group have a high risk of disease progression (14% after 10 years according to the 2021 EAU NMIBC scoring model). In these patients full-dose intravesical BCG for one to 3 years (induction plus 3-weekly instillations at 3, 6, 12, 18, 24, 30 and 36 months), is indicated. The additional beneficial effect of the second and third years of maintenance should be weighed against its added costs, side effects and problems associated with BCG shortage. Because of the high risk of progression, immediate RC may also be discussed with the patient. Radical cystectomy is the safest approach from an oncological point of view, it is, however, associated with the risk of complications and QoL impairment and represents over-treatment in some patients.

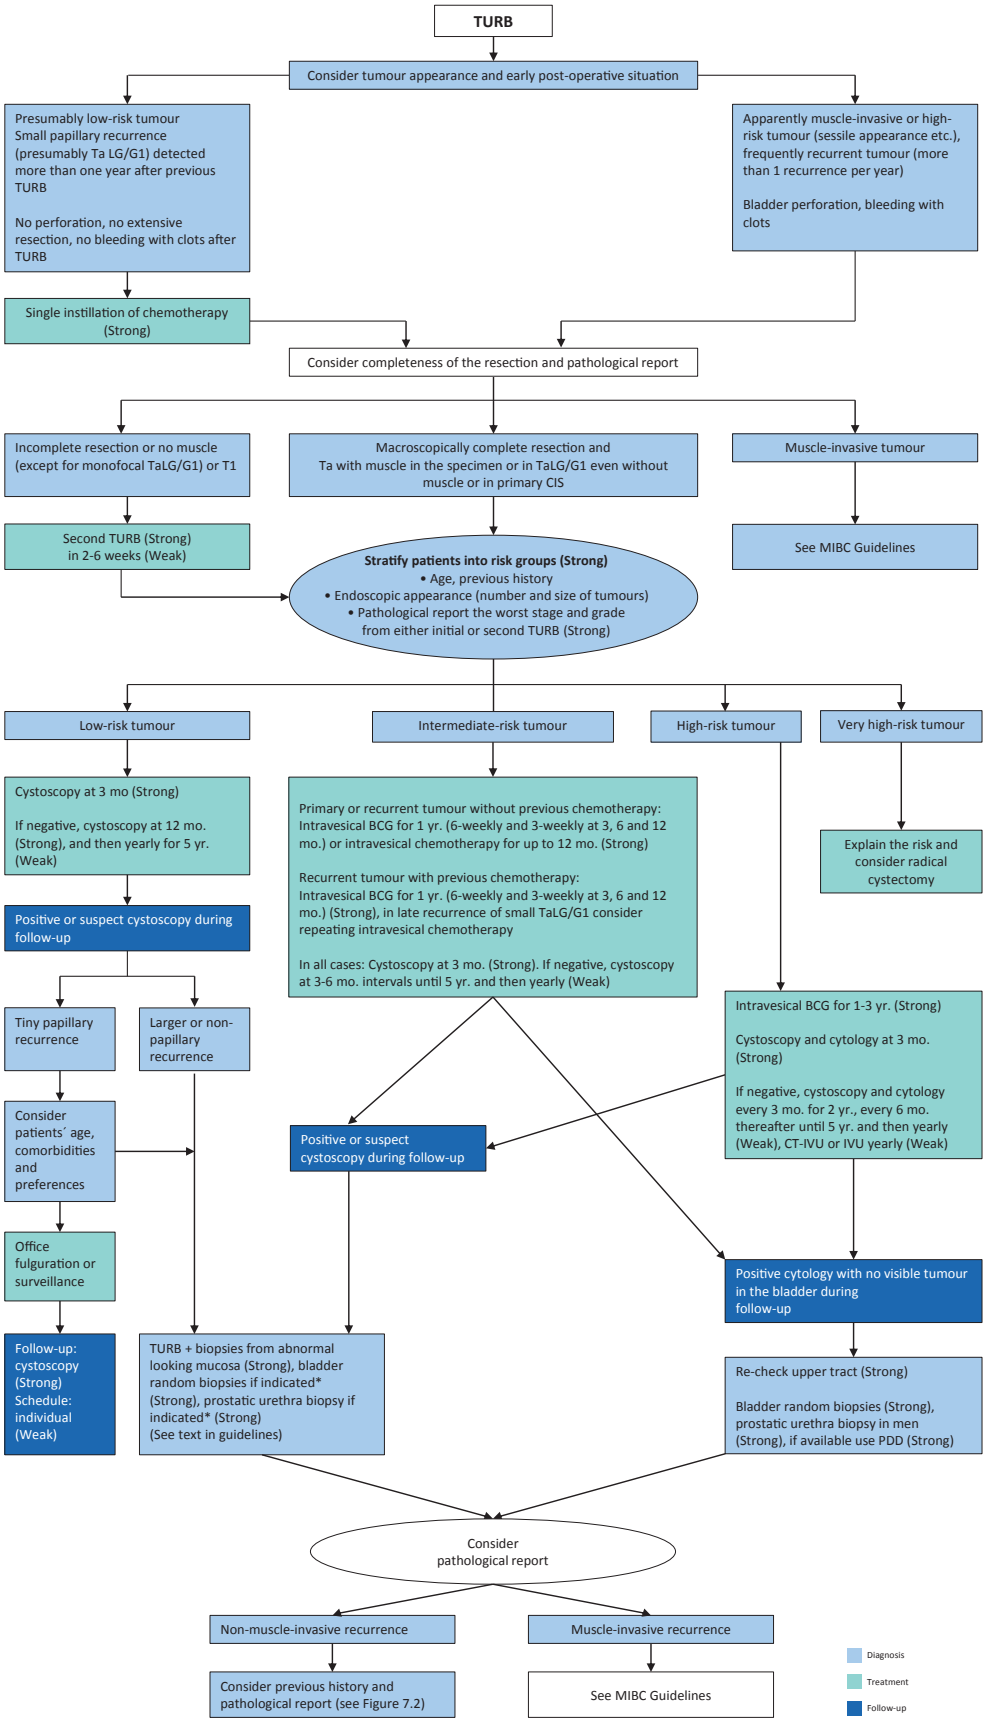
- Treatment of very high-risk disease
  Patients in the very high-risk group have an extremely high risk of tumour progression (53.1 and 58.6% after 10 years according to the 2021 EAU NMIBC scoring model). Immediate RC should be discussed with these patients. In case RC is not feasible or refused by the patient, full-dose intravesical BCG for one to 3 years should be offered.

- Treatment of carcinoma *in situ*
  Patients with carcinoma *in situ* cannot be managed by an endoscopic procedure alone and should be offered either intravesical BCG instillations or RC. BCG treatment of CIS increases the complete response rate, the overall percentage of patients who remain disease free, and reduces the risk of tumour progression. In comparison, immediate RC for CIS results in excellent tumour-specific survival rates although a large proportion of patients might be over-treated [232].

7.8 Multidisciplinary tumour board

A multidisciplinary tumour board (MDT) approach including reassessment of radiology and pathology is associated with a changed treatment plan in up to 44% of BC patients [390-393], such as refraining from or recommending cystectomy in 7% of stage T1 patients [391-393], often as a result of the pathologic review [68, 392]. Thus, patients with high-risk and very high-risk NMIBC will especially benefit from MDT discussion and such an approach is recommended for these patients. Figure 7.1 presents a treatment flow chart based on risk category, which may guide management of an individual patient.

Figure 7.1: Treatment strategy in primary or recurrent tumour(s) without previous BCG*



** For details and explanations see the text of the guidelines.*
BCG = bacillus Calmette-Guérin; CIS = carcinoma in situ; CT = computed tomography; IVU = intravenous urography; MIBC = muscle-invasive bladder cancer; PDD = photodynamic diagnosis; TURB = transurethral resection of the bladder.

7.9 Treatment of failure of intravesical therapy

7.9.1 Recurrence during or after intravesical chemotherapy

Patients with NMIBC recurrence during or after a chemotherapy regimen can benefit from BCG instillations. Prior intravesical chemotherapy has no impact on the effect of BCG instillations [285].

7.9.2 Treatment failure after intravesical BCG immunotherapy

Several categories of BCG failures, broadly defined as any HG disease occurring during or after BCG therapy, have been proposed (see Table 7.2). Non-muscle-invasive BC may not respond at all (BCG refractory) or may relapse after initial response (BCG relapsing). Some evidence suggests that patients with BCG relapse have better outcomes than BCG refractory patients [394].

To be able to specify the subgroup of patients where additional BCG is unlikely to provide benefit, the category of **BCG-unresponsive** tumour was defined. Further BCG instillations in these patients are associated with an increased risk of progression [236, 395]. The category of BCG-unresponsive tumours comprises BCG-refractory and some of BCG-relapsing tumours (see Table 7.2) [396]. The definition was developed in consultation with the U.S. Food and Drug Administration (FDA), in particular to promote single-arm trials to provide primary evidence of effectiveness in this setting [397]. Patients who experience recurrence with high-grade NMIBC after BCG without meeting BCG-unresponsive criteria may benefit from additional BCG therapy. This category of high risk patients that lies between BCG-naïve and BCG-unresponsive NMIBC is termed **BCG-exposed** [398, 399], and includes:

1. BCG-resistant: persistent or recurrent Ta HG and/or CIS disease at three months following at least five of six doses of induction BCG. According to the definition of adequate BCG (table 7.2), these patients have received inadequate BCG.
2. Delayed relapse after inadequate BCG: to indicate Ta/T1 HG or CIS patients found disease free at the three-months evaluation that recur in between 6 and 24 months without receiving more than an induction course.
3. Delayed relapse after adequate BCG: to indicate patients that are disease free after adequate BCG, but subsequently experience a high-grade recurrence outside of the BCG-unresponsive window (>6 mo for Ta/T1 and >12 mo for CIS), up to 24 months.

Non-HG recurrence after BCG is not considered as BCG failure.

Table 7.2: Categories of high-grade recurrence during or after BCG

Whenever a MIBC is detected during follow-up.
BCG-refractory tumour
1. If T1 HG/G3 tumour is present at 3 months [236, 395, 400]. 2. If Ta HG/G3 tumour is present after 3 months and/or at 6 months, after either re-induction or first course of maintenance [368]. 3. If CIS (without concomitant papillary tumour) is present at 3 months and persists at 6 months after either re-induction or first course of maintenance. If patients with CIS present at 3 months, an additional BCG course can achieve a complete response in > 50% of cases [65, 364, 368]. 4. If HG tumour appears during BCG maintenance therapy*.
BCG-relapsing tumour
Recurrence of HG/G3) tumour after completion of BCG maintenance, despite an initial response [401].
BCG-unresponsive tumour
BCG-unresponsive tumours include all BCG refractory tumours and those who develop T1/Ta HG recurrence within 6 months of completion of adequate BCG exposure** or develop CIS within 12 months of completion of adequate BCG exposure [396].
BCG-exposed tumour [398, 399]
1. If Ta HG/G3 or CIS is present at three months evaluation after induction BCG only 2. delayed relapse after adequate or inadequate BCG
BCG intolerance
Severe side effects that prevent further BCG instillation before completing treatment [337].

** Patients with LG recurrence during or after BCG treatment are not considered to be a BCG failure.*

*** Adequate BCG is defined as the completion of at least 5 of 6 doses of an initial induction course plus at least 2 out of 6 doses of a second induction course or 2 out of 3 doses of maintenance therapy.*

7.9.3 ***Treatment of BCG-unresponsive tumours, BCG-exposed tumours, BCG relapses and LG recurrences after BCG treatment***

Patients with BCG-unresponsive disease are unlikely to respond to further BCG therapy; RC is therefore the standard and preferred option. Currently, several bladder preservation strategies are being investigated such as cytotoxic intravesical therapies [402-405], device assisted instillations [406-408], intravesical immunotherapy [409, 410], combination therapies (mainly sequential chemotherapies see section 7.4.4.3), systemic immunotherapy [411] or gene therapy [412-414].

A phase III RCT including predominantly high-risk NMIBC patients failing at least a previous induction course of BCG, MMC combined with microwave-induced hyperthermia provided 35% overall DFS at 2 years as compared to 41% in the control arm (treated with either BCG, MMC or MMC and electromotive drug administration at the discretion of the investigator). In the pre-planned sub-analysis, MMC and microwave- induced thermotherapy showed lower response rates in CIS recurrences but higher DFS in non-CIS papillary tumours (53% vs. 24%) [408].

Promising data on BCG-unresponsive cohorts of patients with CIS alone or concomitant to papillary tumours were recently reported following new immunotherapies. Systemic pembrolizumab achieved a 40% complete response rate in a prospective phase II study which was maintained in 48% of patients for up to 12 months (n = 101), resulting in FDA approval of the study drug for this patient population [415]. Promising data from a phase III multicentre RCT with intravesical nadofaragene firadenovec showed a complete response in 53.4% of patients with BCG-unresponsive CIS which was maintained in 45% at one year in those who initially responded [416]. A secondary analysis indicates that a combination of post- treatment titres of serum anti–human adenovirus type-5 antibody and fold change from baseline can predict treatment efficacy [417]. Additional ongoing studies are addressing combination of intravesical or systemic immunotherapy [418, 419].

A systematic review and meta-analysis including 4 RCTs and 24 single-arm studies (all currently available prospective studies) assessed bladder-sparing treatments following BCG failure [420]. The significant heterogeneity of both trial designs and patient characteristics included in these studies, the different definitions of BCG failures used, and missing information on prior BCG courses may account for the variability in efficacy for the different compounds assessed across different trials. A higher number of previous BCG courses, BCG refractory/unresponsive or CIS predicted lower response rates. The pooled 12-month response rates were 24% for trials with > 2 prior BCG courses and 36% for those with > 1 BCG courses. Initial response rate did not predict durable responses highlighting the need for longer-term follow-up. More recently, a systematic review assessing 42 prospective trials on bladder-preserving treatments after BCG showed that patients with papillary-only recurrences appeared more effectively treated (median recurrence free rate of 44% at 1 year, median progression-free rate of 89% at a median follow-up of 19 months) than CIS-containing tumours (median complete response rate of 17% at 1 year with a median progression-free rate of 95% at a median follow-up of 12 months), highlighting potential biological differences between these two tumour entities which should be analysed separately when reporting results of clinical trials [421].

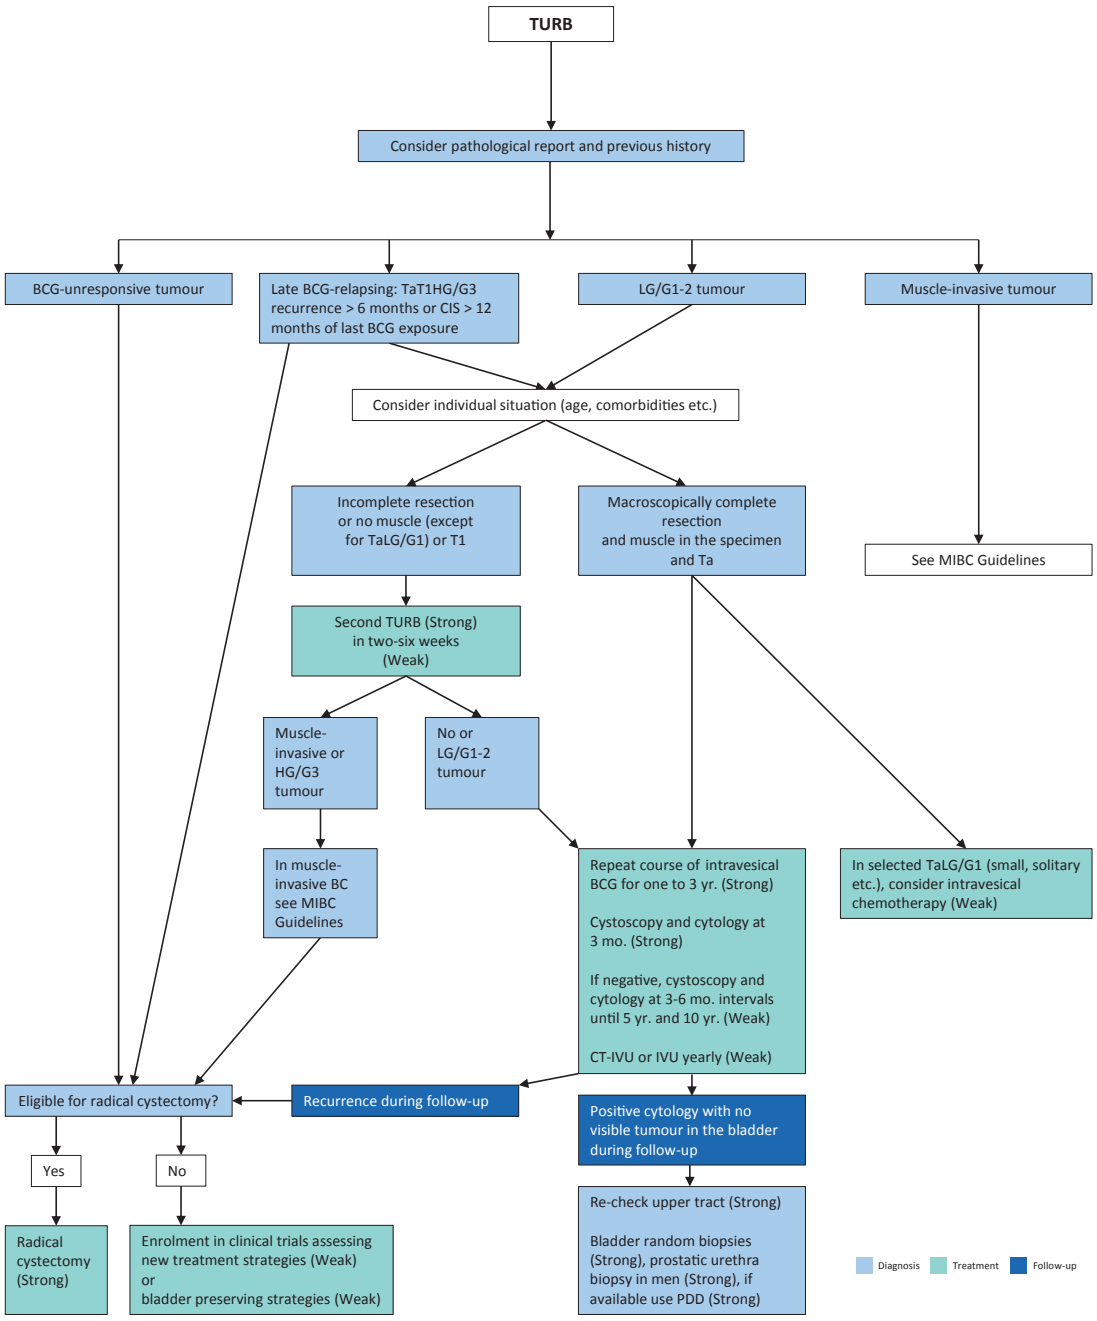
At the present time, treatments other than RC are considered oncologically inferior in patients with BCG-unresponsive disease [236, 395, 400]. Various studies suggest that repeat-BCG therapy is appropriate for non-HG and even for some HG recurrent tumours; namely those relapsing beyond one year after BCG exposure (cases which do not meet the criteria of BCG-unresponsive disease) [399, 422]. BCG exposed patients and late BCG relapses (beyond 24 months) are likely to benefit from further BCG [398, 399].

Treatment decisions in LG recurrences after BCG (which are not considered as any category of BCG failure) should be individualised according to tumour characteristics. Little is known about the optimal treatment in patients with high-risk tumours who could not complete BCG instillations because of intolerance.

7.9.4 ***Summary of evidence - treatment failure of intravesical therapy***

Summary of evidence	**LE**
Prior intravesical chemotherapy has no impact on the effect of BCG instillation.	1a
Treatments other than RC must be considered oncologically inferior in patients with BCG-unresponsive tumours.	3

Figure 7.2: Treatment strategy in recurrence during or after intravesical BCG



BCG = bacillus Calmette-Guérin; CIS = carcinoma in situ; HG = high-grade; IVU = intravenous urography; LG = low-grade; PDD = photodynamic diagnosis; TURB = transurethral resection of the bladder.

7.10 Guidelines for adjuvant therapy in TaT1 tumours and for therapy of carcinoma *in situ*

General recommendations	Strength rating
Counsel smokers to stop smoking.	Strong
The type of further therapy after transurethral resection of the bladder (TURB) should be based on the risk groups shown in Section 6.3 and Table 6.1. For determination of a patient's risk group use the 2021 EAU risk group calculator available at www.nmibc.net.	Strong
In patients with tumours presumed to be at low risk and in those with small papillary recurrences (presumably Ta LG/G1) detected more than one year after previous TURB, offer one immediate single chemotherapy instillation.	Strong
Offer post-operative saline or water continuous irrigation of the bladder to patients who cannot receive a single instillation of chemotherapy.	Strong
Patients with small recurrent low-grade Ta tumours can be effectively and safely offered office fulguration.	Strong
Only offer active surveillance to selected patients with presumed low-grade tumours not amendable to endoscopic ablation.	Weak
In patients with intermediate-risk tumours (with or without immediate instillation), offer instillations of chemotherapy (the optimal schedule is not known) or one-year full-dose Bacillus Calmette-Guérin (BCG) treatment (induction plus 3-weekly instillations at 3, 6 and 12 months). Chemotherapy is a reasonable first option in the majority of cases; however, the final choice should be made in a shared decision-making process with the patient, reflecting his/her risk of recurrence and progression, as well as the efficacy and side effects of each treatment modality.	Strong
Administer a full-dose intravesical bacillus Calmette-Guérin (BCG) for one to three years in patients with high-risk tumours (a complete BCG schedule comprises an induction phase of six-weekly instillations, followed by a maintenance phase of three-weekly instillations at 3, 6, 12, 18, 24, 30 and 36 months, respectively). The additional beneficial effect of the second and third years of maintenance should be weighed against its added costs, side effects and access to BCG. Immediate radical cystectomy (RC) may also be discussed with the patient.	Strong
Discuss immediate RC in patients with very high-risk tumours. Intravesical full-dose BCG instillations for one to three years remains an option for selected patients, particularly those who decline or are unfit for RC.	Strong
Offer transurethral resection of the prostate, followed by intravesical instillation of BCG to patients with CIS in the epithelial lining of the prostatic urethra if a bladder sparing strategy is considered.	Weak
Cautiously offer quinolones to treat BCG-related side effects*.	Weak
The definition of 'BCG-unresponsive' should be respected as it most precisely defines the patients who are unlikely to respond to further BCG instillations.	Strong
Offer a RC to patients with BCG-unresponsive tumours.	Strong
Offer patients with BCG-unresponsive tumours, who are not candidates for RC due to comorbidities, preservation strategies (intravesical chemotherapy, chemotherapy and microwave-induced hyperthermia, electromotive administration of chemotherapy, intravesical- or systemic immunotherapy; preferably within clinical trials).	Weak
Discuss high-risk and very high-risk patients within a multidisciplinary board, when possible.	Weak
Recommendations - technical aspects for treatment	
Intravesical chemotherapy	
If given, administer a single immediate instillation of chemotherapy within 24 hours after TURB.	Weak
Omit a single immediate instillation of chemotherapy in any case of overt or suspected bladder perforation or bleeding requiring bladder irrigation.	Strong

The optimal schedule and duration of further intravesical chemotherapy instillation is not defined; however, it should not exceed one year.	Weak
If intravesical chemotherapy is given, use the drug at its optimal pH and maintain the concentration of the drug by reducing fluid intake before and during instillation.	Strong
The length of individual instillation should be a minimum of one, and up to two hours.	Weak
BCG intravesical immunotherapy	
Absolute contraindications of BCG intravesical instillation are: • during the first two weeks after TURB; • in patients with visible haematuria; • after traumatic catheterisation; • in patients with symptomatic urinary tract infection.	Strong

**The side-effect profile of quinolones and fluoroquinolones resulted in the adoption of European regulation restricting their use [341].*

7.11 Guidelines for the treatment of TaT1 tumours and carcinoma *in situ* according to risk stratification

Recommendations	Strength rating
EAU risk group: Low	
Offer one immediate instillation of intravesical chemotherapy after transurethral resection of the bladder (TURB).	Strong
EAU Risk Group: Intermediate	
In general, chemotherapy (the optimal schedule is unknown) is a reasonable first-line option in the majority of patients. One-year full-dose BCG treatment (induction plus three-weekly instillations at 3, 6 and 12 months), is an alternative option. The final choice should reflect the individual patient's risk of recurrence and progression as well as the efficacy and side effects of each treatment modality. Offer one immediate chemotherapy instillation to patients with small papillary recurrences detected more than one year after previous TURB.	Strong
EAU risk group: High	
Offer intravesical full-dose BCG instillations for one to three years but discuss immediate radical cystectomy (RC).	Strong
EAU risk group: Very High	
Offer RC or intravesical full-dose BCG instillations for one to three years, particularly to those who decline or are unfit for RC.	Strong

Table 7.3: Treatment options for the various categories of BCG failure

Category	Treatment options
BCG-unresponsive	1. Radical cystectomy (RC). 2. Enrolment in clinical trials assessing new treatment strategies. 3. Bladder-preserving strategies in patients unsuitable or refusing RC.
Late BCG relapsing: TaT1 HG recurrence > 6 months or CIS > 12 months of last BCG exposure	1. Radical cystectomy or repeat BCG course according to a patient's individual situation. 2. Bladder-preserving strategies. 3. Enrolment in clinical trials assessing new treatment strategies.
LG recurrence after BCG for primary intermediate-risk tumour	1. Repeat BCG or intravesical chemotherapy. 2. Enrolment in clinical trials assessing new treatment strategies.

8. FOLLOW-UP OF PATIENTS WITH NMIBC

Due to the risk of recurrence and progression, patients with NMIBC need follow-up after treatment. The first cystoscopy after TURB at 3 months is an important prognostic indicator for recurrence and progression [230, 235, 250, 253, 423]. Therefore, the first cystoscopy should always be performed 3 months after TURB in all patients with TaT1 tumours and CIS. The subsequent frequency and duration of cystoscopy and imaging follow-up should reflect the individual patient's degree of risk. This can be defined by using the EAU NMIBC prognostic factor risk groups (section 6.3, Tables 6.1 and 6.2) or further prognostic models for specific patient populations (section 6) which predict, the short- and long- term risks of recurrence and progression in individual patients (section 8.1) [221, 223]. However, recommendations for follow-up are mainly based on retrospective data and there is a lack of RCTs investigating the possibility of safely reducing the frequency of follow-up cystoscopy.

8.1 Intravesical surveillance during follow-up

*8.1.1 **Follow-up of low-risk NMIBC***

Low-risk group is nearly always low stage and LG/G1. Small, Ta LG/G1 papillary recurrence does not present an immediate danger to the patient and early detection is not essential for successful therapy [252, 424]. In addition, recurrence after 5 recurrence-free years is low [253] (LE: 3). Therefore, in low-risk tumours, after 5 years of follow-up, discontinuation of cystoscopy or its replacement with less invasive methods should be considered [423].

*8.1.2 **Follow-up of intermediate-risk NMIBC***

Patients in the intermediate-risk group carry a risk of progression somewhere in between the low and high risk categories [227]; therefore, the intensity of any follow-up scheme could be adapted in line with this. Based on the safety of a reduced intensity follow-up scheme compared to high-risk NMIBC, in a small RCT on multiple and/or recurrent low grade tumours [425], low-grade intermediate-risk NMIBC can be safely followed-up with a cystoscopy at 3 months and, if negative, with 6 monthly cystoscopies for 2 years followed by yearly cystoscopies up to 10 years. This surveillance scheme for this disease category has already been adopted by the Scottish Access Collaborative Workstream [426]. Due to lack of data supporting the safety of a reduced scheme in the subgroup of high-grade intermediate-risk NMIBC the panel recommend this group be followed-up in the same way of high-risk NMIBC.

*8.1.3 **Follow-up of high- and very high-risk NMIBC***

In tumours originally, high risk, or very high risk treated conservatively the prompt detection of muscle-invasive and HG/G3 non-muscle-invasive recurrence is crucial and the percentage of tumours missed should be as low as possible because a delay in diagnosis and therapy can be life-threatening. Therefore, the best surveillance strategy for these patients will continue to include frequent cystoscopy and cytology. Recurrences after ten years tumour-free are not unusual [427]. Therefore, the optimal surveillance strategy for these patients includes initial frequent cystoscopy and cytology and life-long follow-up [423].

*8.1.4 **Follow-up of extravesical sites urothelium***

The follow-up strategy must reflect the risk of extravesical recurrence (prostatic urethra in men and UUT in both genders). This risk becomes significant for both sites in high-risk tumours [94], with 10 year tumour rates in UUT varing between 2.8% in CIS [428] and 25% in patients with multiple and recurrent high risk NMIBC [429]. Urine cytology, cystoscopy and CT urography are key investigations for early detection of extravesical recurrence.

*8.1.5 **Aids for tumour detection during follow-up***

8.1.5.1 Enhanced visualisation

There may be a role for newer methods of tumour visualisation in follow-up cystoscopy. In two prospective studies of blue light flexible cystoscopy (BLFC) for surveillance of NMIBC, BLFC allowed identification of 4 to 5.7% of recurrences that would have been missed in case of WL cystoscopy alone [430, 431]. On the other hand, a prospective study of NBI for NMIBC surveillance failed to show any benefit for NBI over WL cystoscopy alone [432].

8.1.5.2 Ultrasound

In patients initially diagnosed with Ta LG/G1–2 BC, US of the bladder and/or a urinary marker may be a mode of surveillance in case cystoscopy is not possible or refused by the patient [133, 433, 434].

8.1.5.3 Urinary molecular markers and urine cytology

Non-invasive follow-up strategies include urine cytology and urinary molecular marker tests as adjunct (or companion) tests to improve detection at the time of flexible cystoscopy or as replacement tests to reduce the number of flexible cystoscopies. Research has been carried out into the usefulness of urinary cytology vs. urinary molecular markers in the follow-up of NMIBC [112, 115, 120, 130, 433, 435]. In order to reduce or replace cystoscopy altogether, urinary markers should be able to detect recurrence in all risk groups. However, the reported low sensitivity for LG recurrences limits their utility in this group [130, 436] although more recent studies have shown reasonable sensitivity in low grade recurrences sensitivity of 40–65% [118, 437]. According to current knowledge, no urinary marker can replace cystoscopy during follow-up or lower cystoscopy frequency in a routine fashion. Nonetheless, some urinary markers have shown fairly high sensitivities to detect tumour recurrence, particularly in HG disease, along with very high NPVs to make the premises for their future implementation in follow-up [117, 437-439] (Table 8.1).

Table 8.1: Urinary markers in the surveillance setting*

Marker	Sensitivity overall	HG	Specificity overall	HG	PPV overall	HG	NPV overall	HG	N studies/ patients
XPERT BC® MONITOR	0.72	0.88	0.76	0.75	0.43	0.18	0.92	0.99	10/> 2000
EpiCheck™	0.74	0.91	0.84	0.81	0.48	0.43	0.94	0.98	5/1600
ADX Bladder™	0.57	0.71	0.62	0.76	0.29	0.37	0.82	0.93	3/1600
CX BLADDER	0.91	-	0.61	-	0.16	-	0.98	-	2/1000
FDFGR3+TERT	0.93	-	0.79	-	0.67	-	0.96	-	2/250

**Data extracted from a pooled analyses of systematic review [435].*
HG = high grade; NMIBC = non-muscle-invasive bladder cancer; PPV = positive predictive value; NPV = negative predictive value; n = number.

Table 8.2: Proposed follow-up schedule based on patient's risk category

Risk group	Cytology*	Cystoscopy	Imaging	Duration of follow-up
Low	No	At 3 and 12 months Then annually	Not systematic	5 years
Intermediate (not including HG/G3 subgroup)*	No	At 3 months Then every 6 months for 2 years Then annually	Not systematic	10 years
High and Very High	Yes**	Every 3 months for 2 years Then every 6 months up to 5 years Then annually	CT annually up to 5 years Then CT every 2 years up to 10 years	Life long

**Intermediate-risk HG/G3 subgroup should be followed-up as high-risk*
*** At the same intervals as cystoscopy*

8.2 Summary of evidence and recommendations for follow-up of patients after transurethral resection of the bladder for non-muscle-invasive bladder cancer

Summary of evidence	LE
The first cystoscopy after transurethral resection of the bladder at 3 months is an important prognostic indicator for recurrence and progression.	1a
The risk of upper urinary tract recurrence increases in patients with multiple- and high-risk tumours.	3

Recommendations	Strength rating
Base follow-up of TaT1 tumours and carcinoma *in situ* (CIS) on regular cystoscopy.	Strong
Patients with low-risk Ta tumours should undergo cystoscopy at three months. If negative, subsequent cystoscopy is advised nine months later, and then yearly for five years.	Weak
Patients with high-risk and those with very high-risk tumours treated conservatively should undergo cystoscopy and urinary cytology at three months. If negative, subsequent cystoscopy and cytology should be repeated every three months for a period of two years, and every six months thereafter until five years, and then annually lifelong.	Weak
Perform cystoscopy at three months for patients with intermediate-risk Ta low-grade tumours. If negative, subsequent cystoscopy can be repeated every six months for two years, and then annually for ten years. The subgroup of intermediate-risk that are high grade should be followed up as high-risk.	Weak
Take regular and long-term upper tract imaging (computed tomography urography) for high-risk and very high-risk tumours.	Weak
Perform endoscopy under anaesthesia and bladder biopsies when office cystoscopy shows suspicious findings or if urinary cytology is positive.	Strong
During follow-up in patients with positive cytology and no visible tumour in the bladder, mapping biopsies or PDD-guided biopsies (if equipment is available) and investigation of extravesical locations (CT urography, prostatic urethra biopsy) are recommended.	Strong

9. PATIENT REPORTED OUTCOME MEASURES AND QUALITY INDICATORS FOR NMIBC

9.1 PROMS and PREMS in NMIBC

As NMIBC is associated with a significant number of hospital visits and interventions (TURBT, re-TURBT, surveillance cystoscopy, intravesical instillations) survivorship has a significant effect on patient QoL [440, 441]. Several Patient Reported Outcome Measures (PROMs) and Patient Reported Experience Measures (PREMs) have been developed to gauge the impact of treatment and surveillance on patients with a view to improving quality of care; however, due to lack of standardisation and heterogeneity none of them can currently be recommended for use in clinical practice [442]. Regardless, in order to provide the best possible care, clinicians should always be cognisant of the impact of disease and treatment (including surveillance) on their patients' QoL. The use of PROMs is an important endpoint for quality metrics and RCTs should systematically incorporate PROs for patient-centred research design.

9.2 Quality Indicators (QI) in Bladder Cancer

Evidence based Quality Indicators (QIs) and Quality Performance Indicators (QPIs) are designed to be surrogates of good practice and consequently, outcomes. They allow for the gap between efficacy and effectiveness to be narrowed, i.e. being able to bring research evidence and guideline recommendations into real world practice by improving compliance to them [443]. They also permit objective monitoring of the quality of care and thus facilitate quality control as well as service and process improvements.

Several QIs for bladder cancer have been suggested [444-447]. The table below represents the general and NMIBC related QIs adapted from Leow *et al.*, [446] and the Scottish Quality Performance Indicator (QPI) programme [447]. Quality indicators and QPIs should be SMART (Specific, Measurable, Achievable, Relevant, Trainable) [443]. Scotland introduced such a programme for Bladder Cancer in 2014 [447], and have been an exemplar by being able to demonstrate high levels of compliance to QPIs while reducing practice variation across country whilst also demonstrating the clinical value of such a programme [161], including development of prognostic models [426].

Successful implementation of a QI programme has the potential to inspire and catalyse clinical excellence in contemporary Bladder Cancer practice [443].

Table 9.1: Quality Indicators for general aspects of bladder cancer and NMIBC care adapted from [446, 447].

General aspects of bladder cancer care	Recommended Quality Indicators
Appropriate imaging for patients newly diagnosed with bladder cancer	Newly diagnosed bladder cancer patients who have cross-sectional imaging of upper urinary tract (eg, CT, MRI, or US) - as recommended in section 5.4
Participation in clinical trials	Availability of clinical trials to bladder cancer patients who are treated at a particular health care facility.
Aspects of NMIBC care	**Recommended Quality Indicators**
Pre-operative:	
Counselling	At the time of diagnosis, patients should be counselled to discontinue tobacco smoking.
Intra-operative:	
Tumour/patient history	Use of an Intra-operative checklist (as recommended in Table 5.1)
Conduct of TURBT	Patients with muscle present in specimen from initial TURBT (excluding TaLG disease).
	Use of a Bladder Diagram (as per Figure 5.1)
Re-staging TURBT	Restaging TURBT should be performed within 2–6 wk of the initial TURBT and include resection of the primary tumour site as per recommendations in section 5.13.
Post-operative:	
Risk stratification and surveillance counselling for patients with NMIBC	Use the EAU 2021 Risk Stratification for progression and the 2006 EORTC scoring model for recurrence to counsel patients with NMIBC on treatment and surveillance.
Intravesical therapy	Patients who received immediate post-TURBT instillation of intravesical chemotherapy, excluding those with contraindications (eg, incomplete resection, suspected perforation, significant haematuria).
	Intermediate- and high-risk NMIBC patients who were counselled and subsequently initiated adjuvant intravesical chemotherapy or BCG, respectively.
Multidisciplinary Team management	Patients with high risk and very high risk NMIBC should be discussed in a multi-disciplinary meeting to ensure comprehensive review and options.
Appropriate frequency of surveillance based on stage/grade of bladder cancer	Appropriate intervals between cystoscopic surveillance as per Table 8.2.
	Appropriate assessment of the upper urinary tract in high-risk patients.

11. CONFLICT OF INTEREST

All members of the Non-Muscle-Invasive Bladder Cancer guidelines working group have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is open access available on the European Association of Urology website: https://uroweb.org/guidelines/non-muscle-invasive-bladder-cancer/panel.

This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

12. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Paris 2024. ISBN 978-94-92671-23-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, The Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/.

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

Guidelines Office: E-J. Smith, H. Ali

European Association of Urology

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aims and scope

This overview represents the updated European Association of Urology (EAU) Guidelines for Muscle-invasive and Metastatic Bladder Cancer (MIBC). The aim is to provide practical recommendations on the clinical management of MIBC with a focus on clinical presentation. Separate EAU guidelines are available addressing upper urinary tract (UUT) tumours [1], non-muscle-invasive bladder cancer (TaT1 and carcinoma *in situ*) (NMIBC) [2], and primary urethral carcinomas [3].

It must be emphasised that clinical guidelines present the best evidence available to the experts, but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and references/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Guidelines Panel consists of an international multidisciplinary group of clinicians, including urologists, oncologists, a pathologist, a radiologist, radiotherapists and patient representatives. Section 5.3 - MIBC and health status, was developed with the assistance of Prof.Dr. S. O'Hanlon, consultant geriatrician, International Society of Geriatric Oncology (SIOG) representative. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website Uroweb: https://uroweb.org/guidelines/muscle-invasive-and-metastatic-bladder-cancer/panel.

1.3 Available publications

A quick reference document (Pocket Guidelines) is available. This is an abridged version which may require consultation together with the full text version. Several scientific publications are available, the latest dating to 2023 [4]. All documents are accessible through the EAU website: http://uroweb.org/guideline/bladder-cancer-muscle-invasive-and-metastatic/.

1.4 Publication history and summary of changes

*1.4.1 **Publication history***

The EAU Guidelines on Muscle Invasive Bladder Cancer were first published in 2004. Standard procedure for EAU Guidelines includes an annual assessment of newly published literature in the field to guide future updates This 2024 MIBC Guidelines present a limited update of the 2023 publication.

*1.4.2 **Summary of changes***

For the 2024 MIBC Guidelines new and relevant evidence was identified, collated and appraised through a structured assessment of the literature for all sections of the Guidelines. Key changes include:

- new updates to the guidelines and evidence in section 5.2 on the magnetic resonance imaging for local staging of MIBC;
- new text and evidence updates in section 7.2.3 on local therapy (surgery or radiotherpy) in oligometastatic disease;
- new text and evidence updates in section 7.3.4.2 on therapeutic value of lymphadenectomy, and section 7.3.5 on robotic-assisted laparoscopic cystectomy;
- new text updates in section 7.5.2 on external beam radiotherapy;
- new text and evidence updates in section 7.5.4 on trimodality bladder-preserving treatment;
- new text, evidence and guidelines updates in section 7.7 on the management of metastatic disease.

2. METHODS

2.1 Data identification

For the 2024 MIBC Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the MIBC Guideline was performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between the 1st of May 2022 and 1st May 2023. A total of 1,076 unique records were

identified, retrieved and screened for relevance. A detailed search strategy is available online: https://uroweb.org/guideline/bladder-cancer-muscle-invasive-and-metastatic/?type=appendices-publications.

Recommendations within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [5];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact and certainty of patient values and preferences on the intervention.

Strong recommendations typically indicate a high degree of evidence quality and/or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [6].

Additional methodology information and a list of associations endorsing the EAU Guidelines can be found in the online: https://uroweb.org/eau-guidelines/methodology-policies.

2.2 Peer-review

The panel intends to submit the 2025 MIBC guidelines for peer review before publication.

2.3 Future goals

Topics considered for inclusion in the 2024 update of the MIBC Guidelines:

- Development of an evidence-based strategy for functional- and oncological follow-up of patients treated for MIBC;
- Participation in developing strategies to ensure meaningful participation of patients in the development and implementation of the MIBC Guidelines.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Bladder cancer is the 7th most commonly diagnosed cancer in males, whilst it drops to 10th position when both genders are considered [7]. The worldwide age-standardised incidence rate (per 100,000 person/years) is 9.5 for men and 2.4 for women [7]. In the European Union, the age-standardised incidence rate is 20 for men and 4.6 for women [7]. In Europe, the highest age-standardised incidence rate has been reported in Belgium (31 in men and 6.2 in women) and the lowest in Finland (18.1 in men and 4.3 in women) [7].

Worldwide, the BC age-standardised mortality rate (per 100,000 person/years) was 3.3 for men vs. 0.86 for women in 2012 [7]. Bladder cancer incidence and mortality rates vary across countries due to differences in risk factors, detection and diagnostic practices, and availability of treatments. The variations are, however, also partly caused by the different methodologies used in the studies and the quality of data collection [8, 9]. The incidence and mortality of BC has decreased in some registries, possibly reflecting the decreased impact of causative agents [10, 11].

Approximately 75% of patients with BC present with disease confined to the mucosa (stage Ta, carcinoma *in situ* [CIS]) or submucosa (stage T1). In younger patients (< 40 years) this percentage is even higher [12]. Patients with TaT1 and CIS have a high prevalence due to long-term survival in many cases and lower risk of cancer-specific mortality (CSM) compared to T2-4 tumours [7, 8].

3.2 Aetiology

3.2.1 Tobacco smoking

Tobacco smoking is the most well-established risk factor for BC, causing 50–65% of male cases and 20–30% of female cases [13, 14]. A causal relationship has been established between exposure to tobacco and cancer in studies in which chance, bias and confounding can be discounted with reasonable confidence [15].

The incidence of BC is directly related to the duration of smoking and the number of cigarettes smoked per day [16]. A meta-analysis looked at 216 observational studies on cigarette smoking and cancer published between 1961 and 2003, and the pooled risk estimates for BC demonstrated a significant association for both current and former smokers [17]. Recently, an increase in risk estimates for current smokers relative to never smokers has been described suggesting this could be due to changes in cigarette composition [13]. Starting to smoke at a younger age increased the risk of death from BC [18]. An immediate decrease in the risk of BC was observed in those who stopped smoking. The reduction was about 40% within one to four years of quitting smoking and 60% after 25 years of cessation [16]. A meta-analysis of nine studies, not distinguishing between MIBC and NMIBC, suggested that smokers who decide to quit during the diagnostic work-up or upon bladder cancer diagnosis do not have a better prognosis than those who continue to smoke [19]. Nethertheless, encouraging people to stop smoking would result in the incidence of BC decreasing equally in men and women [13].

3.2.2 Occupational exposure to chemicals

Occupational exposure is the second-most important risk factor for BC. Work-related cases accounted for 20–25% of all BC cases in several series and it is likely to occur in occupations in which dyes (with the exception of hair dyes [20]), rubbers, textiles, paints, leathers, and chemicals are used [21, 22]. The risk of BC due to occupational exposure to carcinogenic aromatic amines is significantly greater after ten years or more of exposure; the mean latency period usually exceeds 30 years [23, 24]. Population-based studies established the occupational attribution for BC in men to be 7.1%, while no such attribution was discernible for women [8, 25].

3.2.3 Radiotherapy

Increased rates of secondary bladder malignancies have been reported after external-beam radiotherapy (EBRT) for gynaecological malignancies, with relative risks (RR) of 2–4 [22]. In a population-based cohort study, the standardised incidence ratios for BC developing after radical prostatectomy (RP), EBRT, brachytherapy, and EBRT-brachytherapy were 0.99, 1.42, 1.10, and 1.39, respectively, in comparison with the general U.S. population [26].

It has recently been proposed that patients who have received radiotherapy (RT) for prostate cancer with modern modalities such as intensity-modulated RT (IMRT) may have lower rates of in-field bladder- and rectal secondary malignancies [27]. Nevertheless, since longer follow-up data are not yet available, and as BC requires a long period to develop, patients treated with radiation and with a long life expectancy are at a higher risk of developing BC [27].

3.2.4 Dietary factors

Several dietary factors have been related to BC; however, the links remain controversial. The European Prospective Investigation into Cancer and Nutrition (EPIC) study is an on-going multicentre cohort study designed to examine the association between diet, lifestyle, environmental factors and cancer. They found no links between BC and fluid intake, red meat, vegetable and fruit consumption and only recently an inverse association between dietary intake of flavonoids and lignans and the risk of aggressive BC tumours has been described [28].

3.2.5 Metabolic disorders

In a large prospective study pooling six cohorts from Norway, Sweden, and Austria (The Metabolic syndrome and Cancer project, Me-Can 2.0), metabolic aberrations, especially elevated blood pressure and triglycerides, were associated with increased risks of BC among men, whereas high body mass index (BMI) was associated with decreased BC risk. The associations between BMI, blood pressure and BC risk significantly differed between men and women [29].

The association of diabetes mellitus (DM) with the risk of BC has been evaluated in numerous meta-analyses with inconsistent results. When analysing specific subpopulations, DM was associated with BC or CSM risk especially in men [30]. Thiazolidinediones (pioglitazone and rosiglitazone) are oral hypoglycaemic drugs used for the management of type 2 DM. Their use and the association with BC is still a matter of debate. In a recent meta-analysis of observational studies the summary results indicated that pioglitazone use was significantly associated with an increased risk of BC which appears to be linked to higher dose and longer duration of treatment [31]. The U.S. Food and Drug Administration (FDA) recommend that healthcare professionals should not prescribe pioglitazone in patients with active BC [32]. Several countries in Europe have removed this agent

from the market or included warnings for prescription. Moreover, the benefits of glycaemic control vs. unknown risks for cancer recurrence with pioglitazone should be considered in patients with a prior history of BC.

*3.2.6 **Bladder schistosomiasis and chronic urinary tract infection***

Bladder schistosomiasis (bilharzia) is the second most common parasitic infection after malaria, with about 600 million people exposed to infection in Africa, Asia, South America, and the Caribbean [33]. There is a well-established relationship between schistosomiasis and urothelial carcinoma (UC) of the bladder, which can progress to squamous cell carcinoma (SCC), however, better control of the disease is decreasing the incidence of SCC of the bladder in endemic zones such as Egypt [34, 35].

Similarly, invasive SCC has been linked to the presence of chronic urinary tract infection (UTI) distinct from schistosomiasis. A direct association between BC and UTIs has been observed in several case- control studies, which have reported a two-fold increased risk of BC in patients with recurrent UTIs in some series [36]. However, a recent meta-analysis found no statistical association when pooling data from the most recent and highest quality studies which highlights the need for better quality data to be able to draw conclusions [37].

Similarly, urinary calculi and chronic irritation or inflammation of the urothelium have been described as possible risk factors for BC. A meta-analysis of case-control and cohort studies suggests a positive association between history of urinary calculi and BC [38].

*3.2.7 **Gender***

Although men are more likely to develop BC than women, women present with more advanced disease and have worse survival rates. A meta-analysis including nearly 28,000 patients shows that female gender was associated with a worse survival outcome (hazard ratio [HR]: 1.20, 95% CI: 1.09–1.32) compared to male gender after radical cystectomy (RC) [39]. This finding had already been presented in a descriptive nationwide analysis based on 27,773 Austrian patients. After their analysis the authors found that cancer-specific survival (CSS) was identical for pT1-tumours in both sexes, while women had a worse CSS in both age cohorts (< 70 years and ≥ 70 years) with higher tumour stages [40]. However, treatment patterns are unlikely to explain the differences in overall survival (OS) [41]. In a population-based study from the Ontario Cancer Registry analysing all patients with BC treated with cystectomy or radical RT between 1994 and 2008, no differences in OS, mortality and outcomes were found between males and females following radical therapy [42]. The gender-specific difference in survival for patients with BC was also analysed in the Norwegian population. Survival was inferior for female patients but only within the first two years after diagnosis. This discrepancy was partly attributed to a more severe T-stage in female patients at initial diagnoses [43].

A population-based study from the MarketScan Databases suggests that a possible reason for worse survival in the female population may be that women experienced longer delays in diagnosis than men, as the differential diagnosis in women includes diseases that are more prevalent than BC [44]. Furthermore, differences in the gender prevalence of BC may be due to other factors besides tobacco and chemical exposure. In a large prospective cohort study, post-menopausal status was associated with an increase in BC risk, even after adjustment for smoking status. This finding suggests that the differences in oestrogen and androgen levels between men and women may be responsible for some of the difference in the gender prevalence of BC [45-47]. Moreover, a recent population study assessing impact of hormones on BC suggests that younger age at menopause (≤ 45 years) is associated with an increased risk of BC [48].

*3.2.8 **Genetic factors***

There is growing evidence that genetic susceptibility factors and family association may influence the incidence of BC. A recent population-based study of cancer risk in relatives and spouses of UC patients showed an increased risk for first- and second-degree relatives, and suggests genetic or environmental roots independent of smoking-related behaviour [49]. Shared environmental exposure was recognised as a potentially confounding factor [50]. Recent studies detected genetic susceptibility with independent loci, which are associated with BC risk [51].

Genome-wide association studies (GWAS) of BC identified several susceptibility loci associated with BC risk [52, 53].

3.2.9 *Summary of evidence and guidelines for epidemiology and risk factors*

Summary of evidence	LE
Worldwide, bladder cancer is the 10th most commonly diagnosed cancer.	2a
Several risk factors associated with BC diagnosis have been identified.	3
Active and passive tobacco smoking continues to be the main risk factor, while exposure-related incidence is decreasing.	2a
The increased risk of developing BC in patients undergoing EBRT, brachytherapy, or a combination of EBRT and brachytherapy, must be considered during patient follow-up. As BC requires time to develop, patients treated with radiation at a young age are at the greatest risk and should be followed-up closely.	3

Recommendations	Strength rating
Counsel patients to stop active and avoid passive smoking.	Strong
Inform workers in potentially hazardous workplaces of the potential carcinogenic effects of a number of recognised substances, including duration of exposure and latency periods. Protective measures are recommended.	Strong
Do not prescribe pioglitazone to patients with active bladder cancer or a history of bladder cancer.	Strong

3.3 Pathology

3.3.1 *Handling of transurethral resection and cystectomy specimens*

During transurethral resection (TUR), a specimen from the tumour and normal looking bladder wall should be taken, if possible. Specimens should be taken from the superficial and deep areas of the tumour and sent to the pathology laboratory separately, in case the outcome will impact on treatment decisions. If random biopsies of the flat mucosa are taken, each biopsy specimen of the flat mucosa should be submitted separately [54]. The sampling sites must be recorded by the urologist; the pathologist report should include location of tumour tissue in the cystectomy specimen. Anatomical tumour location is relevant for staging and prognosis [55, 56].

In RC, bladder fixation must be carried out as soon as possible. The pathologist must open the specimen from the urethra to the bladder dome and fix the specimen. In a female cystectomy specimen, the length of the urethral segment removed *en bloc* with the specimen should be checked, preferably by the urological surgeon [57].

Specimen handling should follow the general rules as published by a collaborative group of pathologists and urologists [58, 59]. It must be stressed that it may be very difficult to confirm the presence of a neoplastic lesion using gross examination of the cystectomy specimen after TUR or chemotherapy, so the entire retracted or ulcerated area should be inked and included before fixation.

It is compulsory to study the urethra, the ureters, the prostate in men and the radial margins [60]. In urethra-sparing cystectomy; the level of urethral dissection, completeness of the prostate, specifically at the apex (in men), and the inclusion of the entire bladder neck and amount of adjacent urethra, uterus and vaginal vault (in women) have to be documented by the pathologist.

All lymph node (LN) specimens should be provided in their totality, in clearly labelled containers to allow for pTNM staging. In case of doubt or adipose differentiation of the LNs, the entire specimen is to be included. Lymph nodes should be counted and measured on slides; capsular extension and percentage of LN invasion should be reported as well as vascular embols [61, 62]. In case of metastatic spread in the perivesical fat without real LN structures (capsule, subcapsular sinus), this localisation should nevertheless be considered as N+. Potentially positive soft tissue margins should be inked by the pathologist for evaluation [63]. In rare cases, fresh frozen sections may be helpful to determine treatment strategy [64].

3.3.2 *Pathology of muscle-invasive bladder cancer*

All MIBC cases are high-grade UCs. For this reason, no prognostic information can be provided by grading MIBC [65]. Identification of morphological subtypes is important for prognostic reasons and treatment decisions [66-68].

The data presented in these guidelines are based on the 2004/2016 World Health Organization (WHO) classifications [69, 70]. An update was presented in 2022 [71].

Currently the following subtypes of UC are used [71, 72]:

1. urothelial carcinoma (more than 90% of cases);
2. urothelial carcinomas with partial squamous and/or glandular or divergent differentiation;
3. micropapillary UC;
4. nested/microcystic;
5. large nested;
6. microtubular UC;
7. plasmacytoid, signet ring;
8. lymphoepithelioma-like;
9. giant cell, diffuse, undifferentiated;
10. sarcomatoid UC;
11. some UCs with other rare differentiations;
12. urothelial carcinomas with partial NE (neuroendocrine differentiation, % to be given);
13. pure neuroendocrine carcinoma (including small and large cell neuroendocrine carcinomas [Chapter NE carcinomas in the genitourinary tract]).

In the new WHO 2022 all subtypes are considered HG [71]. The percentage of subtype in the specimen must be reported since it has been shown to be of prognostic value [73]. The majority of subtypes are MIBC, with no more than 15–30% being non-muscle invasive [73-80] (LE: 3).

3.3.3 Guidelines for the assessment of tumour specimens

Recommendations	Strength rating
Record the depth of invasion for the entire specimen (categories pT2a and pT2b, pT3a and pT3b or pT4a and pT4b).	Strong
Record margins with special attention paid to the radial margin, prostate, ureter, urethra, peritoneal fat, uterus and vaginal vault.	
Record the total number of lymph nodes (LNs), the number of positive LNs and extranodal spread.	
Record lymphovascular invasion.	
Record the presence of carcinoma *in situ*.	
Record the sampling sites as well as information on tumour size when providing specimens to the pathologist.	

*3.3.4 EAU-ESMO consensus statements on the management of advanced- and variant bladder cancer [81, 82]**

Consensus statement
Bladder UC with small cell neuroendocrine variant should be treated with neoadjuvant chemotherapy followed by consolidating local therapy.
Muscle-invasive pure SCC of the bladder should be treated with primary radical cystectomy and lymphadenectomy.
Muscle-invasive pure adenocarcinoma of the bladder should be treated with primary radical cystectomy and lymphadenectomy.
Muscle-invasive small cell neuroendocrine variant of bladder UC should not receive preventive brain irradiation to avoid brain recurrence.
Differentiating between urachal and non-urachal subtypes of adenocarcinoma is essential when making treatment decisions.
T1 high-grade bladder urothelial cancer with micropapillary histology (established after complete TURBT and/or re-TURBT) should be treated with immediate radical cystectomy and lymphadenectomy.

**Only statements which met the a priori consensus threshold across all three stakeholder groups are listed (defined as ≥ 70% agreement and ≤ 15% disagreement, or vice versa).*

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Pathological staging

For staging, the Tumour, Node, Metastasis (TNM) Classification (2017, 8th edition) is recommended [83]. Blood and lymphatic vessel invasion have an independent prognostic significance [84, 85].

4.2 Tumour, node, metastasis classification

The TNM classification of malignant tumours is the method most widely used to classify the extent of cancer spread [83] (Table 4.1).

Table 4.1: TNM Classification of urinary bladder cancer [83]

T - Primary Tumour		
Tx	Primary tumour cannot be assessed	
T0	No evidence of primary tumour	
Ta	Non-invasive papillary carcinoma	
Tis	Carcinoma *in situ*: "flat tumour"	
T1	Tumour invades subepithelial connective tissue	
T2	Tumour invades muscle	
	T2a	Tumour invades superficial muscle (inner half)
	T2b	Tumour invades deep muscle (outer half)
T3	Tumour invades perivesical tissue:	
	T3a	microscopically
	T3b	macroscopically (extravesical mass)
T4	Tumour invades any of the following: prostate stroma, seminal vesicles, uterus, vagina, pelvic wall, abdominal wall	
	T4a	Tumour invades prostate stroma, seminal vesicles, uterus, or vagina
	T4b	Tumour invades pelvic wall or abdominal wall
N - Regional Lymph Nodes		
Nx	Regional lymph nodes cannot be assessed	
N0	No regional lymph node metastasis	
N1	Metastasis in a single lymph node in the true pelvis (hypogastric, obturator, external iliac, or presacral)	
N2	Metastasis in multiple regional lymph nodes in the true pelvis (hypogastric, obturator, external iliac, or presacral)	
N3	Metastasis in a common iliac lymph node(s)	
M - Distant Metastasis		
M0	No distant metastasis	
	M1a	Non-regional lymph nodes
	M1b	Other distant metastasis

Staging after neoadjuvant chemotherapy (NAC) and RC can be done, but must be mentioned as ypTNM (International Collaboration on Cancer Reporting) [86]. ypT0N0 after NAC and cystectomy is associated with better prognosis [71, 87, 88].

5. DIAGNOSTIC EVALUATION

5.1 Primary diagnosis

5.1.1 Symptoms

Painless visible haematuria is the most common presenting complaint. Other presenting symptoms and clinical signs include nonvisible haematuria, urgency, dysuria, increased frequency, and in more advanced tumours, pelvic pain and symptoms related to urinary tract obstruction.

5.1.2 Physical examination

Physical examination should include rectal and vaginal bimanual palpation. A palpable pelvic mass can be found in patients with locally-advanced tumours. In addition, bimanual examination under anaesthesia should be carried out before and after TUR of the bladder tumour (TURBT) to assess whether there is a palpable mass or if the tumour is fixed to the pelvic wall [89, 90]. However, considering the discrepancy between bimanual examination and pT stage after cystectomy (11% clinical overstaging and 31% clinical understaging), bimanual examination findings need to be interpreted with caution [91].

5.1.3 Bladder imaging

Patients with a bladder mass identified by any diagnostic imaging technique should undergo cystoscopy, biopsy and/or resection for histopathological diagnosis and staging.

Due to the high specificity of diagnostic imaging for detecting BC, patients with imaging positive for BC may avoid diagnostic flexible cystoscopy and go directly to rigid cystoscopy and transurethral resection [92, 93].

5.1.4 Urinary cytology

Examination of voided urine or bladder washings for exfoliated cancer cells has high sensitivity in high-grade tumours and is a useful indicator in cases of high-grade malignancy or CIS. However, positive urinary cytology may originate from an urothelial tumour located anywhere in the urinary tract.

Evaluation of cytology specimens can be hampered by low cellular yield, UTIs, stones or intravesical instillations, but for experienced readers, specificity exceeds 90% [94, 95]. However, negative cytology does not exclude a tumour. There is no known urinary marker specific for the diagnosis of invasive BC [96].

A standardised reporting system, the 'Paris System' redefining urinary cytology diagnostic categories has been updated in 2022 [97]:

- adequacy of urine specimens (Adequacy);
- negative for high-grade UC (Negative);
- atypical urothelial cells (AUC);
- suspicious for high-grade UC (Suspicious);
- high-grade UC (HGUC).

5.1.5 Cystoscopy

Ultimately, the diagnosis of BC is made by cystoscopy and histological evaluation of resected tissue. An (outpatient) flexible cystoscopy is recommended to obtain a complete image of the bladder. However, in daily practice, If a bladder tumour has been visualised unequivocally by imaging studies such as computed tomography (CT), magnetic resonance imaging (MRI), or ultrasound (US), diagnostic cystoscopy may be omitted and the patient can proceed directly to TURB for histological diagnosis and resection. During the procedure, a thorough inspection of the bladder with rigid cystoscopy under anaesthesia is mandatory in order not to miss any tumours at the level of the bladder neck.

A careful description of the cystoscopic findings is necessary. This should include documentation of the site, size, number, and appearance (papillary or solid) of the tumours, as well as a description of any mucosal abnormalities [98]. The use of a bladder diagram is recommended.

The use of PDD could be considered if a T1 high-grade tumour is present and to identify associated CIS. Presence of CIS may lead to a modified treatment plan (see EAU Guidelines on Non-muscle-invasive Bladder Cancer [2]). Photodynamic diagnosis is highly sensitive for the detection of CIS and in experienced hands the rate of false-positive results may be similar to that with regular white-light cystoscopy [85, 99].

5.1.6 Transurethral resection of invasive bladder tumours

The goal of TURB is to enable histopathological diagnosis and staging, which requires the inclusion of bladder muscle in the resection specimen.

In case MIBC is suspected, tumours need to be (ideally) resected separately in parts, which include the exophytic part of the tumour, the underlying bladder wall with the detrusor muscle, and the edges of the resection area. At least the deeper part of the resection specimen must be referred to the pathologist in a separate labelled container to enable making a correct diagnosis and staging. In cases in which RT is considered and CIS is to be excluded, PDD can be used [100].

The involvement of the prostatic urethra and ducts in men with bladder tumours has been reported in up to 1 in 3 patients [58, 101, 102]. Under-reporting possibly also means that the exact risk is not known, but it seems to be higher if the tumour is located on the trigone or bladder neck, with concomitant bladder CIS, and in the case of multiple tumours [56, 103, 104]. Involvement of the prostatic urethra can be determined either at the time of primary TURB or by frozen section during the cystoprostatectomy procedure. A frozen section has a higher negative-predictive value and is more accurate [105-107].

A negative urethral frozen section can reliably identify patients in whom urethrectomy should be avoided. However, a positive pre-operative biopsy seems to have limited utility as these findings are not reliably associated with final margin status [105, 108].

Diagnosis of a urethral tumour before cystectomy will result in a urethrectomy which could be a contraindication for an orthotopic diversion. However, an orthotopic diversion should not be denied based on positive pre-operative biopsy findings alone and frozen section should be part of the RC procedure, particularly in male patients [109, 110].

5.1.7 Summary of evidence and guidelines for the primary assessment of presumably invasive bladder tumours

Summary of evidence	LE
Cystoscopy is necessary for the diagnosis of bladder cancer.	1
Urinary cytology has high sensitivity in high-grade tumours including carcinoma *in situ*.	2b
In men, prostatic urethral biopsy includes resection from the bladder neck to the verumontanum (between the 5 and 7 o'clock position) using a resection loop. In case any abnormal-looking areas in the prostatic urethra are present at this time, these need to be biopsied as well.	2b

Recommendations	Strength rating
Describe all macroscopic features of the tumour (site, size, number and appearance) and mucosal abnormalities during cystoscopy. Use a bladder diagram.	Strong
Take a biopsy of the prostatic urethra in cases of bladder neck tumour, when bladder carcinoma *in situ* is present or suspected, when there is positive cytology without evidence of tumour in the bladder, or when abnormalities of the prostatic urethra are visible.	Strong
In men with a negative prostatic urethral biopsy undergoing subsequent orthotopic neobladder construction, an intra-operative frozen section can be omitted.	Strong
In men with a prior positive transurethral prostatic biopsy, subsequent orthotopic neobladder construction should not be denied a priori, unless an intra-operative frozen section of the distal urethral stump reveals malignancy at the level of urethral dissection.	Strong
In women undergoing subsequent orthotopic neobladder construction, obtain procedural information (including histological evaluation) of the bladder neck and urethral margin, either prior to, or at the time of cystectomy.	Strong
In the pathology report, specify the grade, depth of tumour invasion, and whether the lamina propria and muscle tissue are present in the specimen.	Strong

(For general information on the assessment of bladder tumours, see EAU Guidelines on Non-muscle-invasive Bladder Cancer [2]).

5.1.8 *EAU-ESMO consensus statements on the management of advanced- and variant bladder cancer [81, 82]**

Consensus statement
Differentiating between urachal and non-urachal subtypes of adenocarcinoma is essential when making treatment decisions.

**Only statements which met the a priori consensus threshold across all three stakeholder groups are listed (defined as ≥ 70% agreement and ≤ 15% disagreement, or vice versa).*

5.2 Imaging for staging of MIBC

In clinical practice, tumour stage and histopathological grade are used to guide treatment and determine prognosis [111-113]. Imaging is essential for local- and distant staging of BC.

The goal of imaging patients with BC is to:

- Detect bladder tumours;
- Differentiate T1 from T2 tumours as their treatment will differ;
- Determine presence of any obstruction to the upper UT;
- Evaluate the extent of locally-advanced tumour stage or tumour spread to LNs;
- Assess synchronous tumour in the upper UT or other distant organs (e.g., liver, lungs, bones, peritoneum, pleura, and adrenal glands).

Table 5.1: The role of imaging in treatment planning

Goal	Imaging modality
Differentiate T1 from T2 tumours	MRI using the Vesical Imaging Reporting and Data System [VI-RADS] score
Evaluate locally-advanced stage or spread to LNs	CT scan and MRI for abdominal- and pelvic LNs or PET/CT scan
Assess UUT or other distant organs	CT urography for evaluating the UUT and PET/CT to detect distant organ metastasis

5.2.1 *Detection*

Imaging modalities used to detect bladder tumours are: US, CT and MRI-scan. Bladder tumours are often detected as part of the haematuria work-up (including cystoscopy) or as an incidental finding on imaging.

Ultrasound can visualise intraluminal masses in the bladder and additional signs such as hydronephrosis, but cannot rule out all possible causes of haematuria. According to the results of the DETECT I trial, CT urogram can be safely replaced by renal and bladder US in patients who have non-visible haematuria [114].

5.2.2 *Local staging of the bladder and upper tract*

5.2.2.1 *Magnetic resonance imaging for local staging of MIBC*

Differentiation between NMIBC and MIBC is crucial for BC treatment. Magnetic resonance imaging has superior soft tissue contrast resolution compared with CT and can evaluate post-biopsy reaction as enhancement of the tumour occurs earlier than that of the normal bladder wall due to neovascularisation [115, 116].

The accuracy of MRI for primary tumour staging ranges from 73% to 96% (mean 85%). Huang *et al.*, in a systematic review, showed a pooled sensitivity and specificity of 90% and 88%, respectively, with results increasing to 92% and 96% when a 3T scan was used, with diffusion-weighted (DW) MRI as part of the acquisition protocol [117].

A systematic review evaluating 20 studies (n = 1,724), showed a pooled sensitivity and specificity of MRI for differentiating between stages ≤ T1 and ≥ T2 of 0.92 (95% CI: 0.88–0.95) and 0.88 (95% CI: 0.78–0.94), respectively [118]. More recently, multiparametric (mp) MRI using the VI-RADS scoring system has been introduced to differentiate between T1 vs. T2 bladder tumours with a high diagnostic accuracy [119]. The VI-RADS offers a standardised approach to both acquisition and reporting of mpMRI for BC; however, the best practice of using mpMRI in this setting and the exact cut-off levels for VI-RADS scoring still need to be determined [116]. To date, the VI-RADS score has been validated by several research groups, showing good diagnostic performance in detecting MIBC [120, 121]. Also, a high diagnostic performance for the detection of muscle invasion of urothelial carcinoma subtypes was found [122].

VI-RADS assessment scoring proved to be an independent predictor of muscle-invasiveness, which might facilitate a shift toward a more aggressive approach to selection of patients at high risk of MIBC, according to a novel proposed predictive pathway [123].

A meta-analysis found that the pooled sensitivity and specificity of mpMRI with VI-RADS acquisition and scoring for predicting MIBC were 83% and 90%, respectively [124]. The diagnostic performance of using VI-RADS scoring is similar to the diagnostic performance of a conventional bladder MRI in determining MIBC based on a previous meta-analysis of 24 studies [124]. The analysis found substantial inter-reader agreement, with kappa (κ) values ranging from 0.81 to 0.92 [124]. A systematic review and meta-analysis (n = 1,016) showed a pooled weighted mean κ estimate of 0.83 (95% CI: 0.78–0.88) [125]. The potential role of mpMRI as first-line test for local staging of BC rather than TURB has been demonstrated in a recent clinical trial [126].

A modified Delphi methodology was recently developed by a panel of highly experienced, internationally recognised radiologists, urologists, oncologists, radiation oncologists and a representative from a patient advocacy group, to provide consensus-based recommendations for urinary bladder MRI to help formulate international guidelines, particularly for pre-operative cancer staging and the assessment of the response to systemic therapy. Among several statements that reached agreement, experts recommend acquiring and interpreting MR images according to VI-RADS recommendations and always perform MRI before TURBT, if available [127].

Considering the link established between the use of gadolinium-based contrast agents and nephrogenic systemic fibrosis (NSF) in patients with impaired renal function, contrast medium should be managed according to the European Society of Urogenital Radiology (ESUR) Guidelines [128]. Interest is growing in the role of non-contrast MRI for the assessment of MIBC using VI-RADS with studies demonstrating how non-contrast-enhanced VI-RADS scoring achieved similar predictive accuracy for diagnosis of MIBC to that of conventional VI-RADS; however, further additional evidence is needed to provide any recommendation on the use of non-contrast MRI for bladder cancer staging [129].

5.2.2.2 CT imaging for local staging of MIBC

General advantages of CT imaging include high spatial resolution, shorter acquisition time, wider coverage in a single breath hold, and lower susceptibility to variable patient factors. Computed tomography is unable to differentiate between stages Ta to T3a tumours, but it is useful for detecting invasion into the perivesical fat (T3b) and adjacent organs. The accuracy of CT in determining extravesical tumour extension increases with more advanced disease [130].

Both CT and MRI may be used for assessment of local invasion by T3b disease, or higher, but they are unable to accurately diagnose microscopic invasion of perivesical fat (T2 vs. T3a) [131]. Contrast-enhanced CT using iodinated contrast media can be considered as an alternative to MRI when MRI is contraindicated or not available [128].

5.2.2.3 Computed tomography urography for local staging of the upper tract

For local staging of the UUT, CTU has the highest diagnostic accuracy of the available imaging techniques. The sensitivity of CTU for UTUC is 0.67–1.0 and specificity is 0.93–0.99 [132].

Rapid acquisition of thin sections allows high-resolution isotropic images that can be viewed in multiple planes to assist with diagnosis without loss of resolution. Epithelial 'flat lesions' without mass effect or urothelial thickening are generally not visible with CT. The secondary sign of hydronephrosis is associated with advanced disease and poor oncological outcome [133]. The presence of enlarged LNs is highly predictive of metastases in UTUC [134].

5.2.2.4 Magnetic resonance urography for local staging of the upper tract

Magnetic resonance urography is indicated in patients who cannot undergo CTU, usually when radiation or iodinated contrast media are contraindicated [135]. The sensitivity of MR-urography is 0.75 after contrast injection for tumours < 2 cm [135]. The use of MR-urography with gadolinium-based contrast media should be limited in patients with severe renal impairment (< 30 mL/min creatinine clearance), due to the risk of NSF. Computed tomography urography is generally preferred to MR-urography for diagnosing and staging UTUC.

*5.2.3 **Distant staging of lymph nodes and other sites***

5.2.3.1 Imaging of lymph nodes in MIBC

Assessment of LN metastases based on size alone is limited; both CT and MRI are unable to identify metastases in normal-sized or minimally-enlarged nodes. The sensitivity of these modalities for detection of LN metastases is low (48–87%). Specificity is also low because nodal enlargement may be due to benign

disease. Overall, CT and MRI show similar results in the detection of LN metastases in a variety of primary pelvic tumours [135-137]. Pelvic nodes > 8 mm and abdominal nodes > 10 mm in maximum short-axis diameter, detected by CT or MRI, should be regarded as pathologically enlarged [138]. In a recent paper including 1,104 patients, conventional cross-sectional imaging showed slight concordance (64.9%) between cN and pN stages (sensitivity: 30%; specificity: 84%) [139]. An artificial intelligence-assisted lymph node metastases diagnostic model (LNMDM) on whole slide images (CT, MRI and PET/CT) has been developed and applied in a cohort of 1,012 patients with bladder cancer who had radical cystectomy and pelvic lymph node dissection with the AUC for accurate diagnosis of the LNMDM ranged from 0.978 (95% CI 0.960–0.996) to 0.998 (95% CI: 0.996–1.000) in the five validation sets [140].

^{18}F-fluorodeoxy glucose-Positron emission tomography (FDG-PET) combined with CT is increasingly being used in clinical practice but its exact role still needs to be further evaluated [141, 142]. According to a systematic review and meta-analysis including 785 patients, FDG-PET/CT showed a low sensitivity and high specificity for the detection of metastatic LNs in patients with newly diagnosed BC [143]. However, most studies evaluating FDG-PET/CT for LN assessment reported higher sensitivity than CT, with comparable specificity [144]. PET/CT can provide additional information to guide local treatment in case of presence of pelvic nodes metastases [145].

However, in a clinical trial assessing the role of PET/CT in evaluating LN involvement in patients receiving neoadjuvant pembrolizumab. The performance of PET/CT did not justify its routine use in cN0 MIBC patients, but proved useful in optimising selection of MIBC patients suited for neoadjuvant immunotherapy (IO) strategies in a clinical trial setting [146]. Several studies have demonstrated the possible role of radiomics for the detection of pathological lymph nodes in bladder cancer patients; however, the level of evidence remains low.

5.2.3.2 Distant metastases

Prior to any curative treatment, it is essential to evaluate the presence of distant metastases. Computed tomography and MRI are the diagnostic techniques of choice to detect e.g., lung [147] and liver metastases [148], respectively.

Evidence for the role of FDG-PET/CT for staging distant metastases of MIBC is still limited. In a recent series of 711 patients, FDG-PET/CT has shown to provide important staging information through the detection of distant metastases, which may impact the clinical management of MIBC patients [145].

Bone and brain metastases are rare at the time of presentation of invasive BC. In a recent retrospective, large sample, study bone scan has been shown to have an impact on patients' intended management in only 19 out of 1,148 (1.7%) patients, therefore it should not be routinely used [149]. Whole-body MRI is more sensitive and specific for diagnosing bone metastases than bone scintigraphy [150]. Also, additional brain imaging is not routinely indicated unless the patient has specific symptoms or signs to suggest brain metastases.

*5.2.4 **Response to therapy***

Pre-operative MRI conducted in various clinical settings may provide useful information regarding treatment response. In the neoadjuvant setting, the first study evaluating the performance of MRI in assessing therapeutic response to chemotherapy showed superiority of DWI over T2-weighted and dynamic contrast-enhanced (DCE)-MRI [151]. The high specificity of DWI indicates its usefulness in accurate predicting a complete histopathological response, allowing for better patient selection for bladder-sparing protocols [152]. Dynamic contrast-enhanced MR imaging may also be useful for predicting a patient's response to chemotherapy. In addition, quantitative DWI/MRI analysis has shown to provide an accurate and non-invasive assessment of bladder RT response. However, multicentre validation is required before prospective testing to inform MIBC follow-up schedules and decision making [153].

In the previously cited consensus-based recommendations, experts agreed upon the performance on MRI to assess response to systemic therapy to select patients for radical treatment, for surveillance, and for bladder-sparing surgery [127].

A meta-analysis investigated the predictive role of 18F-FDG PET/CT for assessment of tumour response to neoadjuvant chemotherapy in a total of 278 patients, showed a pooled sensitivity of 0.84 (95% CI, 0.72–0.91), and specificity of 0.75 (95% CI, 0.59–0.86). Among the five studies, only three used both of CR and pCR as reference standard [154].

The performance of PET/CT in evaluating LN involvement in patients receiving neoadjuvant pembrolizumab did not justify its routine use in cN0 MIBC patients [146].

5.2.5 *Future perspectives*

Potential future application of the VI-RADS score may include prediction of response to treatment as well as peri-operative outcomes using its modified version: the NAC VI-RADS (nacVI-RADS), however, prospective evidence is warranted [155].

Future trends might include image analysis radiomic-based techniques in predicting MIBC. A meta-analysis (n = 860) provided summary estimates for sensitivity and specificity in predicting MIBC of 82% (95% CI: 77–86%) and 81% (95% CI: 76–85%), respectively [156].

PET/MRI combining the benefits of MRI with functional imaging could be evisioned for the detection of metastatic BC lesions not seen on CT in patients who cannot receive intravenous iodine contrast, and may lead to improved treatment planning and monitoring for BC [157].

Among the novel approaches and radiotracers, in a pilot study, Rietbergen *et al.*, showed that the sentinel node (SN) biopsy in bladder cancer using the hybrid tracer $^{ICG-\ 99mTc}$-nanocolloid is feasible, and in patients with a successful pre-operative SN mapping using lymphoscintigraphy and SPECT/CT, the intraoperative SN guidance and detection are effective, even outside the extended pelvic lymph node dissection (ePLND) area [158].

5.2.6 *Summary of evidence and guidelines for staging in muscle-invasive bladder cancer*

Summary of evidence	LE
Imaging as part of staging in muscle-invasive bladder cancer (MIBC) provides information about prognosis and assists in selection of the most appropriate treatment.	2b
The diagnosis of upper tract UC depends on CT urography and, if needed, ureteroscopy.	2b
In local staging, MRI is superior to CT in terms of differentiating T1 from T2 disease.	2b
MRI is accurate for the assessment of tumour response to systemic therapy	3
Bone scintigraphy has limited value in the staging of invasive BC.	3
FDG-PET/CT can provide additional information to guide treatment.	2b

Recommendations	Strength rating
Always perform MRI before TURBT, if available.	Weak
In patients with confirmed muscle-invasive bladder cancer, use computed tomography (CT) of the chest, abdomen and pelvis for staging, including some form of CT urography with designated phases for optimal urothelial evaluation.	Strong
Use CT urography, unless it is contraindicated for reasons related to contrast adminstration or radiation dose; in that case use magnetic resonance imaging.	Strong
Offer MRI to assess the response to systemic therapy, which aids in the selection of patients for radical treatment, surveillance, and bladder-sparing surgery.	Weak

5.3 Muscle-invasive and metastatic bladder cancer and health status

Complications from RC may be directly related to pre-existing comorbidity as well as the surgical procedure, bowel anastomosis, or urinary diversion. A significant body of literature has evaluated the usefulness of age as a prognostic factor for RC, although chronological age is less important than frailty [159-161]. Frailty is a syndrome of reduced ability to respond to stressors. Patients with frailty have a higher risk of mortality and negative side effects of cancer treatment [162]. Controversy remains regarding age, RC and the type of urinary diversion. Radical cystectomy is associated with the greatest risk reduction in disease-related and non-disease-related death in patients aged < 80 years [163].

The largest retrospective study on RC in septuagenarians and octogenarians based on data from the National Surgical Quality Improvement Program database (n = 1,710) showed no significant difference for wound, cardiac, or pulmonary complications. However, the risk of mortality in octogenarians compared to septuagenarians is higher (4.3% vs. 2.3%) [164]. Although some octogenarians successfully underwent a neobladder procedure, most patients were treated with an ileal conduit diversion. It is important to evaluate functioning and quality of life (QoL) of older patients using a standardised geriatric assessment, as well as carrying out a standard medical evaluation [165].

Sarcopenia has been shown to be an independent predictor for OS and CSS in a large multi-centre study with patients undergoing RC for BC [166]. In order to predict CSM after RC in patients receiving NAC, sarcopenia should be assessed after completing chemotherapy [167]. Other risk factors for morbidity include prior abdominal surgery, extravesical disease, and prior RT [168]. Female gender, an increased BMI and lower pre-operative albumin levels are associated with a higher rate of parastomal hernias [169]. Low pre-operative serum albumin is also associated with impaired wound healing, gastrointestinal (GI) complications and a decrease of recurrence-free and OS after RC [170, 171]. Therefore, it could be used as a prognostic biomarker for patients undergoing RC.

Metformin has been suggested as having possibly anticancer activity in bladder cancer by inhibiting tumour growth as well as being synergistic with Cisplatin. A systematic review and meta-analysis of 4,006 patients suggests that Metformin use was associated with lower cancer specific and overall moratlity in patients with MIBC [172].

5.3.1 Evaluation of comorbidity, frailty and cognition

Rochon *et al.*, have shown that evaluation of comorbidity provides a better indicator of life expectancy in MIBC than patient age [173]. Evaluation of comorbidity helps to identify factors likely to interfere with, or have an impact on, treatment and the evolution and prognosis of MIBC [174].

The value of assessing overall health before recommending and proceeding with surgery was emphasised by Zietman *et al.*, who have demonstrated an association between comorbidity and adverse pathological and survival outcomes following RC [175]. Similar results were found for the impact of comorbidity on cancer-specific and other-cause mortality in a population-based competing risk analysis of > 11,260 patients from the Surveillance, Epidemiology, and End Results (SEER) registries. Age carried the highest risk for other-cause mortality but not for increased cancer-specific death, while the stage of locally-advanced tumour was the strongest predictor for decreased CSS [176].

Stratifying older patients according to frailty using a multidisciplinary approach will help select patients most likely to benefit from radical surgery and to optimise treatment outcomes [177]. There are many different screening tools available for frailty and local approaches can be used. Examples include the G8 and the Clinical Frailty Scale (See Table 5.2 and Figure 5.1 below).

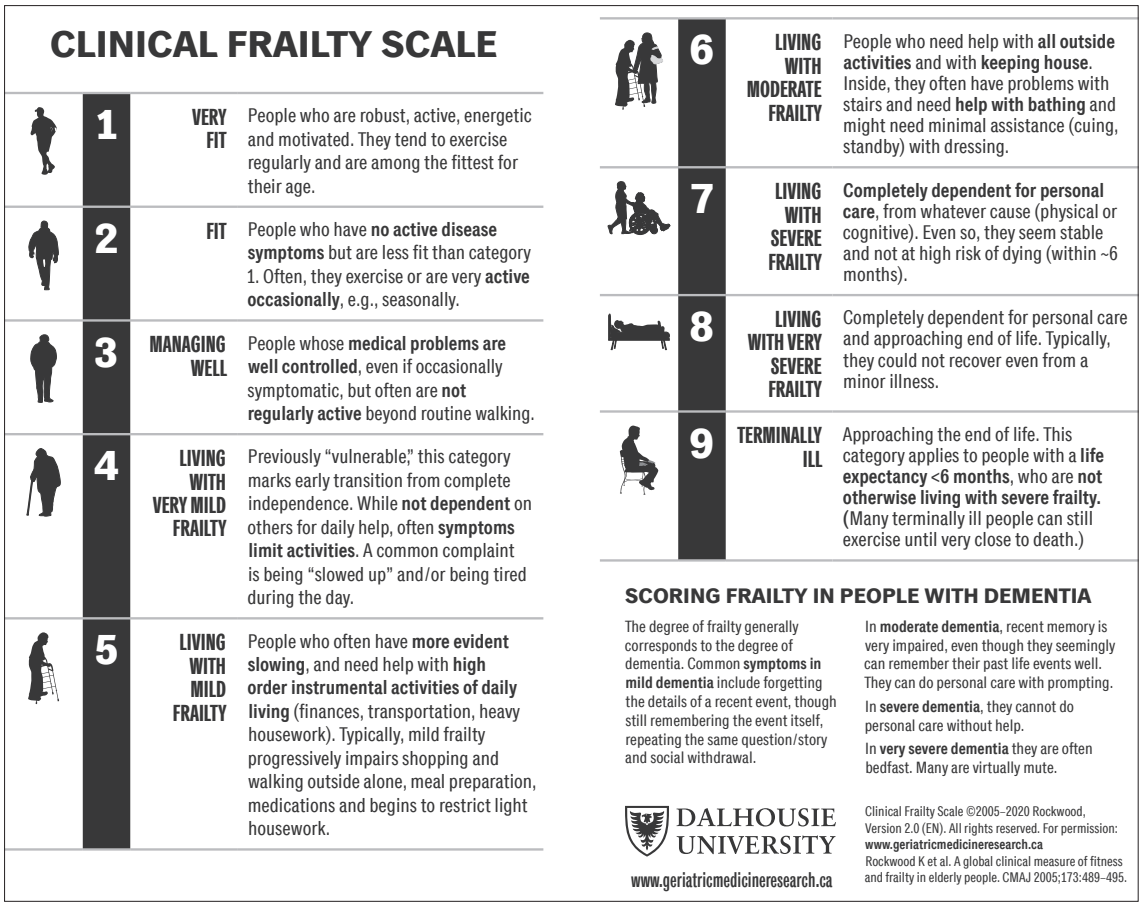
Cognitive impairment can be screened for by using a tool such as the mini-COG (https://mini-cog.com/), which consists of three-word recall and a clock-drawing test, and can be completed within 5 minutes. A score of ≤ 3/5 indicates the need to refer the patient for full cognitive assessment. Patients with any form of cognitive impairment (e.g., Alzheimer's or vascular dementia) may need a capacity assessment of their ability to make an informed decision, which is an important factor in health status assessment. Cognitive impairment also predicts risk of delirium, which is important for patients undergoing surgery [178].

Table 5.2: G8 screening tool (adapted from [179])

	Items	Possible responses (score)
A	Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing, or swallowing difficulties?	0 = severe decrease in food intake
		1 = moderate decrease in food intake
		2 = no decrease in food intake
B	Weight loss during the last 3 months?	0 = weight loss > 3 kg
		1 = does not know
		2 = weight loss between 1 and 3 kg
		3 = no weight loss
C	Mobility?	0 = bed or chair bound
		1 = able to get out of bed/chair but does not go out
		2 = goes out
D	Neuropsychological problems?	0 = severe dementia or depression
		1 = mild dementia
		2 = no psychological problems
E	BMI? (weight in kg)/(height in m^2)	0 = BMI < 19
		1 = BMI 19 to < 21
		2 = BMI 21 to < 23
		3 = BMI ≥ 23

F	Takes more than three prescription drugs per day?	0 = yes
		1 = no
G	In comparison with other people of the same age, how does the patient consider his/her health status?	0.0 = not as good
		0.5 = does not know
		1.0 = as good
		2.0 = better
H	Age	0 = ≥ 85
		1 = 80–85
		2 = < 80
	Total score	**0–17**

Figure 5.1: Clinical Frailty Scale©, Version 2.0* [180]



**Permission to reproduce the Clinical Frailty Scale© has been granted by the copyright holder.*

5.3.2 Comorbidity scales, anaesthetic risk classification and geriatric assessment

A range of comorbidity scales has been developed [181], seven of which have been validated [182-188]. The Charlson Comorbidity Index (CCI) ranges from 0 to 30 according to the importance of comorbidity described at four levels and is calculated by healthcare practitioners based on patients' medical records. The score has been widely studied in patients with BC and found to be an independent prognostic factor for peri-operative mortality [189, 190], overall mortality [191], and CSM [163, 92-194]. Only the age-adjusted version of the CCI was correlated with both cancer-specific and other-cause mortality [195]. The age-adjusted CCI (Table 5.3) is the most widely used comorbidity index in cancer for estimating long-term survival and is easily calculated [196].

Health assessment of oncology patients must be supplemented by measuring their activity level. Extermann *et al.*, have shown that there is no correlation between morbidity and competitive activity level [197]. The Eastern Cooperative Oncology Group (ECOG) performance status (PS) scores and Karnofsky index have been validated to measure patient activity [198]. Performance score is correlated with patient OS after RC [193] and palliative chemotherapy [199-201].

Patients who have screened positive for frailty or cognitive impairment benefit from an assessment by a geriatrician. This allows identification of geriatric syndromes and any scope for optimisation. The most complete protocol is the Comprehensive Geriatric Assessment (CGA) [202] which is useful in the care of cancer patients [203]. In BC, the CGA has been used to adapt gemcitabine chemotherapy in previously untreated older patients with advanced BC [204].

Table 5.3: Calculation of the Charlson Comorbidity Index

Number of points	Conditions
1	50–60 years
	Myocardial infarction
	Heart failure
	Peripheral vascular insufficiency
	Cerebrovascular disease
	Dementia
	Chronic lung disease
	Connective tissue disease
	Ulcer disease
	Mild liver disease
	Diabetes
2	61–70 years
	Hemiplegia
	Moderate to severe kidney disease
	Diabetes with organ damage
	Tumours of all origins
3	71–80 years
	Moderate to severe liver disease
4	81–90 years
5	> 90 years
6	Metastatic solid tumours
	AIDS

Interpretation:

1. Calculate Charlson Comorbidity Score or Index = i
    a. Add comorbidity score to age score
    b. Total denoted as 'i' in the Charlson Probability calculation (see below).
    i = sum of comorbidity score to age score
2. Calculate Charlson Probability (10-year mortality = Y)
    a. Calculate $Y = 10^{(i \times 0.9)}$
    b. Calculate $Ƶ = 0.983^{Y}$ (where Ƶ is the 10-year survival)

5.3.3 Summary of evidence and guidelines for comorbidity scales

Summary of evidence	LE
Chronological age is of limited relevance.	3
It is important to screen for frailty and cognitive impairment and provide a Comprehensive Geriatric Assessment (CGA) where optimisation is needed.	3

Recommendations	Strength rating
Base the decision on bladder-sparing treatment or radical cystectomy in older/frail patients with invasive bladder cancer on tumour stage and frailty.	Strong
Assess comorbidity by a validated score, such as the Charlson Comorbidity Index. The American Society of Anesthesiologists score should not be used in this setting (see Section 5.3.2).	Strong

6. MARKERS

6.1 Introduction

Both patient and tumour characteristics guide treatment decisions and prognosis of patients with MIBC.

6.2 Prognostic markers

6.2.1 Histopathological and clinical markers

The most important histopathological prognostic variables after RC and LN dissection are tumour stage and LN status [205]. In addition, other histopathological parameters of the RC specimen have been associated with prognosis.

The value of lymphovascular invasion was reported in a systematic review and meta-analysis including 78,000 patients from 65 studies treated with RC for BC [206]. Lymphovascular invasion was present in 35% of the patients and correlated with a 1.5-fold higher risk of recurrence and CSM, independent of pathological stage and peri-operative chemotherapy. This correlation was even stronger in those patients with node-negative disease [207].

In a systematic review and meta-analysis including 23 studies and over 20,000 patients, the presence of concomitant CIS in the RC specimen was associated with a higher odds ratio (OR) of ureteral involvement (pooled OR: 4.51, 2.59–7.84). Concomitant CIS was not independently associated with OS, recurrence-free survival (RFS) and DSS in all patients, but in patients with organ-confined disease concomitant CIS was associated with worse RFS (pooled HR: 1.57, 1.12–2.21) and CSM (pooled HR: 1.51, 1.001–2.280) [207].

Tumour location has been associated with prognosis. Tumours located at the bladder neck or trigone of the bladder appear to have an increased likelihood of nodal metastasis (OR: 1.83, 95% CI: 1.11–2.99) and have been associated with decreased survival [205, 208-210].

Prostatic urethral involvement at the time of RC was also found to be associated with worse survival outcomes. In a series of 995 patients, prostatic involvement was recorded in 31% of patients. The 5-year CSS in patients with CIS of the prostatic urethra was 40%, whilst the prognosis of patients with UC invading the prostatic stroma was worse with a 5-year CSS of only 12% [211].

Neutrophil-to-lymphocyte ratio (NLR) has emerged as a prognostic factor in UUT tumours [1] and other non-urological malignancies. In a pooled analysis of 21 studies analysing the prognostic role of NLR in BC, the authors correlated elevated pre-treatment NLR with OS, RFS and disease-free survival (DFS) in both localised and metastatic disease [212]. In contrast, a secondary analysis of the Southwest Oncology Group (SWOG) 8710 trial, a randomised phase III trial assessing cystectomy ± NAC in patients with MIBC, suggests that NLR is neither a prognostic nor a predictive biomarker for OS in MIBC [213].

In patients with LN-positive disease, the American Joint Committee on Cancer (AJCC)-TNM staging system provides 3 subcategories. In addition, several other prognostic LN-related parameters have been reported. These include, but are not limited to, the number of positive LNs, the number of LNs removed, LN density (the ratio of positive LNs to the number of LNs removed) and extranodal extension. In a systematic review and meta-analysis, it was reported that LN density was independently associated with OS (HR: 1.45, 95%, CI: 1.11–1.90) [214]. It has been suggested that LN density outperforms the AJCC-TNM staging system for LN-positive disease in terms of prognostic value [215, 216]. However, in spite of these studies supporting the use of LN density, LN density relies on the number of LNs removed which, in turn, is subject to surgical and pathological factors. This makes the concept of LN density difficult to apply uniformly [217].

Two studies investigated whether any of the reported LN-related parameters may be superior to the routinely used AJCC-TNM staging system [217, 218]. Whilst the conclusion was that the AJCC-TNM staging system for LN status did not perform well, none of the other tested variables outperformed the AJCC system.

6.2.2 *Molecular markers*

6.2.2.1 *Molecular variants based on the Cancer Genome Atlas cohort*

The updated Cancer Genome Atlas (TCGA) reported on 412 MIBCs and identified two main groups; luminal and basal-squamous - consisting of five mRNA expression-based molecular variant including luminal- papillary, luminal-infiltrated, luminal; basal-squamous; and neuronal; a variant associated with poor survival in which part of tumours do not have small cell or neuroendocrine histology. Each variant is associated with distinct mutational profiles, histopathological features and prognostic and treatment implications [219].

The basal-squamous variant is characterised by expression of basal keratin markers, immune infiltrates and is felt to be chemosensitive. The different luminal variants are characterised by fibroblast growth factor receptor 3 (FGFR3) alterations (luminal-papillary [LumP]), epithelial-mesenchymal transition (EMT) markers (luminal-infiltrated) and may be associated with chemotherapy resistance [67, 68, 219, 220]. In 2019, a consensus on molecular variant classification was reported [221]. The authors analysed 1,750 MIBC transcriptomic profiles from 18 datasets and identified six MIBC molecular classes that reconcile all previously published classification schemes. The molecular variant classes include LumP, luminal non-specified (LumNS), luminal unstable (LumU), stroma-rich, basal/squamous (Ba/Sq), and neuroendocrine-like (NE-like). Each class has distinct differentiation patterns, oncogenic mechanisms, tumour micro-environments and histological and clinical associations. However, the authors stressed that consensus was reached for biological rather than clinical classes. Therefore, at this time, the classification should be considered as a research tool for retrospective and prospective studies until future studies establish how these molecular variants can be used best in a clinical setting.

Molecular classification of MIBC is still evolving and treatment tailored to molecular variant is not a standard yet. A novel 12-gene signature derived from patients in the TCGA utilising published gene signatures has been developed and externally validated to predict OS in MIBC [222]. Interestingly, an analysis of molecular typing in MIBC demonstrated that although molecular variants reflect the heterogeneity of bladder tumours and are associated with tumour grade, clinical parameters outperformed variants for predicting outcome [223]. In the coming years, new insights into BC carcinogenesis may change our management of the disease and our ability to better predict outcomes [224]. Outside clinical trials, molecular examination, either by expression profiling or immunohistochemistry, is not yet part of routine clinical work-up awaiting more conclusive data.

6.3 *Predictive markers*

6.3.1 *Clinical and histopathological markers*

Based on retrospective data only, patients with secondary MIBC have a worse response to NAC compared to patients with primary MIBC [225]. Pietzak *et al.*, retrospectively analysed clinico-pathologic outcomes comparing 245 patients with clinical T2–4a N0M0 primary MIBC and 43 patients with secondary MIBC treated with NAC and RC. They found that patients with secondary MIBC had lower pathologic response rates following NAC than those with primary MIBC (univariable 26% vs. 45%, multivariable OR: 0.4 [95% CI: 0.18–0.84, p = 0.02]). They also found that MIBC patients progressing after NAC had worse CSS as compared to patients treated with cystectomy alone (p = 0.002).

Subtypes and non-UC have also been linked to worse outcomes after NAC, but there is, as yet, insufficient data to conclude that they can be considered as predictive markers [226].

6.3.2 *Molecular markers*

Several predictive biomarkers have been investigated such as serum vascular endothelial growth factor (VEGF) [227], circulating tumour cells, immune and stromal signatures, as well as expression of or defects in DNA damage repair (DDR) genes including ERCC2, ATM, MRE11, RB1 and FANCC that may predict response to cisplatin-based NAC [228, 229] or chemoradiation [230-233]. More recently, alterations in FGFR2/3 including both mutations and gene fusions have been shown to be associated with response to FGFR inhibitors [234, 235].

More recent efforts have focused on markers for predicting response to immune checkpoint inhibition. Programmed death-ligand 1 (PD-L1) expression by immunohistochemistry has been evaluated in several studies with mixed results which may in part be related to the use of different antibodies and various scoring systems evaluating different compartments, i.e., tumour cells, immune cells, or both. The major limitation of PD-L1 staining relates to the significant proportion of PD-L1-negative patients that respond to immune checkpoint blockade. For example, in the IMvigor 210 phase II study of atezolizumab in patients with advanced/metastatic UC who progressed after platinum-based chemotherapy, responses were seen in 18% of patients with low/no PD-L1 expression [236]. At present, the only indication for PD-L1 testing relates to the use of immune checkpoint inhibitors as monotherapy in patients with locally-advanced or metastatic UC unfit for cisplatin-containing chemotherapy who have not received prior therapy. In this setting, atezolizumab (the European Medicines Agency [EMA] approval) or pembrolizumab (EMA approval) should only be used in patients unfit for cisplatin-containing chemotherapy whose tumours overexpress PD-L1 (i.e., in case of atezolizumab; tumour-

infiltrating immune cells [IC] covering ≥ 5% of the tumour area using the SP142 assay; in case of pembrolizumab, a combined positive score (CPS) of ≥ 10 using the Dako 22C33 platform) [237]. The FDA revised the label for pembrolizumab in patients with advanced UC with approval in first line only for patients not eligible for any platinum-based chemotherapy, however, irrespective of PD-L1 status.

Urothelial cancer is associated with a high tumour mutational burden (TMB) [238]. Both predicted neoantigen burden and TMB have been associated with response to immune checkpoint blockade in several malignancies. High TMB has been associated with response to immune checkpoint inhibitors in metastatic BC [236, 239]. Conflicting results have been seen in studies evaluating immune checkpoint inhibitors in the neoadjuvant setting with the Pembrolizumab as Neoadjuvant Therapy Before Radical Cystectomy in Patients With Muscle- Invasive Urothelial Bladder Carcinoma (PURE)-01 study demonstrating an association of high TMB with response while there was no association with atezolizumab in the Phase II study investigating the safety and efficacy of neoadjuvant atezolizumab in MIBC (ABACUS) [240, 241].

Other markers that have been evaluated in predicting response to immune checkpoint inhibitors include molecular subtypes as discussed earlier, CD8 expression by immunohistochemistry and other immune gene cell signatures. Recent work has focused on the importance of stroma including the role of transforming growth factors (TGFs) in predicting response to immune checkpoint blockade [242, 243]. Powles *et al.*, have reported on the potential for ctDNA to guide the use of adjuvant IO in UC [244]. In 581 patients from a phase III RCT of adjuvant atezolizumab vs. observation in UC, ctDNA testing at the start of therapy identified 214 (37%) patients who were positive for ctDNA and who had poor prognosis (observation arm HR = 6.3, 95% CI: 4.45–8.92; p < 0.0001). Patients who were positive for ctDNA had improved DFS and OS in the atezolizumab arm vs. the observation arm (DFS: HR = 0.58 [95% CI: 0.43–0.79]; p = 0.0024, OS: HR = 0.59 [95% CI: 0.41–0.86]). There was no difference in DFS or OS between treatment arms for patients who were negative for ctDNA. The rate of ctDNA clearance at week 6 was higher in the atezolizumab arm (18%) than in the observation arm (4%) (p = 0.0204). An ongoing clinical trial (IMvigor011) is evaluating atezolizumab as adjuvant therapy in patients with high-risk MIBC who are ctDNA positive following cystectomy [245].

A exploratory analysis in patients with metastatic UC who received pembrolizumab in the first-line (KEYNOTE-052 trial) and salvage (KEYNOTE-045 trial) settings, demonstrated that TMB and T-cell inflammed gene expression profile were significantly associated with improved outcomes, however PD-L1 was associated with improved outcomes and stromal signature with worse outcomes in KEYNOTE-052, but not KEYNOTE-045 suggesting that these biomarkers may perform differently in different clinical disease states i.e. first line versus salvage settings [246]. In a second study, a scoring system (CPT) based on CD39, PD-L1 and TMB was shown to predict response to PD-L1 blockade and platinum-based chemotherapy in patients with MIBC [247].

Although promising, there are currently no validated predictive molecular markers that are routinely used in clinical practice. Further validation studies are awaited.

6.4 Conclusion

The updated TCGA and other efforts have refined our understanding of the molecular underpinnings of BC biology. Molecular variants, immune gene signatures as well as stromal signatures may ultimately have an important role in predicting response to IO. Although PD-L1 expression by immunohistochemistry and TMB have demonstrated predictive value in certain settings, additional studies are needed. Prospectively validated prognostic and predictive molecular biomarkers will present valuable adjuncts to clinical and pathological data, but large phase III RCTs with long-term follow-up will be needed to clarify the many questions remaining.

6.5 *Summary of evidence for urothelial markers*

Summary of evidence	LE
There is insufficient evidence to use TMB, molecular variants , immune- or other gene expression signatures for the management of patients with urothelial cancer.	NR

7. DISEASE MANAGEMENT

7.1 Neoadjuvant therapy

7.1.1 Introduction

The standard treatment for patients with urothelial MIBC and MIBC with subtypes is RC. However, RC only provides 5-year survival in about 50% of patients [248-250]. To improve survival in patients with cN0M0 disease, cisplatin-based NAC has been used since the 1980s [248-252].

7.1.2 Role of cisplatin-based chemotherapy

There are theoretical advantages and disadvantages of administering chemotherapy before planned definitive surgery to patients with resectable muscle-invasive cN0M0 UC of the bladder:

- Chemotherapy is delivered at the earliest time-point, when the burden of micrometastatic disease is expected to be low.
- Potential reflection of *in vivo* chemosensitivity.
- Tolerability of chemotherapy and patient compliance are expected to be better pre-cystectomy.
- Patients may respond to NAC and have a favourable pathological response as determined mainly by achieving ypT0, ≤ ypT1, ypN0 and negative surgical margins. An analysis to identify the optimal definition of pathological response reported a significantly higher risk of recurrence in patients with ypTaN0 or ypT1N0 disease (with or without Tis) at RC and thus proposed that optimal pathological response after NAC be defined as attainment of ypT0N0/ypTisN0 at RC [253].
- Delayed cystectomy might compromise the outcome in patients not sensitive to chemotherapy [254-256]. A comparative survival analysis of patients treated with NAC and RC vs. RC alone based on data from the U.S. National Cancer Database showed that organ-confined disease (≤ pT2) after NAC was associated with decreased risk of death (HR: 0.85, 95% CI: 0.79–0.91) compared to RC alone, whereas > pT2 was associated with increased risk of death (HR: 1.46, 95% CI: 1.34–1.60) [257]. However, there are no prospective trials indicating that delayed surgery due to NAC has a negative impact on survival. In the phase III VESPER trial, comparing gemcitabine/cisplatin (GC) vs. high-dose-intensity methotrexate, vinblastine, doxorubicine and cisplatin (HD-MVAC) in the peri-operative setting, approximately 90% of patients proceeded to surgery (with median delay of 48 days for GC and 51 days for dd-MVAC) [258].
- Neoadjuvant chemotherapy does not seem to affect the outcome of surgical morbidity. In a recently reported large multicenter retrospective analysis, NAC did not lead to an increased risk of post-operative complications after RC [259]. In the combined Nordic trials (n = 620), NAC did not have a major adverse effect on the percentage of performable cystectomies. The cystectomy frequency was 86% in the experimental arm and 87% in the control arm with 71% of patients receiving all three chemotherapy cycles [260].
- Clinical staging using bimanual palpation, CT or MRI may result in over- and understaging and have a staging accuracy of only 70% [87]. Overtreatment is a possible negative consequence.
- Gender may have an impact on chemotherapeutic response and oncologic outcomes [261, 262]. Female patients tend to have a better cancer-related response to NAC as compared to male patients.
- Neoadjuvant chemotherapy should only be used in patients eligible for cisplatin-combination chemotherapy; other combinations (or monotherapies) are inferior in metastatic BC and have not been fully tested in a neoadjuvant setting [263-270].

7.1.2.1 Summary of available data

Several phase III RCTs addressed the potential survival benefit of NAC administration [263-267, 271-274]. The main differences in trial designs were the type of chemotherapy (i.e., single-agent cisplatin or combination chemotherapy) and the number of cycles provided. Patients had to be fit for cisplatin. Since these studies differed considerably for patient numbers, patient characteristics (e.g., clinical T-stages included) and the type of definitive treatment offered (cystectomy and/or RT), pooling of results was not possible.

Three meta-analyses were undertaken to establish if NAC prolongs survival [268-270]. In a meta-analysis including updated patient data from 11 randomised trials (n = 3,005), a significant survival benefit was shown in favour of NAC [270]. The most recent meta-analysis included four additional RCTs, and used the updated results from the Nordic I, Nordic II, and BA06 30894 trials including data from 427 new patients and updated information from 1,596 patients. The results of this analysis confirmed the previously published data and showed an 8% absolute improvement in survival at five years with a number needed-to-treat of 12.5 [275]. Only cisplatin-combination chemotherapy with at least one additional chemotherapeutic agent resulted in a meaningful therapeutic benefit [268, 270]; the regimens tested were methotrexate, vinblastine, adriamycin (epirubicin) plus cisplatin (MVA(E)C), cisplatin, methotrexate plus vinblastine (CMV), cisplatin plus methotrexate (CM), cisplatin plus adriamycin and cisplatin plus 5-fluorouracil (5-FU) [276].

The updated analysis of a large phase III RCT [264] with a median follow-up of eight years confirmed previous results and provided additional findings:

- 16% reduction in mortality risk;
- improvement in 10-year survival from 30% to 36% with neoadjuvant CMV;
- benefit with regard to distant metastases;
- the addition of neoadjuvant CMV provided no benefit for locoregional control and locoregional DFS, independent of the definitive treatment.

More modern chemotherapeutic regimens such as GC have shown similar pT0/pT1 rates as methotrexate, vinblastine, adriamycin plus cisplatin in retrospective series and pooled data analyses [276-279]. Modified dd-MVAC was tested in two small single-arm phase II studies demonstrating high rates of pathologic complete remission [280, 281]. Moreover, a large cross-sectional analysis showed higher rates of down-staging and pathological complete response for dd-MVAC [282].

In the GETUG/AFU V05 VESPER RCT of peri-operative chemotherapy, 500 patients were randomised to either 6 cycles of dd-MVAC once every 2 weeks vs. 4 cycles of GC once every 3 weeks prior to surgery (neoadjuvant group) or after surgery (adjuvant group) with a primary endpoint of progression-free survival (PFS) at 3 years. In 493 patients (437 neoadjuvant and 56 adjuvant), a similar pathologic response rate (ypT0N0) in patients treated with dd-MVAC 42% and GC 36% (p = 0.2) was seen. The < ypT2N0 rate was 63% and 50% in the dd-MVAC and GC patients, respectively. Organ-confined response (< ypT3N0) was observed more frequently in the dd-MVAC arm (77% vs. 63%, p = 0.001). For all patients in the trial, 3-year PFS was improved in the dd-MVAC arm, but the study did not meet its primary endpoint (3-year rate: 64% vs. 56%, HR: 0.77 [95% CI: 0.57–1.02], p = 0.066); nevertheless, the dd-MVAC arm was associated with a significantly longer time to progression (3-year rate: 69% vs. 58%, HR: 0.68 [95% CI: 0.50–0.93], p = 0.014). In the neoadjuvant group, PFS at 3 years was significantly higher in the dd-MVAC arm (66% vs. 56%, HR: 0.70 [95% CI: 0.51–0.96], p = 0.025). Dose- dense MVAC was associated with more severe asthenia and GI side effects than GC [258, 283]. In a single-center retrospective analysis in patients with MIBC, neoadjuvant accelerated MVAC was safe and efficacious irrespective of age, provided that patients were fit and deemed suitable candidates for cisplatin [284]. Another dose- dense regimen using GC was reported in two small phase II trials [285, 286]. While pathological response rates (< pT2) in the range of 45%–57% were achieved, one trial had to be closed prematurely due to high rates of severe vascular events [285]. This approach is therefore not recommended outside of clinical trials.

As an alternative to the standard dose of cisplatin-based NAC with 70 mg/m2 on day 1, split-dose modifications regimens are often used with 35 mg/m2 on days 1+8 or days 1+2. In a retrospective analysis the standard schedule was compared to a split-dose schedule in terms of complete and partial pathological response. A lower number of complete and partial response rates was seen in the split-dose group, but these results were not statistically significant [287].

Efforts aimed at improving the efficacy of NAC in MIBC are ongoing. In the double- blind, randomised, placebo-controlled, phase II NEOBLADE trial of neoadjuvant gemcitabine and cisplatin chemotherapy with nintedanib, a small molecule inhibitor that targets tyrosine kinases PDGFR, FGFR-1, and VEGFR-2, or placebo, in locally-advanced MIBC, the addition of nintedanib to chemotherapy was safe but did not improve the rate of pathological complete response [288].

There seem to be differences in the outcomes of patients treated with NAC for primary or secondary MIBC with retrospective data suggesting that patients with primary MIBC have better pathologic response rates to NAC in comparison to patients with secondary MIBC [289]. However, in the absence of prospective data, patients with secondary MIBC should be treated similarly to those presenting with primary MIBC [225].

It is unclear, if patients with non-UC histology will also benefit from NAC. A retrospective analysis demonstrated that patients with neuroendocrine tumours had improved OS and lower rates of non-organ-confined disease when receiving neoadjuvant cisplatinum/etoposide chemotherapy. In case of micropapillary differentiation, sarcomatoid differentiation and adenocarcinoma, lower rates of non-organ confined disease were found, but no statistically significant impact on OS. Patients with SCC did not benefit from NAC [290]. A 2019 systematic review showed benefit of NAC for patients with micropapillary-, plasmacytoid-, sarcomatoid-, and mixed variants but especially for patients with neuroendocrine tumours [66]. A U.S. National Cancer Database study evaluating potential associations between receipt of NAC, pathological downstaging and OS for patients with histological subtype MIBC demonstrated that NAC was associated with pathological downstaging for all MIBC histological subtypes (UC; sarcomatoid UC; micropapillary UC; SCC; neuroendocrine carcinoma; and adenocarcinoma), with improved OS for patients with UC, sarcomatoid variant UC and neuroendocrine carcinoma [291].

7.1.3 ***The role of imaging and predictive biomarkers*** *(see also section 5.2)*

Data from small imaging studies aiming to identify responders in patients treated with NAC suggest that response after two cycles of treatment is predictive of outcome. Although mpMRI has the advantage of better resolution of the bladder wall tissue planes as compared to CT, it is not ready yet for standard patient care. However, bladder mpMRI may be useful to inform on tumour stage after TURB and response to NAC [119]. So far PET/CT, MRI or DCE-MRI cannot accurately assess treatment response [292-295]. To identify progression during NAC, imaging is being used in many centres notwithstanding the lack of supporting evidence.

For responders to NAC, especially in those with a complete response (pT0 N0), treatment has a major positive impact on OS [296, 297]. Therefore, reliable predictive markers to identify patients most likely to benefit from chemotherapy are needed. A study investigated how molecular subtypes impact pathological response and survival in patients receiving pre-operative cisplatin-based chemotherapy [298]. Patients with genomically unstable (GU) and urothelial-like (Uro) tumours had higher proportions of complete pathological response (16/31 [52%] and 17/54 [31%] vs. 5/24 (21%) for the basal/squamous (Ba/ Sq) subtype) following NAC and RC. Molecular subtype was independently associated with improved survival for patients with GU tumours (HR: 0.29, 95% CI: 0.11–0.79) and UroC tumours (HR: 0.37, 95% CI: 0.14–0.94) compared with Ba/Sq tumours, adjusting for clinical stage. Molecular tumour profiling might guide the use of NAC in the future but, as yet, this is not applicable in routine practice [299-301] (see Chapter 6 - Markers).

7.1.4 ***Role of neoadjuvant immunotherapy and chemo-immunotherapy***

Inhibition of PD-1/PD-L1 checkpoint has demonstrated significant benefit in patients with unresectable and metastatic BC in the second-line setting and in platinum-ineligible PD-L1+ patients as first-line treatment using different agents. Checkpoint inhibitors are increasingly tested also in the neoadjuvant setting; either as monotherapy or in combination with chemotherapy or CTLA-4 checkpoint inhibition. Data from two phase II trials have been presented with encouraging results [241, 242]. The results of PURE-01, a phase II trial using the PD-1 inhibitor pembrolizumab reported a complete pathological remission (pT0) in 42% and pathological response (< pT2) in 54% of patients, whereas in the single-arm phase II trial with atezolizumab a pathologic complete response rate of 31% was reported. In an update to the ABACUS trial using single-agent atezolizumab, two-year DFS and OS were 68% (95% CI: 58–76) and 77% (95% CI: 68–85), respectively with two-year DFS in patients achieving a pathological complete response of 85% (95% CI: 65–94) [302]. In a update of PURE-01, after a median follow-up of 39 months, 36-month EFS and OS were 74% (95% CI: 68-82) and 84% (95% CI: 78-90), respectively with RFS in patients achieving a complete pathologic response of 96% (95% CI: 89-100) [303]. The combination of anti-CTLA4 and anti-PD1 therapy has also been investigated in the neoadjuvant setting. In the NABUCCO study using pre-operative ipilimumab and nivolumab, the pathologic complete response was 46% with 58% having no remaining invasive disease (pT0N0/pTisN0/pTaN0) [304]. In a second study using pre-operative tremelimumab and durvalumab in cisplatin-ineligible patients, the pathological complete response was 37.5% and downstaging to pT1 or less was seen in 58% of patients who completed surgery [305].

Three studies have been published to date investigating the use of neoadjuvant chemo-immunotherapy in patients with MIBC. In a phase II study of gemcitabine plus split-dose cisplatin and pembrolizumab in patients with MIBC, 22 of 39 patients (56% [95% CI: 40–72]) achieved < pT2N0 and 14 of 39 (36% [95% CI: 21–53]) achieved pT0N0 [306]. In a second phase II study evaluating neoadjuvant atezolizumab with gemcitabine and cisplatin; 27 of 39 patients (69%) were < pT2N0 and 16 (41%) pT0N0. No patient with < pT2N0 relapsed and four (11%) with ≥ pT2N0 relapsed with a median follow-up of 16.5 months (range: 7.0–33.7 months) [307]. A third phase II study evaluating NAC with GC plus durvalumab including adjuvant durvalumab with a primary endpoint of EFS demonstrated EFS at 3 years of 73% (95% CI, 59 to 83). Complete pathologic response was achieved in 17 of 52 patients (33%), and 31 (60%) had pathologic response <ypT2 ypN0. Overall survival (OS) was 81% (95% CI, 67 to 89) at 3 years. With the promising pathologic response rates, several larger studies are currently investigating the potential role for neoadjuvant chemo-immunotherapy in patients with MIBC [308].

At present, the results with immunotherapy alone, or in combination with chemotherapy, are promising but not yet approved in routine practice.

7.1.5 Summary of evidence and guidelines for neoadjuvant therapy

Summary of evidence	LE
Neoadjuvant cisplatin-containing combination chemotherapy improves OS (8% at five years).	1a
Neoadjuvant treatment may have a major impact on OS in patients who achieve ypT0 or ≤ ypT2.	2a
Currently immunotherapy with checkpoint inhibitors as monotherapy, or in different combinations with or without chemotherapy, is being tested in phase II and III trials. Initial results are promising.	-
There are still no reliable tools available to select patients who have a higher probability of benefitting from NAC. In the future, genetic markers in a personalised medicine setting might facilitate the selection of patients for NAC and differentiate responders from non-responders.	-

Recommendations	Strength rating
If eligible for cisplatin-based chemotherapy, offer neoadjuvant cisplatin-based combination chemotherapy to patients with muscle-invasive bladder cancer (T2-T4a, cN0 M0).	Strong
Do not offer NAC to patients who are ineligible for cisplatin-based combination chemotherapy.	Strong
Only offer neoadjuvant immunotherapy to patients within a clinical trial setting.	Strong

7.2 Pre- and post-operative radiotherapy in muscle-invasive bladder cancer

7.2.1 Post-operative radiotherapy

Given the high rates of local-regional failure after RC in patients with locally-advanced (pT3–4) BC, estimated at ~30%, as well as the high risk of distant failure and poor survival for these patients, there is an interest in adjuvant therapies that address both the risk of local and distant disease. Data on adjuvant RT after RC are limited and further prospective studies are needed, but a more recent phase II trial compared adjuvant sequential chemotherapy and radiation vs. adjuvant chemotherapy alone in 120 patients with locally-advanced disease and negative margins after RC (with one or more risk factors: ≥ pT3b, grade 3, or node-positive), in a study population with 53% UC and 47% SCC. Addition of adjuvant RT to chemotherapy alone was associated with a statistically significant improvement in local relapse-free survival (at 2 years 96% vs. 69% favouring the addition of RT). Disease-free survival and OS also favoured the addition of RT, but those differences were not statistically significant and the study was not powered for those endpoints. Late-grade ≥ 3 GI toxicity in the chemoradiation arm was low (7% of patients) [309].

A 2019 systematic review evaluating the efficacy of adjuvant radiation for BC or UTUC found no clear benefit of adjuvant radiation following radical surgery (e.g., cystectomy), although the combination of adjuvant radiation with chemotherapy may be beneficial in locally-advanced disease [310].

Adjuvant radiation might be considered in patients with pT3/pT4 pN0–2 urothelial BC following RC, although this approach has been evaluated in only a limited number of studies without conclusive data demonstrating improvements in OS. Radiation fields should encompass areas at risk for harbouring residual microscopic disease based on pathologic findings at surgery and may include the cystectomy bed and pelvic LNs. Doses in the range of 45 to 50.4 Gy may be considered. A phase II trial with 72 patients showed that a dose of 50.4 of radiotherapy Gy can be used with acceptable toxicity and a high rate of local control [311]. A small retrospective study of 25 patients (median age 64 years) evaluated acute and late toxicity of moderate doses of pelvic RT (range, 45–50.4 Gy). After a median follow-up of 10.4 months the authors concluded that orthotopic ileal neobladders can tolerate moderate radiation doses without significant induced morbidity. Most of the acute GI toxicity seen was grade 1, four patients developed acute grade 2 toxicity; three of whom had been treated by NAC [312]. For patients not treated with NAC, it may be reasonable to sandwich adjuvant radiation between cycles of adjuvant chemotherapy. The safety and efficacy of concurrent radiosensitising chemotherapy in the adjuvant setting needs further study.

7.2.2 Pre-operative radiotherapy

To date, six RCTs have been published investigating pre-operative RT, although all are from several decades ago. In the largest trial, pre-operative RT at a dose of 45 Gy was used, resulting in a significant increase in pathological complete response (9% to 34%) in favour of pre-operative RT, which was also a prognostic factor for survival [313]. The OS data were difficult to interpret since chemotherapy was used in a subset of patients only and more than 50% of patients (241/475) did not receive the planned treatment and were excluded from the final analyses. Two smaller studies using a dose of 20 Gy showed only a small survival advantage

in ≥ T3 tumours [314, 315]. Two other small trials confirmed downstaging after pre-operative RT [316, 317]. In a retrospective analysis of 1,846 evaluable patients, only 34 patients received RT prior to orthotopic neobladder reconstruction. The authors conclude that following pelvic RT, a neobladder is possible in highly selected patients with statistically similar peri-operative complication rates compared to patients who did not receive prior RT. Patient selection, with oncologic factors (positive urethral margins, nodal involvement, and extravascular disease) more commonly than technical factors (adhesions/difficult dissection, bleeding, urethral stricture) influencing conversion from a planned neobladder reconstruction [318].

A meta-analysis of five RCTs showed a difference in 5-year survival (OR: 0.71, 95% CI: 0.48–1.06) in favour of pre-operative RT [319]. However, the meta-analysis was potentially biased by data from the largest trial in which patients were not given the planned treatment. When the largest trial was excluded from the analysis, the OR became 0.94 (95% CI: 0.57–1.55), which was not significant.

A more recent RCT, comparing pre-operative vs. post-operative RT and RC (n = 100), showed comparable OS, DFS and complication rates [320]. Approximately half of these patients had UC, while the other half had SCC. In general, such older data is limited in being able to provide a robust evidence base for modern guideline recommendations.

7.2.3 Local therapy (surgery or radiotherapy) in oligometastatic disease

The other disease state for which there may be an emerging role for adding local therapy Is oligometastatic bladder cancer. Oligometastatic status is defined as a situation with a limited number of metastatic sites. In a recent consensus, a maximum of three metastatic sites, all either resectable or amenable to stereotactic therapy, was proposed as the definition of oligometastatic bladder cancer [321]. Studies from other tumour types (prostate cancer, colorectal cancer and lung cancer) suggest possible survival benefit when adding local therapy. In bladder cancer, some retrospective studies suggest a potential survival benefit when incorporating local therapy to the bladder (including radiation therapy over chemotherapy alone) in metastatic disease [322, 323], and when employing metastasis-directed therapy. [324-327] A favourable response to systemic treatment was proposed as the criterion for selection of patients for any metastasis-directed therapy [321]. However, the data in oligometastatic disease are limited and further prospective study in bladder cancer patients is needed.

7.2.4 Summary of evidence and guidelines for pre- and post-operative radiotherapy

Summary of evidence	LE
No contemporary data exists to support that pre-operative RT for operable MIBC increases survival.	2a
Pre-operative RT for operable MIBC, using a dose of 45–50 Gy in fractions of 1.8–2 Gy, results in down-staging after 4 to 6 weeks.	2
Limited evidence supports the safe use of pre- and post-operative RT in case a neobladder is planned or *in situ*.	3
Limited high-quality evidence supports the use of pre-operative RT to decrease local recurrence of MIBC after RC.	3
Addition of adjuvant RT to chemotherapy is associated with an improvement in local relapse-free survival following cystectomy for locally-advanced bladder cancer (pT3b–4, or node-positive).	2a
There are no randomised trials showing an effect for local therapy in oligometastastic bladder cancer.	1
Retrospective case series show some survival benefit for the additional of local therapy (to the primary and to sites of metastases) in oligometastatic bladder cancer.	3

Recommendations	Strength rating
Do not offer pre-operative radiotherapy (RT) for operable muscle-invasive bladder cancer since it will only result in down-staging, but will not improve survival.	Strong
Do not offer pre-operative RT when subsequent radical cystectomy (RC) with urinary diversion is planned.	Strong
Consider offering adjuvant RT in addition to chemotherapy following RC, based on pathologic risk (pT3b–4 or positive nodes or positive margins).	Weak
Inform patients with oligometastatic disease about local therapy treatment options. Patients should be carefully selected for treatment and fully informed of the potential benefits and harms of the different treatment modalities as well as the fact that there is no definitive evidence supporting local therapy inoligometastatic disease.	Weak

7.3 Radical surgery and urinary diversion

*7.3.1 **Removal of the tumour-bearing bladder***

7.3.1.1 Introduction

For decades, the standard treatment for patients with MIBC consisted of RC, pelvic LN dissection, and urinary diversion, with or without NAC [603]. However, an increasing focus on quality of life contributes to a growing trend to use bladder-sparing approaches such as RT or TMT in selected patients (see section 7.5). A multi-institutional propensity score matched and weighted analysis showed comparable oncological outcomes between radical cystectomy and TMT for selected MIBC patients [328]. Performance status and life expectancy obviously influence the choice of primary treatment, as does the type of urinary diversion, with RC being reserved for patients with longer life expectancy without concomitant disease and better PS.

7.3.1.2 Radical cystectomy: timing

A meta-analysis including 19 studies concluded that a delay of > 3 months has a negative effect on OS (HR: 134, 95% CI: 1.18–1.53). Authors highlighted the lack of standardisation regarding the definition of delays which made it impossible to identify a clear cut-off time [329]. Overall conclusion was that BC patients scheduled for RC should be treated without delays to maximise survival.

*7.3.2 **Radical cystectomy: indications***

Radical cystectomy is recommended in patients with T2–T4a, N0M0 disease, very high-risk NMIBC, BCG-refractory, BCG-relapsing and BCG-unresponsive NMIBC (see EAU Guidelines on Non-muscle-invasive Bladder Cancer [2]), as well as extensive papillary disease that cannot be controlled with TURBT and intravesical chemotherapy/immunotherapy alone.

Salvage cystectomy is indicated in non-responders to conservative therapy, i.e., recurrence after bladder-sparing treatment. It is also used as a purely palliative intervention, including for fistula formation, pain and recurrent uncontrollable haematuria (see Section 7.4.1 - Palliative cystectomy).

*7.3.3 **Radical cystectomy: technique and extent***

Different approaches have been described to improve voiding and sexual function in patients undergoing RC for BC. No consensus exists regarding which approach preserves function best. Concern remains regarding the impact of 'sparing-techniques' on oncological outcomes.

7.3.3.1 Radical cystectomy in men

In men, standard RC includes removal of the bladder, prostate, seminal vesicles, distal ureters, and regional LNs.

7.3.3.1.1 Concomitant prostate cancer

A systematic review and meta-analysis of 13,140 patients showed an incidental prostate cancer rate of 24% [330]. Incidental prostate cancer was associated with higher age and lower 5-year OS. However, the lower OS can be explained by the higher age of patients with incidental prostate cancer. Pathological reporting of the specimens should follow the recommendations as presented in the EAU-EANM-ESTRO-ESUR-ISUP-SIOG Guidelines on Prostate Cancer [331].

7.3.3.1.2 Sexual-preserving techniques

Four main types have been described:

1. **Prostate sparing cystectomy:** part of or the whole prostate is preserved including seminal vesicles, vas deferens and neurovascular bundles.
2. **Capsule sparing cystectomy:** the capsule or peripheral part of the prostate is preserved with adenoma (including prostatic urethra) removed by TURP or *en bloc* with the bladder. Seminal vesicles, vas deferens and neurovascular bundles are also preserved.
3. **Seminal sparing cystectomy:** seminal vesicles, vas deferens and neurovascular bundles are preserved.
4. **Nerve-sparing cystectomy:** the neurovascular bundles are the only tissue left in place.

The systematic review on oncological and functional outcomes of sexual function-preserving cystectomy in men indentified 12 studies (n = 1,098) [332]. In the majority of cases, an open surgical approach was used and the urinary diversion of choice was an orthotopic neobladder. Median follow-up was longer than three years in nine studies, with three studies presenting results with a median follow-up longer than five years.

The majority of the studies included patients who were potent pre-operatively with organ-confined disease without tumour in the bladder neck and/or prostatic urethra. Prostate cancer was ruled out in all of the sexual-preserving cystectomy (SPC) techniques, except in the nerve-sparing approach [331].

Oncological outcomes did not differ between groups in any of the comparative studies that measured local recurrence, metastatic recurrence, DSS and OS, at a median follow-up of three to five years.

For techniques preserving prostatic tissue (prostate- or capsule-sparing), rates of incidental prostate cancer in the intervention group ranged from 0–15%. Incidental prostate cancer with ISUP grade ≥ 4 was not reported.

Post-operative potency was significantly better in patients who underwent any type of SPC technique compared to conventional RC ($p < 0.05$), ranging from 80–90%, 50–100% and 29–78% for prostate-, capsule- or nerve-sparing techniques, respectively. Urinary continence, defined as the use of 'no pads' in the majority of studies, ranged from 88–100% (day-time continence) and from 31–96% (night-time continence) in the prostate-sparing cystectomy patients. No major differences were seen with regard to continence rates between any of these approaches.

The evidence base suggest that these procedures may yield better sexual outcomes than standard RC without compromising oncological outcomes. However, the overall quality of the evidence was moderate, and hence if a SPC technique is offered, patients must be carefully selected, counselled and closely monitored.

7.3.3.1.3 Summary of evidence and recommendations for sexual-preserving techniques in men

Summary of evidence	**LE**
The majority of eligible patients motivated to preserve their sexual function will benefit from sexual-preserving techniques.	2a
None of the sexual-preserving techniques (prostate/capsule/seminal/nerve-sparing) have shown to be superior, and no particular technique can be recommended.	3

Recommendations	**Strength rating**
Only offer sexual-preserving techniques to eligible men very motivated to preserve their sexual function.	Strong
Select patients based on: • organ-confined disease; • absence of any kind of tumour at the level of the prostate, prostatic urethra or bladder neck.	Strong

7.3.3.2 Radical cystectomy in women

Historically, standard RC in women includes removal of the bladder, the entire urethra and adjacent vagina, uterus, distal ureters, and regional LNs. Pelvic floor disorders, sexual and voiding dysfunction in female patients are prevalent after RC [333]. As part of the pre-operative evaluation a gynaecological history should be obtained and patients should be counselled on the potential negative impact of RC on sexual function and/ or vaginal prolapse. Most importantly, a history of cervical cancer screening, abnormal vaginal bleeding and a family history of breast and/or ovarian cancer should be recorded, as well as ruling out possible pelvic organ prolapse. Post-operatively, screening for sexual and urinary function and prolapse, is mandatory.

Pelvic organ-preserving techniques involve preserving the neurovascular bundle, vagina, uterus, ovaries or variations of any of the stated techniques. From an oncological point of view, concomitant malignancy in gynaecological organs is rare and local recurrences reported after RC are infrequent [334, 335]. In premenopausal women, by preserving ovaries, hormonal homeostasis will be preserved, decreasing risk of cognitive impairment, cardiovascular diseases and loss of bone density. In case of an increased risk of hereditary breast or ovarian cancer (i.e., BRCA1/2 mutation carriers or patients with Lynch syndrome), salpingooophorectomy should be advised after childbearing and to all women over 40 years of age [336]. On the other hand, preservation of the uterus and vagina will provide the necessary support for the neobladder, thereby reducing the risk of urinary retention. It also helps to avoid post-operative prolapse as removal of the uterus predisposes to an anterior or posterior vaginal prolapse. In case of an already existing prolapse of the uterus, either isolated or combined with a vaginal prolapse, removing the uterus will be beneficial. It is noteworthy that by resecting the vaginal wall, the vagina shortens which could impair sexual satisfaction and function.

Based on retrospective low quality data only, a systematic review evaluating the advantages and disadvantages of sexual-function preserving RC and orthotopic neobladder in female patients concluded that in well-selected patients, sparing female reproductive organs during RC appears to be oncologically safe and provides improved functional outcomes [337]. Historically, patients selection has been limited to cT2 disease, but there are recent encouraging reports that support including women with more advanced T-stage and histological subtypes without compromising oncological outcomes [338]. Nevertheless, a cross-sectional survey

of more than 100 members of the US Society of Urologic Oncology identified significant gaps in adoption of sexual preserving techniques fo rwomen with organ-confined disease; however, in 80% a non-sexual preserving technique was still applied [339].

Pelvic organ-preserving RC could be considered also in elderly and fragile patients as it may be beneficial from the point of reduced blood loss and quicker bowel recovery [340]. Nevertheless, a cross-sectional study among more than 100 members of the Society of Urologic Oncology showed that in the US a non-sex-sparing technique is still used in 80% of cases [339].

7.3.3.2.1 Summary of evidence and recommendations for sexual-preserving techniques in women

Summary of evidence	LE
Data regarding pelvic organ-preserving RC for female patients remain immature.	3

Recommendations	Strength rating
Offer sexual organ-preserving techniques to eligible women to preserve their sexual function.	Strong
Select patients based on: • absence of tumour in the area to be preserved to avoid positive soft tissue margins; • absence of pT4 urothelial carcinoma.	Strong

*7.3.4 **Lymphadenectomy: role and extent***

The optimal extent of lymphadectomy (LND) has not been established to date. Standard LND in MIBC patients involves removal of nodal tissue cranially up to the common iliac bifurcation, with the ureter being the medial border, and including the internal iliac, presacral, obturator fossa and external iliac nodes. The lateral borders are the genitofemoral nerves, caudally the circumflex iliac vein, the lacunar ligament and the LN of Cloquet [341]. Limited LND includes the nodes from the true pelvis, but excluding the deep obturator nodes. Extended LND includes the same boundaries as a standard LND, except for the cranial limit which is the region of the aortic bifurcation [342]. A super-extended LND extends cranially to the level of the inferior mesenteric artery [343].

Controversies in the clinical importance of LND are related to the question whether it should be considered a staging tool, a therapeutic procedure, or both.

7.3.4.1 Diagnostic value of lymphadenectomy

To understand the lymphatic spread in MIBC, two important autopsy studies have been performed. The first study analysed 367 patients with a history of cystectomy or MIBC at the time of autopsy. In total, 215 patients (59%) had node-positive disease [344]. In these patients 92% of the positive LNs were regional (perivesical or pelvic), 72% retroperitoneal and 35% abdominal.

The second autopsy study focused on the nodal yield when super-extended pelvic LND was performed. Substantial inter-individual differences were found with counts ranging from 10 to 53 nodes [345]. These findings demonstrate the limited utility of node count as a surrogate for extent of dissection, supporting a template-based LND instead.

In addition to autopsy studies, several authors adressed the spread of lymphatic disease by performing LN mapping studies in MIBC patients undergoing RC and (super)extended PLND [346-348]. These studies have demonstrated that LN-positive disease is present in approximately 25% of patients. In the group of node-positive patients, positive LNs cranial to the iliac bifurcation were present in over 40% of patients, however, skip LN metastasis were very rare (1%), as seen in autopsy studies. From a staging perspective only, these studies suggest that a standard LND should be sufficient to identify nearly all patients with node-positive disease.

7.3.4.2 Therapeutic value of lymphadenectomy

The therapeutic value of LND is a topic of continuous debate. To assess the oncological outcomes of different LND templates, a systematic review including 19 studies was performed [349]. Five studies compared LND vs. no LND and reported better oncological outcomes for the LND group. Seven out of twelve studies comparing (super)extended with limited or standard LND reported a beneficial outcome for (super)extended LND in at least a subset of patients. Two studies did not show a difference in outcome between extended and super-extended LND [349].

The two prospective randomised trials investigating the anatomic extend of the LND are the German LEA trial and the US/Canadien SWOG S1011 trial. In the LEA trial, patients with MIBC (n = 346) or T1G3 disease (n = 55) were included. Patients underwent either a limited LND (n= 203) or extended LND (n = 198). Survival differences between the groups were seen, in favour of extended LND. However, extended LND failed to show a significant advantage (the trial was designed to show an absolute improvement of 15% in 5-year RFS by extended LND) over limited LND for RFS, CSS, and OS. The results of the SWOG S1011 trial comparing standard versus extended LND, presented at the 2023 ASCO meeting, showed in patients with clinically localised bladder cancer after a median six years follow-up no DFS (HR 1.10 [95%CI 0.87-1.42] p=0.4) or OS (HR 1.15 [95%CI 0.89-1,48] p=0.29) benefit for an extended LND. It does, however, increase the risk of side effects and post-operative mortality.

In conclusion, based on these two RCT's, an extended LND, is not associated with improved survival and increases the risk of morbidity.

7.3.5 ***Robotic-assisted laparoscopic cystectomy***

A 2019 Cochrane SR of five RCTs compared robotic radical cystectomy (RARC) with extacorporeal urinary diversion and open radical cystectomy (ORC) [350]. One study included an laparoscopic radical cystectomy arm (LRC) [351]. No differences were found in complications, time to recurrence, QoL and surgical margin rate for RARC and ORC. RARC was associated with lower transfusion rate and shorter length of hospital stay (median 0.7 days). The study had very-low to moderate certainty of evidence.

In 2023, an updated SR and meta-analysis was published including eight RCTs of which three studies performed intracorporeal urinary diversion [352]. The ERAS pathway was adopted in one study with extracorporeal urinary diversion and in three studies with intracorporeal urinary diversion [351, 353-355]. The following outcomes were reported:

- Longer length of hospital stay for ORC (0.2 days); however, differences were seen depending on geographical location. In four USA and two UK trials longer hospital stay for ORC was reported (0.6 and 1.5 days, respectively) whilst in two EU based trials longer hospital stay for RARC was reported (0.9 days).
- Higher venous trombo-events (OR 1.8) and transfusion rates (0.5 blood units) for ORC.
- Longer operative time for RARC (mean difference: 76 min).
- No differences in 90-day complication rate and post-operative ileus rate.
- No differences in positive surgical margin rate.
- No differences in QoL except for the domain of phsyical functioning favouring RARC.
- No differences in OS and RFS (median follow-up time: 36 months).

It should be noted that the meta-analysis did not distinguish between intracorporeal and extracorporeal approaches for urinary diversion in the RARC group.

Long-term oncological outcomes were also reported in a large (n = 595) single-centre study with a median follow-up of over five years. In this study comparable recurrence and survival data, including atypical recurrences (defined as one or a combination of the following: portsite metastasis or peritoneal carcinomatosis) [356]. Interrestingly, another study detected residual cancer cells in pelvic washing specimens during or after, but not before, RARC in approximately half of the patients (9/17), which was associated with aggressive histological subtypes and cancer recurrence; however, these findings requirer confirmation in larger studies [357].

An economic evaluation (healthcare and societal perspective) of a Dutch prospective multi-centre comparative effectiveness study asessing ORC (n = 168) vs. RARC (n = 180) showed that both mean healthcare costs and societal costs per patient were significantly higher after RARC, resulting in an increase in QALYs of 0.02 [358].

Data on post-RC uretero-enteric stricture rates for both ORC and RARC remain inconclusive. Results are mainly reported by high-volume centres or derive from population-based studies with a large variety of endpoints and poor controlling of potential confounders, making comparison difficult [359-363]. Especially those managed by extracorporeal diversion (RARC-ECUD) tend to have more strictures compared to intracorporeal diversion (RARC-ICUD) [363]. This is explained by the need for more extensive dissection of ureter in RARC-ECUD, more tension, resulting in impaired blood supply [364, 365].

7.3.5.1 Summary of evidence and guidelines for robotic-assisted laparoscopic cystectomy

Summary of evidence	LE
Robot-assisted radical cystectomy (RARC) and open radical cystectomy (ORC) provide similar 90-day complication rates, surgical margin rates, median-term oncological outcomes and quality of life outcome.	1a
Operative time is longer for RARC compared to ORC (1 to 1.5 hours), but with less blood loss and possibly shorter length of hospital stay compared to ORC.	1a
Surgeons experience and institutional volume are considered the key factor for outcome of both RARC and ORC, not the technique.	4

Recommendations	Strength rating
Inform the patient of the advantages and disadvantages of open radical cystectomy (ORC) and robot-assisted radical cystectomy (RARC) to allow selection of the proper procedure.	Strong
Select experienced centres, not specific techniques, both for RARC and ORC.	Strong

*7.3.6 **Urinary diversion after radical cystectomy***

Different types of segments of the intestinal tract can be used to reconstruct the urinary tract, including the ileum, colon and appendix, with ileum used in most cases. Several studies have compared advantages and disadvantages in terms of QoL, sexual function, urinary continence and body image between different urinary diversions [366], but further research evaluating the impact of tumour stage, functional- and socio-economic status are needed.

7.3.6.1 Different types of urinary diversion

For the choice of urinary diversion, comorbidity, cardiac, pulmonary and cognitive function are important factors that should be considered, along with the patient's social support and preference (see Section patient selection/ comorbidities). Age > 80 years is often considered to be the threshold after which neobladder reconstruction is not recommended. However, there is no exact age for a strict contraindication [367]. Randomised controlled trials comparing conduit diversion with neobladder or continent cutaneous diversion have not been performed.

7.3.6.1.1 Uretero-cutaneostomy

Ureteral diversion to the abdominal wall is the simplest form of cutaneous diversion. Operating time, complication rate, blood loss, transfusion rate, stay at intensive care and length of hospital stay are lower in patients treated with ureterocutaneostomy as compared to ileal conduit [368]. In frail patients and/or in those with a solitary kidney who need a supravesical diversion, uretero-cutaneostomy is the preferred procedure. In case patients have both kidneys and need a uretero-cutaneostomy, either one ureter, to which the other shorter one is attached end-to-side, is connected to the skin (trans-uretero-cutaneostomy) or both ureters may be directly anastomosed to the abdominal wall creating a stoma.

Due to the smaller diameter of the ureters, stoma stenosis and ascending UTIs have been observed more frequently for this technique as compared to using small or large bowel to create an intestinal stoma [369].

7.3.6.1.2 Ileal conduit

The ileal conduit is an established option with well-known/predictable results. Early complications (30-day cut off, used in most publications) include UTIs, pyelonephritis, ureteroileal leakage and stenosis which occur in 48% of patients [370].

7.3.6.1.3 Orthotopic neobladder

According to Dutch-, German- and Spanish bladder cancer registry data, an orthotopic bladder substitution to the urethra is used in approximately 10–20% of both male and female patients. Emptying of the reservoir anastomosed to the urethra requires abdominal straining, and sphincter relaxation. The terminal ileum is the GI segment most often used for orthotopic bladder substitution. Early and late morbidity in up to 22% of patients is reported [371].

Various forms of UUT reflux protection, including a simple isoperistaltic tunnel, ileal intussusception, tapered ileal prolongation implanted subserosally, and direct (sub)mucosal or subserosal ureteral implantation, have been described [372, 373]. According to the long-term results, the UUT is protected sufficiently by either method [371].

A study comparing cancer control and patterns of disease recurrence in patients with neobladder and ileal conduit showed no difference in CSS between the two groups when adjusting for pathological stage [374]. Urethral recurrence in neobladder patients seems rare (0.8–13.7% [pooled estimate of 4.6% in both male and female patients, also considering the significantly higher recurrence rates in male patients]) [375]. These results indicate that neobladder in male and female patients does not compromise the oncological outcome of cystectomy.

7.3.6.1.4 Continent cutaneous urinary diversion

Continent cutaneous urinary diversion (a low-pressure detubularised ileal reservoir for self-catheterisation) and uretero-rectosigmoidostomy are rarely used techniques nowadays, due to their high complication rates, including stomal stenosis, incontinence in the continent cutaneous diversion, UUT infections and stone formation in case of uretero-rectosigmoidostomy [376].

7.3.6.2 Patient selection

Ensuring that patients make a well-informed decision about the type of urinary diversion is associated with less decision regret post-operatively, independent of the method selected [377]. Therefore, all applicable forms of urinary diversion should be discussed, taking into account patient preference, comorbidities, age and tumour characteristics.

Diagnosis of an invasive urethral tumour prior to cystectomy leads to urethrectomy which is a contraindication for a neobladder reconstruction. Non-muscle-invasive BC in prostatic urethra or bladder neck biopsies does not necessarily preclude orthotopic neobladder substitution, provided that patients undergo regular follow-up cystoscopy and urinary cytology [378]. In women undergoing RC the rate of concomitant urethral malignancy has been reported to range from 12–16% [379]. Localisation of the primary tumour at the bladder neck correlated strongly with concomitant urethral malignancy. Bladder neck biopsies prior to RC are important in women scheduled for an orthotopic bladder substitute [380].

In the presence of positive LNs, orthotopic neobladder can be considered in case of N1 disease, but not in N2 or N3 tumours [381].

Oncological results after orthotopic neobladder or illial conduit are similar in terms of local or distant metastasis recurrence, but secondary urethral tumours seem less common in patients with a neobladder compared to those with conduits or continent cutaneous diversions [382].

Patients undergoing continent urinary diversion must be motivated to learn about their diversion and to be manually skilful to be able to deal with their diversion. Contraindications to continent urinary diversions include:

- debilitating neurological and psychiatric illnesses;
- limited life expectancy;
- severe impaired liver or renal function.

Relative contraindications for an orthotopic neobladder are high-dose pre-operative RT, complex urethral strictures and severe urethral sphincter-related incontinence [383].

A retrospective study including 1,383 patients showed that the risk of a decline in estimated glomerular filtration rate (eGFR) did not significantly differ after ileal conduit vs. neobladder in patients with pre-operative chronic kidney disease 2 (eGFR 60–89 mL/min/1.73 m2) or 3a (eGFR 45–59 mL/min/1.73 m2) [384]. Only age and anastomotic strictures were found to be associated with a decline in eGFR.

Currently, it is not possible to recommend a particular type of urinary diversion. However, most institutions prefer ileal orthotopic neobladders and ileal conduits based on clinical experience. In selected patients, such as patients with a single kidney, uretero-cutaneostomy is surgically the least burdensome type of diversion. Recommendations related to RC and urinary diversions are listed in Section 7.3.10.

7.3.6.3 Peri-operative care

Similar to other tumour types, such as colorectal cancer, the application of a multimodal prehabilitation programme (i.e. physiotherapy, nutritional intervention, cessation of smoking) may improve patient health status prior to surgery and subsequently reduce postoperative complication rates [385]. However, evidence on this is limited and randomised controlled trials are missing.

Patients treated according to a 'Fast track'/ERAS (Early Recovery After Surgery) protocol have shown to score better on the emotional and physical functioning scores and suffer less from wound healing disorders, fever and thrombosis [386].

Pre-operatively, the ERAS protocol recommends no bowel prepation or fasting. Other components are, for example, same day admission, as well as carbohydrate loading and a pre-operative exercise programme.

Important post-operative components of the ERAS protocol are pain management, which involves reducing the use of opioids; increasing the use of high-dose acetaminophen and/or ketorolacs (only as breakthrough pain medication) and patients on ERAS experience more pain as compared to patients on a traditional protocol (Visual Analogue Scale [VAS] 3.1 vs. 1.1, $p < 0.001$), but post-operative ileus decreased from 22% to 7.3% ($p = 0.003$) [387].

Venous thromboembolism (VTE) prophylaxis may be implemented as part of an ERAS protocol. A single- centre non-randomised study showed a significant lower 30-day VTE incidence rate in patients treated for 28 days with enoxaparin compared to patients without prophylaxis [388]. Data from the Ontario Cancer Registry including 4,205 cystectomy patients of whom 1,084 received NAC showed that VTE rates are higher in patients treated with NAC as compared to patients treated with cystectomy only (12% vs. 8%, $p = 0.002$) [389].

7.3.7 ***Morbidity and mortality***

In four retrospective studies and one population-based cohort study, the peri-operative mortality after RC was reported as 2.1–3.2% at 30 days and 3.4–8.0% at 90 days [390, 391]. Morbidity rates differ strongly according to the reporting system used. Using the Clavien-Dindo Classification system complication rates ranged from 50–88% (I–IV) and severe complications from 30–42% (≥ III) [392-395]. In large national databases and institutional series, readmission rates are approximately 25% within 30 days of discharge [396]. Late morbidity was usually linked to the type of urinary diversion (see also above). Early morbidity associated with RC for NMIBC (at high risk for disease progression) is similar and no less than that associated with muscle-invasive tumours [397, 398]. In general, lower morbidity and (peri-operative) mortality have been observed by surgeons and in hospitals with a higher case load and therefore more experience [399-402]. A retrospective analysis of 1,303 patients managed in 7 (non-academic) Dutch hospitals revealed variation in treatment preferences between them; however, despite this there was no significant difference in overall survival [403].

Table 7.1: Management of neobladder morbidity (30-64%) [404]

CLAVIEN System		Morbidity	Management
Grade I	Any deviation from the normal post-operative course without the need for pharmacological treatment or surgical, endoscopic and radiological interventions. Allowed therapeutic regimens are: drugs such as antiemetics, antipyretics, analgesics, diuretics and electrolytes and physiotherapy. This grade also includes wound infections opened at the bedside.	**Immediate complications:**	
		Post-operative ileus	Nasogastric intubation (usually removed at day 1) Chewing gum Avoid fluid excess and hypovolemia (provoke splanchnic hypoperfusion)
		Post-operative nausea and vomiting	Antiemetic agent (decrease opioids) Nasogastric intubation
		Urinary infection	Antibiotics, no ureteral catheter removal Check the 3 drainages (ureters and neobladdder)
		Ureteral catheter obstruction	Inject 5 cc saline in the ureteral catheter to resolve the obstruction Increase volume infusion to increase diuresis
		Intra-abdominal urine leakage (anastomosis leakage)	Check and reposition drainages, if needed
		Anaemia well tolerated	Martial treatment (give iron supplement)
		Late complications:	
		Non-compressive lymphocele	Watchful waiting
		Mucus cork	Catheterise and rinse the bladder
		Incontinence	Urine analysis (infection), echography (post-void residual) Physiotherapy
		Retention	Drainage and self-catheterisation education
		Ureteral reflux	No treatment if asymptomatic
Grade II	Requiring pharmacological treatment with drugs other than those allowed for grade I complications. Blood transfusions and total parenteral nutrition are also included.	Anaemia badly tolerated or if myocardial cardiopathy history	Transfusion[1]
		Pulmonary embolism	Heparinotherapy[2]
		Pyelonephritis	Antibiotics and check kidney drainage (nephrostomy if necessary)
		Confusion or neurological disorder	Neuroleptics and avoid opioids
Grade III	Requiring surgical, endoscopic or radiological intervention	Ureteral catheter accidentally dislodged	Reposition the ureteral catheter
		Anastomosis stenosis (7%)	Renal drainage (ureteral catheter or nephrostomy)
III-a	Intervention not under general anaesthesia	Compressive lymphocele	Transcutaneous drainage

III-b	Intervention under general anaesthesia	Ileal anastomosis leakage	Ileostomy, as soon as possible
		Evisceration	Surgery in emergency
		Compressive lymphocele	Surgery (marsupialisation)
Grade IV	Life-threatening complication (including central nervous system complications: brain haemorrhage, ischaemic stroke, subarachnoid bleeding, but excluding transient ischaemic attacks) requiring intensive care/ intensive care unit management.	Neobladder rupture	Nephrostomy and indwelling catheter/surgery for draining the neobladder
		Severe sepsis	Antibiotics and check all the urinary drainages and CT scan in emergency
IV-a	Single organ dysfunction	Non-obstructive renal failure	Bicarbonate/aetiology treatment (including dialysis)
IV-b	Multi-organ dysfunction	Obstructive pyelonephritis and septicaemia	Treatment at intensive care unit, including urinary drainage and antibiotics
Grade V	Death of a patient		
Suffix 'd'	*If the patient suffers from a complication at the time of discharge, the suffix "d" (for 'disability') is added to the respective grade of complication. This label indicates the need for a follow-up to fully evaluate the complication.*		

[1] *A systematic review showed that peri-operative blood transfusion (PBT) in patients who undergo RC correlates with increased overall mortality, CSM and cancer recurrence. The authors hypothesised that this may be caused by the suggested immunosuppressive effect of PBT. In a retrospective study, Buchner and co-workers showed 5-year decreased CSS in cases where intra-operative blood transfusion (CSS decreased from 67% to 48%) or post-operative blood transfusion (CSS decreased from 63% to 48%) were given [405].*

[2] *Hammond and co-workers reviewed 20,762 cases of VTE after major surgery and found cystectomy patients to have the second-highest rate of VTE among all cancers studied [406]. These patients benefit from 30 days low-molecular-weight heparin prophylaxis. Subsequently, it was demonstrated that BMI > 30 and non-urothelial BCs are independently associated with VTE after cystectomy. In these patients extended (90 days) heparin prophylaxis should be considered [389].*

7.3.8 ***Survival***

Of all cancers, bladder cancer ranks 13th in terms of mortality, with rates decreasing particularly in the most developed countries [407].

Disease-free survival and OS in a large population-based study was 35% and 58% at ten years, respectively [408]. However, the 5-year OS in node-positive patients who underwent cystectomy was 18% [409].

A systematic review including 57 studies (n = 30,293) assessed the long-term survical of patients treated with trimodality therapy (TMT) and RC [408]. Ten-year OS was 30.9% and 35.1%, for TMT and RC, respectively with a mean DSS of 50.9% for TMT and 57.8% for RC. For T2 disease, 10-year DSS was 69% and 78.9% for TMT and RC, respectively and for T3/T4 disease 43.5% and 43.1% for TMT and RC, respectively. Three percent of the patients (812 of 27,867) received NAC, resulting in 5-year OS and DSS in downstaged patients (≤ pT1) at RC of 75.7% and 88.3%, respectively.

7.3.9 ***Impact of hospital and surgeon volume on treatment outcomes***

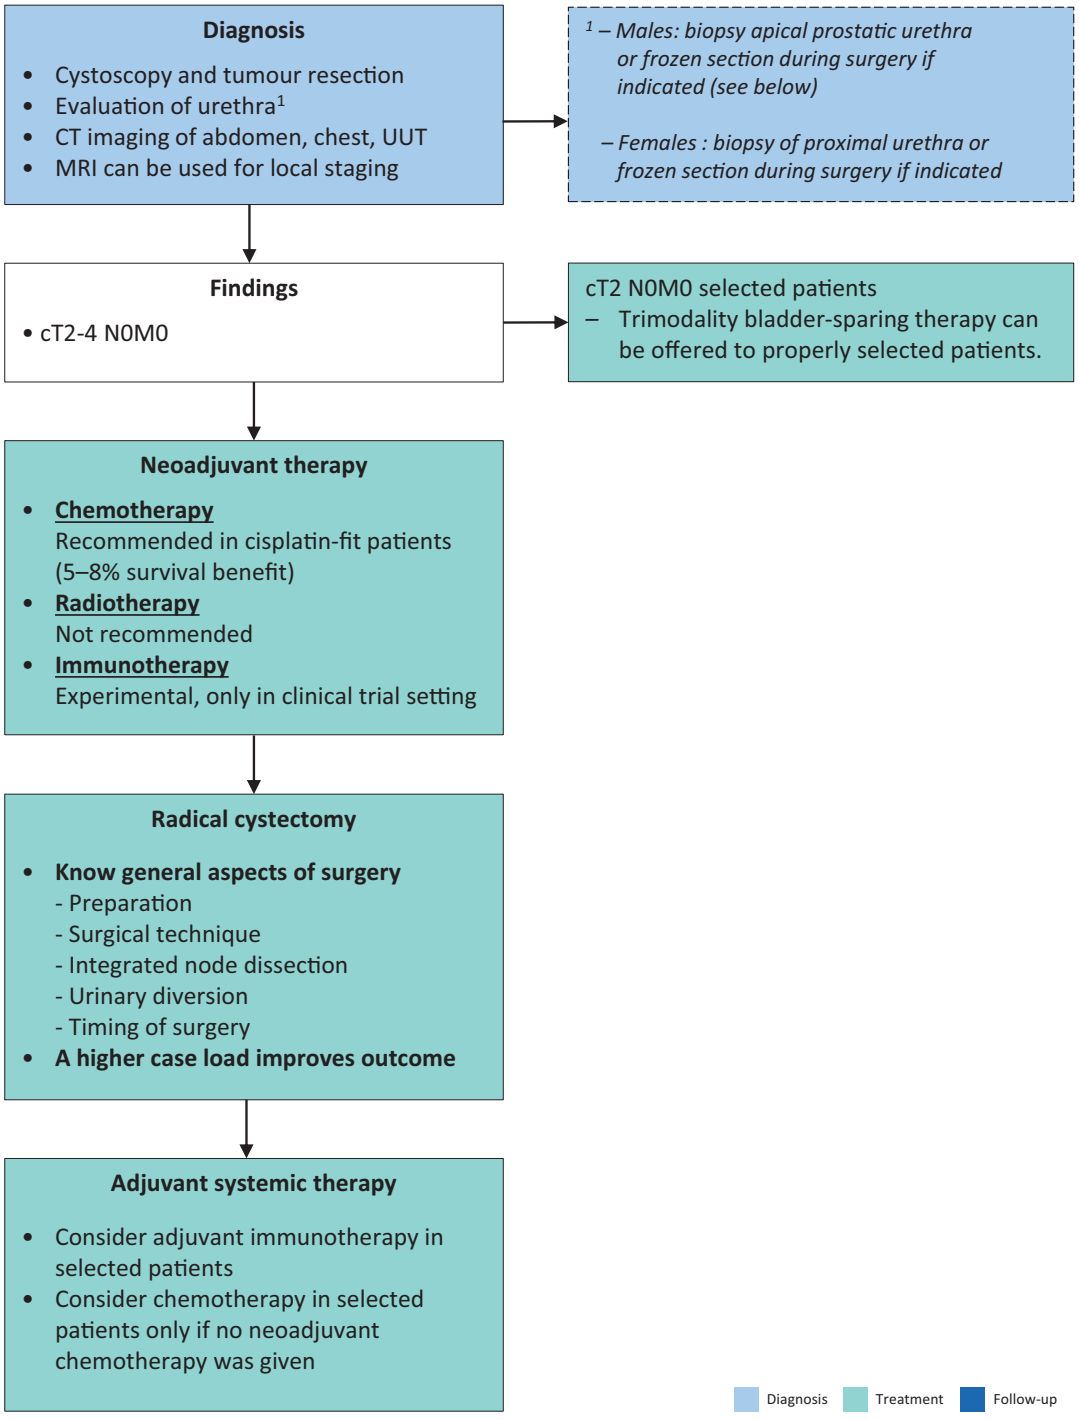
In a systematic review including 40 retrospective studies with 56,000 patients, the impact of hospital and/ or surgeon volume and peri-operative outcomes of RC was assessed [410]. A higher hospital volume was associated with lower in-hospital, 30-day and 90-day mortality. In addition, higher volume hospitals were more likely to have lower positive surgical margins, higher number of LNDs and neobladders and lower complication rates. For surgeon volume, less evidence was available. This study suggested performing at least 10 RCs per centre annually and preferably more than 20. Recently, a nationwide analysis of the Dutch Cancer Registry including almost 9,500 patients between 2008 and 2018 reported decreased 30- and 90-day mortality rates for annual hospital volumes of > 30 RCs. Furthermore, this study showed no true plateau curve for 30- and 90-day mortality beyond 30 RCs supporting the 'more is better' principle [411, 412].

7.3.10 *Summary of evidence and guidelines for radical cystectomy and urinary diversion*

Summary of evidence	LE
Higher RC hospital volume is associated with lower post-operative mortality rates and higher quality of care.	3
Radical cystectomy includes removal of regional LNs.	3
There are data to support that extended vs. standard LND improves survival after RC.	3
No conclusive evidence exists as to the optimal extent of LND.	2a
Ensuring that patients are well informed about the various urinary diversion options prior to making a decision may help prevent or reduce decision regret, independent of the method of diversion selected.	3
The type of urinary diversion does not affect oncological outcome.	3
The use of extended VTE prophylaxis significantly decreases the incidence of VTE after RC.	3
In patients aged > 80 years with MIBC, cystectomy is an option.	3
Surgical complications of cystectomy and urinary diversion should be reported using a uniform grading system. Currently, the best-adapted grading system for cystectomy is the Clavien Dindo grading system.	2b

Recommendations	Strength rating
Do not delay radical cystectomy (RC) for > 3 months as it increases the risk of progression and cancer-specific mortality, unless the patient receives neoadjuvant chemotherapy.	Strong
Perform at least 10, and preferably > 20, RCs per hospital/per year.	Strong
Before RC, fully inform the patient about the benefits and potential risks of all possible alternatives. The final decision should be based on a balanced discussion between the patient and the surgeon.	Strong
Do not offer an orthotopic bladder substitute diversion to patients who have an invasive tumour in the urethra or at the level of urethral dissection.	Strong
Do not offer pre-operative bowel preparation.	Strong
Employ ‘Fast track’ measurements to reduce the time to bowel recovery.	Strong
Offer pharmacological VTE prophylaxis, such as low-molecular-weight heparin to RC patients, starting the first day post-surgery, for a period of at least 4 weeks.	Strong
Offer RC to patients with T2–T4a, N0M0 disease or very high-risk non-muscle-invasive bladder cancer.	Strong
Perform a lymph node dissection as an integral part of RC.	Strong

Figure 7.1: Flow chart for the management of T2–T4a N0M0 urothelial bladder cancer



CT = computed tomography; MRI = magnetic resonance imaging; UUT = upper urinary tract.

7.4 Palliative and salvage cystectomy

Unresectable locally-advanced tumours (T4b, invading the pelvic or abdominal wall) may be accompanied by debilitating symptoms, including bleeding, pain, dysuria and urinary obstruction. These patients are candidates for palliative treatments, such as palliative RT. If control of the symptoms is not possible by less invasive methods, patients may be offered a palliative cystectomy with urinary diversion or urinary diversion only. Palliative cystectomy carries the greatest morbidity, particularly in patients with a poor PS. In a series of 74 patients who underwent palliative cystectomy, severe complications (Clavien-Dindo grade ≥ 3) occurred in 30%. The 30-day mortality rate was 9% and at eight months follow-up, 70% had died [413].

In a retrospective single-centre analysis, Pieretti et al., grouped 265 patients into salvage cystectomy post-TMT, primary cystectomy or primary cystectomy with prior history of non-TMT abdominal or pelvic RT. Post-TMT salvage cystectomy was associated with a higher incidence of any late (HR: 2.3, p = 0.02) and major late complications (HR: 2.1, p < 0.05) but there was no difference in DSS (p = 0.8) or OS (p = 0.9) between the groups [414].

*7.4.1 **Guidelines for palliative and salvage cystectomy***

Recommendations	Strength rating
Offer radical cystectomy as a palliative treatment to patients with locally-advanced tumours (T4b).	Weak
Offer palliative cystectomy to patients with symptoms if control is not possible by less invasive methods.	Weak

*7.4.1.1 EAU-ESMO consensus statements on the management of advanced- and variant bladder cancer [81, 82]**

Consensus statement
In patients with clinical T4 or clinical N+ disease (regional), radical chemoradiation can be offered accepting that this may be palliative rather than curative in outcome.
Chemoradiation should be given to improve local control in cases of inoperable locally-advanced tumours.

**Only statements which met the a priori consensus threshold across all three stakeholder groups are listed (defined as ≥ 70% agreement and ≤ 15% disagreement, or vice versa).*

*7.4.2 **Supportive care***

7.4.2.1 Obstruction of the upper urinary tract

Unilateral (best kidney) or bilateral nephrostomy tubes provide the easiest solution for UUT obstruction, but patients find the tubes inconvenient and prefer ureteral stenting. However, stenting can be difficult to achieve. Stents must be regularly replaced and there is the risk of stent obstruction or displacement. Another possible solution is a urinary diversion with, or without, a palliative cystectomy.

7.4.2.2 Bleeding and pain

In the case of bleeding, the patient must be screened first for coagulation disorders or the patient's use of anticoagulant drugs must be reviewed. Transurethral (laser) coagulation may be difficult in a bladder full of tumour or with a bleeding tumour. Intravesical rinsing of the bladder with 1% silver nitrate or 1–2% alum can be effective [415]. This can usually be done without any anaesthesia. The instillation of formalin (2.5–4% for 30 minutes) is a more aggressive and painful procedure, requiring anaesthesia. Formalin instillation has a higher risk of side-effects, e.g., bladder fibrosis, but is more likely to control the bleeding [415]. Vesicoureteral reflux should be excluded to prevent renal complications.

Radiation therapy is another common strategy to control bleeding and is also used to control pain. An older study reported control of haematuria in 59% of patients and pain control in 73% [416]. Irritative bladder and bowel complaints due to irradiation are possible, but are usually mild. Non-conservative options are embolisation of specific arteries in the small pelvis, with success rates as high as 90% [415]. Radical surgery is a last resort and includes cystectomy and diversion (see above, Section 7.4.1).

7.5 Bladder-sparing treatments for localised disease

*7.5.1 **Transurethral resection of bladder tumour***

Transurethral resection of bladder tumour alone in MIBC patients is only possible as a therapeutic option if tumour growth is limited to the superficial muscle layer and if re-staging biopsies are negative for residual (invasive) tumour [417]. In general, approximately 50% of patients will still have to undergo RC for recurrent MIBC with a disease-specific mortality rate of up to 47% in this group [418]. A disease-free status at re-staging TURB appears to be crucial in making the decision not to perform RC [419, 420]. A prospective study by Solsona *et al.*, including 133 patients after radical TURB and re-staging negative biopsies, reported a 15-year follow-up [420]. Thirty per cent of patients had recurrent NMIBC and went on to intravesical therapy, and 30% (n = 40) progressed, of which 27 died of BC. After five, ten, and fifteen years, the results showed CSS rates of 81.9%, 79.5%, and 76.7%, respectively and PFS rates with an intact bladder of 75.5%, 64.9%, and 57.8%, respectively.

In conclusion, TURB alone should only be considered as a therapeutic option for muscle-invasive disease after radical TURB, when the patient is unfit for cystectomy, or refuses open surgery, or as part of a TMT bladder-preserving approach.

7.5.1.1 *Guideline for transurethral resection of bladder tumour*

Recommendation	Strength rating
Do not offer transurethral resection of bladder tumour alone as a curative treatment option as most patients will not benefit.	Strong

7.5.2 ***External beam radiotherapy***

Current RT techniques with soft-tissue matching and image guidance result in superior bladder coverage and a reduced integral dose to the surrounding tissues. The target total dose (to bladder and/or bladder tumour) for curative EBRT in BC is 64–66 Gy [421, 422]. A reasonable alternative is moderately hypofractionated EBRT to 55 Gy in 20 fractions which has been suggested to be non-inferior to 64 Gy in 32 fractions in terms of invasive locoregional control, OS, and late toxicity. In a phase II study, 55 patients (median age 86) with BC, unfit for cystectomy or even daily RT, were treated with 6-weekly doses of 6 Gy [423]. Forty-eight patients completed EBRT with acceptable toxicity and 17% showed local progression after two years demonstrating good local control with this more ultra-hypofractionated schedule.

Elective treatment to the LNs is optional and should take into account patient comorbidities and the risks of toxicity to adjacent critical structures. For node-positive disease, consider boosting grossly involved nodes to the highest achievable dose that does not violate normal tissue constraints based on the clinical scenario.

The use of modern standard EBRT techniques results in major related late morbidity of the urinary bladder or bowel in less than 5% of patients [424]. Acute diarrhoea is reduced even more with intensity-modulated RT [425]. Important prognostic factors for outcome include response to EBRT, tumour size, hydronephrosis, presence of CIS, and completeness of the initial TURB. Additional prognostic factors reported are age and stage [426].

With the use of modern EBRT techniques, efficacy and safety results seem to have improved over time. A 2002 Cochrane analysis demonstrated that RC has an OS benefit compared to RT [427], although this was not the case in a 2014 retrospective review using a propensity score analysis [428].

In a 2017 retrospective cohort study of U.S. National Cancer Database data, patients over 80 were identified with cT2–4, N0–3, M0 BC, who were treated with curative EBRT (60–70 Gy, n = 739) or concurrent chemoradiotherapy (n = 630) between 2004 and 2013 [429]. The 2-year OS was 42% for EBRT vs. 56% for chemoradiotherapy ($p < 0.001$). For EBRT a higher RT dose and a low stage were associated with improved OS.

In conclusion, although EBRT results seem to improve over time, EBRT alone does not seem to be as effective as surgery or TMT therapy (see Section 7.5.4). Factors that influence outcome should be considered. However, EBRT can be an alternative treatment in patients unfit for radical surgery or concurrent chemotherapy, and it can also be effective in helping control bleeding.

The results of several studies show that radiotherapy delivered in a hypofractionated regime (such as 21 Gy in 3 fractions evaluated in the MRC BA09 randomised control trial [430], can provide rapid relief of local bladder cancer symptoms, including in particular symptomatic hematuria. Other fractionation regimes include 35 Gy in 10 fractions, 30 Gy in 5 fractions, 36 Gy in 6 fractions given once weekly [431], and even a single 8 Gy fraction. In the palliative setting, symptom resolution typically lasts for the majority of the patients' remaining lifespan.

7.5.2.1 *Summary of evidence and guideline for external beam radiotherapy*

Summary of evidence	LE
External beam RT alone should only be considered as a therapeutic option when the patient is unfit for cystectomy or chemoradiation.	3
Radiotherapy can also be used to stop bleeding from the tumour when local control cannot be achieved by transurethral manipulation.	1b

Recommendation	Strength rating
Do not offer radiotherapy alone as primary therapy for localised bladder cancer.	Strong

*7.5.2.2 EAU-ESMO consensus statements on the management of advanced and variant bladder cancer [81, 82]**

Consensus statement
Radiotherapy alone (single block) is not the preferred radiotherapeutic schedule.
Radiotherapy for bladder preservation should be performed with IMRT and IGRT to reduce side effects.
Dose escalation above standard radical doses to the primary site in case of bladder preservation, either by IMRT or brachytherapy, is not recommended.

**Only statements which met the a priori consensus threshold across all three stakeholder groups are listed (defined as ≥ 70% agreement and ≤ 15% disagreement, or vice versa).*
IGRT = image-guided radiotherapy; IMRT = intensity-modulated radiotherapy.

7.5.3 Chemotherapy

Chemotherapy alone rarely produces durable complete remissions. In general, a clinical complete response rate of up to 56% is reported in some series, which must be weighed against a staging error of > 60% [432, 433]. Response to chemotherapy is a prognostic factor for treatment outcome and eventual survival although it may be confounded by patient selection [434].

Several groups have reported the effect of chemotherapy on resectable tumours (neoadjuvant approach), as well as unresectable primary tumours [263, 274, 435, 436]. Neoadjuvant chemotherapy with two to three cycles of MVAC or CMV has led to a down-staging of the primary tumour in various prospective series [263, 274, 435].

A bladder-conserving strategy with TURB and systemic cisplatin-based chemotherapy has been reported several years ago and could lead to long-term survival with intact bladder in a highly selected patient population [437].

A recent large retrospective analysis of a U.S. National Cancer Database cohort reported on 1,538 patients treated with TURB and multi-agent chemotherapy [438]. The two and 5-year OS for all patients was 49% and 32.9% and for cT2 patients it was 52.6% and 36.2%, respectively. While these data show that longterm survival with intact bladder can be achieved in a subset of patients it is not recommended for routine use.

7.5.3.1 Summary of evidence and guideline for chemotherapy

Summary of evidence	LE
Complete and partial local responses have been reported with cisplatin-based chemotherapy as primary therapy for locally-advanced tumours in highly selected patients.	2b

Recommendation	Strength rating
Do not offer chemotherapy alone as primary therapy for localised bladder cancer.	Strong

7.5.4 Trimodality bladder-preserving treatment

Bladder preservation as an alternative to RC is generally reserved for patients with smaller solitary tumours, no extensive or multifocal CIS, no tumour-related hydronephrosis, and good pre-treatment bladder function. Trimodality bladder-preserving treatment should also be considered in all patients with a contraindication for surgery, either a relative or absolute contraindication since the factors that determine fitness for surgery and chemoradiotherapy differ.

Trimodality therapy combines TURB, chemotherapy and RT. The rationale to combine TURB with RT is to achieve maximal local tumour control in the bladder and adjacent nodes. The addition of radiosensitising chemotherapy or other radiosensitisers (mentioned below) is aimed at the potentiation of RT. Micrometastases are targeted by platinum-based combination chemotherapy (for details see Section 7.1). The aim of TMT is to preserve the bladder and QoL without compromising oncological outcome. There are no definitive contemporary data supporting the benefit of using neoadjuvant or adjuvant chemotherapy combined with chemoradiation. Patient selection is critical in achieving good outcomes [439]. Whether a node dissection should be performed before TMT as in RC remains unclear [81, 82].

In the case of TMT, two distinct patterns of care emerge; treatment aimed at patients fit for cystectomy who elect TMT or refuse cystectomy, and treatment aimed at older, less fit, patients. For the former category, TMT presents selective bladder preservation and in this case the initial step is a radical TURB where as much tumour as possible should be resected. In this case appropriate patient selection (e.g., T2 tumours, no CIS) is crucial

[440, 441]. Even in case of an initial presumed complete resection, a second TUR has been suggested to reveal tumour in > 50% of patients and subsequently improves 5-year OS in case of TMT [442]. For patients who are not candidates for cystectomy, less stringent criteria can be applied, but extensive CIS and poor bladder function should both be regarded as relative contraindications.

A collaborative review has described the principles of TMT [439]. For radiation, two schedules are most commonly used; historically within the RTOG a split-course format with interval cystoscopy [443] and single-phase treatment which is now more commonly used [444]. A conventional radiation schedule includes EBRT to the bladder and limited pelvic LNs with an initial dose of 40-45 Gy, with a boost to the whole bladder of 50–54 Gy and a further tumour boost to a total dose of 60–66 Gy. If not boosting the tumour, it is also reasonable for the whole bladder to be treated to 59.4–66 Gy. For node-positive disease, consider boosting grossly involved nodes to the highest achievable dose that does not violate normal tissue constraints. Therefore, elective treatment to the LNs (when node negative) is optional and should take into account patient comorbidities and the risks of toxicity to adjacent critical structures.

A reasonable radiation dosing alternative to conventional fractionation when treating the bladder-only fields is moderately hypofractionated EBRT to 55 Gy in 20 fractions which has been suggested to be non-inferior to 64 Gy in 32 fractions in terms of invasive loco-regional control, OS and late toxicity [421, 445] in a meta-analysis of individual patient data from the BC2001 and BCON studies.

Different concurrent chemotherapy regimens have been used, but most evidence exists for cisplatin [446] and mitomycin-C plus 5-FU [444]. Alternative regimens that have been evaluated include: single agent gemcitabine [447], capecitabine [448] and hypoxia modification with carbogen/nicotinamide [81, 82]. In a recently published phase II RCT, twice-a-day radiation plus 5-FU/cisplatin was compared to once-daily radiation plus gemcitabine [447]. Both arms were found to result in a > 75% free from distant metastases rates at 3 years (78% and 84%, respectively). Therefore, there are good chemotherapy options for non-cisplatin candidates such as 5-FU/mitomycin-C or low-dose gemcitabine.

Five-year CSS and OS rates vary between 50%–84% and 36%–74%, respectively, with salvage cystectomy rates of 10–30% [439, 440, 444, 446, 449].

There are no successfully completed RCTs comparing the outcome of TMT with RC. The BC2001 trial with 10 year follow-up showed that combined radiotherapy with mitomycin C and fluorouracil significantly improved locoregional control and five year cystectomy rates and non-significantly improved DFS, OS and DSS compared to radiotherapy alone [450] as shown in other studies [443, 444, 451]. Many of the reported series have differing characteristics as compared to the larger surgical series, which typically have median ages in the mid- to-late 60s compared to mid-70s for some large RT series (reviewed by James, *et al.* [444]).

As there are no completed randomised trials, RC and TMT have been compared in systematic reviews, meta-analyses, large population-based studies and multi-institutional propensity score matched and weighted analyses [328, 408, 452]. Overall, in balance, these studies show similar oncological outcomes between radical cystectomy and trimodality therapy for select patients with muscle-invasive bladder cancer. These results support that trimodality therapy, in the setting of multidisciplinary shared decision making, should be offered to all suitable candidates with muscle-invasive bladder cancer and not only to patients with significant comorbidities for whom surgery is not an option [328].

Another study reported no difference in survival outcomes in cN+ patients treated with surgery versus radical RT [453].

The Boston group has also reported on their experience in 66 patients with mixed histological subtypes treated with TMT and found similar complete response, OS, DSS and salvage cystectomy rates as in UC [454]. The majority of recurrences post-TMT are non-invasive and can be managed conservatively [444]. In contemporary series, salvage cystectomy is required in about 10–15% of patients treated with TMT and can be curative [328, 440, 444, 449]. Current data suggest that major late complication rates are slightly higher but remain acceptable for salvage- vs. primary cystectomy [455].

A sub-analysis of two RTOG trials looked at complete response (T0) and near-complete response (Ta or Tis) after TMT [456]. After a median follow-up of 5.9 years 41/119 (35%) of patients experienced a bladder recurrence, and fourteen required salvage cystectomy. There was no difference between complete and near-complete responders. Non-muscle-invasive BC recurrences after complete response to TMT were reported in

25% of patients by the Boston group, sometimes over a decade after initial treatment [457]. A NMIBC recurrence was associated with a lower DSS, although in properly selected patients, intravesical BCG could avoid immediate salvage cystectomy.

Overall significant late pelvic (GI/genitourinary [GU]) toxicity rates after TMT are low and QoL is good [444, 458, 459]. A combined analysis of survivors from four RTOG trials with a median follow-up of 5.4 years showed that combined-modality therapy was associated with low rates of late grade 3 toxicity (5.7% GU and 1.9% GI). No late grade 4 toxicities or treatment-related deaths were recorded [458]. A retrospective study showed QoL to be good after TMT and in most domains better than after cystectomy, although prospective validations are needed [460]. One option to reduce side effects after TMT is the use of IMRT and image-guided RT (IGRT) [81, 82, 461].

A bladder-preserving TMT strategy requires very close multidisciplinary cooperation [81, 82]. This was also highlighted by a Canadian group [462]. In Ontario between 1994 and 2008 only 10% (370/3,759) of patients with cystectomy had a pre-operative radiation oncology consultation, with high geographical variations. Independent factors associated with this consultation included advanced age ($p < 0.001$), greater comorbidity ($p < 0.001$) and earlier year of diagnosis ($p < 0.001$). A bladder-preserving TMT strategy also requires a high level of patient compliance. Even if a patient has shown a clinical response to a TMT bladder-preserving strategy, the bladder remains a potential source of recurrence, hence long-term life-long bladder monitoring is essential and patients should be counselled that this will be required.

7.5.4.1 Summary of evidence and recommednations for trimodality bladder-preserving treatment

Summary of evidence	**LE**
Long-term survival rates of TMT bladder-preserving treatment are comparable to those of early cystectomy . The contraindications for TMT or surgery have to be considered.	2
Combined chemotherapy and radiotherapy is more effective than radiotherapy alone in bladder sparing treatment.	1b

Recommendations	**Strength rating**
Offer surgical intervention or trimodality bladder-preserving treatments (TMT) to appropriate candidates as primary curative therapeutic approaches since they are more effective than radiotherapy alone.	Strong
Advise patients who are candidates for TMT in a mutlidisciplinary setting including urologists, medical oncologists and radiation oncologists concerning the benfits and harms of TMT.	Strong
Offer TMT as an alternative to selected, well-informed and compliant patients, especially for whom radical cystectomy is not an option or not acceptable.	Strong
Advise patients who are candidates for TMT that life-long bladder monitoring is essential.	Strong

*7.5.4.2 EAU-ESMO consensus statements on the management of advanced- and variant bladder cancer [81, 82]**

Consensus statement
Candidates for curative treatment, such as cystectomy or bladder preservation, should be clinically assessed by at least an oncologist, a urologist, a radiation oncologist (in case adjuvant radiotherapy or bladder preservation is considered) and a neutral HCP such as a specialist nurse.
An important determinant for patient eligibility in case of bladder-preserving treatment is absence of carcinoma *in situ*.
An important determinant for patient eligibility in case of bladder-preserving treatment is absence or presence of hydronephrosis.
When assessing patient eligibility for bladder preservation, the likelihood of successful debulking surgery should be taken into consideration (optimal debulking).
In case of bladder preservation with radiotherapy, combination with a radiosensitiser is always recommended to improve clinical outcomes, such as cisplatin, 5-FU/MMC, carbogen/nicotinamide or gemcitabine.
Radiotherapy for bladder preservation should be performed with IMRT and IGRT to reduce side effects.
Dose escalation above standard radical doses to the primary site in case of bladder preservation, either by IMRT or by brachytherapy, is not recommended.

**Only statements which met the a priori consensus threshold across all three stakeholder groups are listed*

(defined as ≥ 70% agreement and ≤ 15% disagreement, or vice versa).
HCP = healthcare professional; IGRT = image-guided radiotherapy; IMRT = intensity-modulated radiotherapy; 5FU = 5-fluorouracil; MMC = mitomycin-C.

7.6 Adjuvant therapy

7.6.1 Role of adjuvant platinum-based chemotherapy

Adjuvant chemotherapy after RC for patients with pT3/4 and/or LN positive (N+) disease without clinically detectable metastases (M0) is still under debate. The general benefits of adjuvant chemotherapy include:

- chemotherapy is administered after accurate pathological staging, therefore, treatment in patients at low risk for micrometastases is avoided;
- no delay in definitive surgical treatment.

The drawbacks of adjuvant chemotherapy are:

- assessment of *in vivo* chemosensitivity of the tumour is not possible and overtreatment is an unavoidable problem;
- delay of or intolerability to chemotherapy, due to post-operative morbidity [463].

There is limited evidence from adequately conducted and accrued phase III RCTs in favour of the routine use of adjuvant chemotherapy [464-469]. An individual patient data meta-analysis [470] of survival data from six RCTs of adjuvant chemotherapy [471-473] included 491 patients (unpublished data from Otto *et al.*, were included in the analysis). All included trials suffered from significant methodological flaws including small sample size (underpowered), incomplete accrual, use of inadequate statistical methods and design flaws (irrelevant endpoints and failing to address salvage chemotherapy in case of relapse or metastases) [464]. In these trials, three or four cycles of CMV, cisplatin, cyclophosphamide, and adriamycin (CISCA), methotrexate, vinblastine, adriamycin or epirubicin, and cisplatin (MVA(E)C) and cisplatin with methotrexate (CM) were used [474], and one trial used cisplatin monotherapy [475]. The data were not convincing to support an unequivocal recommendation for the use of adjuvant chemotherapy. In 2014, this meta-analysis was updated with an additional three studies [467-469] resulting in the inclusion of 945 patients from nine trials [466]. None of the trials had fully accrued and individual patient data were not used in the analysis [466]. For one trial only an abstract was available at the time of the meta-analysis [468] and none of the included individual trials were significantly positive for OS in favour of adjuvant chemotherapy. In two of the trials more modern chemotherapy regimens were used (gemcitabine/cisplatin and paclitaxel/gemcitabine/cisplatin) [467, 468]. The HR for OS was 0.77 (95% CI: 0.59–0.99, p = 0.049) and for DFS 0.66 (95% CI: 0.45–0.91, p = 0.014) with a stronger impact on DFS in case of nodal positivity. Recently, a systematic review and meta-analysis of individual patient data from RCTs in patients treated with adjuvant cisplatin-based chemotherapy for MIBC was conducted [476]. In an analysis of 10 RCTs (n = 1,183), an OS benefit was demonstrated for cisplatin-based adjuvant chemotherapy (HR: 0.82, 95% CI: 0.70–0.96, p = 0.02). This translates into an absolute improvement in survival of 6% at 5 years, from 50% to 56%, and a 9% absolute benefit when adjusted for age, sex, pT stage, and pN category (HR: 0.77, 95% CI: 0.65–0.92, p = 0.004). Adjuvant chemotherapy was also shown to improve RFS (HR: 0.71, 95% CI: 0.60-0.83, p < 0.001), locoregional RFS (HR: 0.68, 95% CI: 0.55–0.85, p < 0.001), and MFS (HR: 0.79, 95% CI: 0.65–0.95, p = 0.01), with absolute benefits of 11%, 11%, and 8%, respectively.

A retrospective cohort analysis including 3,974 patients after cystectomy and LND showed an OS benefit in high-risk subgroups (extravesical extension and nodal involvement) (HR: 0.75, CI: 0.62–0.90) [477]. A publication of the largest RCT (European Organisation for Research and Treatment of Cancer [EORTC] 30994), although not fully accrued, showed a significant improvement of PFS for immediate, compared with deferred, cisplatin-based chemotherapy (HR: 0.54, 95% CI: 0.4–0.73, p < 0.0001), but there was no significant OS benefit [478]. Furthermore, a large observational study including 5,653 patients with pathological T3–4 and/ or pathological node-positive BC, treated between 2003 and 2006 compared the effectiveness of adjuvant chemotherapy vs. observation. Twenty-three percent of patients received adjuvant chemotherapy with a 5-year OS of 37% for the adjuvant arm vs. 29.1% (HR: 0.70, 95% CI: 0.64–0.76) in the observation group [479]. Another large retrospective analysis based on the U.S. National Cancer Database including 15,397 patients with locally-advanced (pT3/4) or LN-positive disease also demonstrated an OS benefit in patients with UC histology [480]. In patients with concomitant histological subtypes, however, no benefit was found.

Patients should be informed about potential chemotherapy options before RC and the limited evidence for adjuvant chemotherapy.

7.6.2 Role of adjuvant immunotherapy

To determine the benefit of PD-1/PD-L1 checkpoint inhibitors, three phase III RCTs have evaluated checkpoint inhibitor monotherapy with atezolizumab, nivolumab or pembrolizumab in patients with muscle-invasive UC. The CheckMate 274 phase III multi-centre, double-blind, RCT of adjuvant nivolumab vs. placebo for up to 1 year in 709 patients with muscle-invasive UC with a high risk of recurrence (pathological stage pT3, pT4a, or pN+) (neoadjuvant cisplatin-based chemotherapy was allowed before trial entry) demonstrated a significant improvement in median DFS (20.8 months [95% CI: 16.5–27.6] with nivolumab and 10.8 months [95% CI: 8.3–13.9] with placebo). The percentage of patients who were alive and disease-free at 6 months was 74.9% with nivolumab and 60.3% with placebo (HR for disease recurrence or death, 0.70; 98.22% CI: 0.55–0.90; p < 0.001). Among patients with a PD-L1 expression level of ≥ 1% (tumor cell [TC] score), the percentage of patients was 74.5% and 55.7%, respectively (HR: 0.55; 98.72% CI: 0.35–0.85; p < 0.001) [481]. In an analysis using both PD-L1 TC score and combined positive score (CPS), more patients had CPS ≥ 1 than TC ≥ 1% and patients with CPS ≥ 1 had improved DFS with nivolumab which may have contributed to the benefit seen with adjuvant nivolumab in patients with TC < 1% and CPS ≥ 1 [482]. There was no clinically meaningful deterioration in health-related quality of life with adjuvant nivolumab compared to placebo [483].

The primary endpoint of DFS was not achieved in a multi-centre RCT of adjuvant atezolizumab vs. observation in patients with ypT2–4a or ypN+ tumours following NAC or pT3–4a or pN+ tumours if no NAC was received (IMvigor010). Median DFS was 19.4 months (95% CI: 15.9–24.8) with atezolizumab and 16.6 months (11.2–24.8) with observation (stratified HR: 0.89, 95% CI: 0.74–1.08, p = 0.24) [484]. A similarly designed trial of pembrolizumab in the adjuvant setting has completed accrual with results awaited.

The FDA has approved nivolumab for adjuvant treatment of patients with UC who are at high risk of recurrence after undergoing surgery [485] whereas the EMA has approved adjuvant nivolumab for the treatment of adults with muscle-invasive UC (MIUC) with tumour cell PD-L1 expression ≥ 1%, who are at high risk of recurrence after undergoing radical resection of MIUC. A promising report (see Marker section) has suggested a potential role for ctDNA to guide the use of adjuvant IO for UC [486].

7.6.3 Summary of evidence and guidelines for adjuvant therapy

Summary of evidence	LE
Adjuvant cisplatin-based chemotherapy for high-risk patients (pT3, 4 and/or or N+ M0) without neoadjuvant treatment can be associated with improvement in DFS and OS but trials are underpowered to adequately answer this question.	2a
To date, studies of immune checkpoint inhibitors in the adjuvant setting in patients with high-risk MIBC who have or have not received NAC have demonstrated conflicting results with the CheckMate 274 study demonstrating an improvement in DFS with adjuvant nivolumab and the IMvigor 010 study failing to show an improvement in DFS with adjuvant atezolizumab.	1b
Circulating tumour DNA holds promise as both a prognostic and predictive biomarker to guide the use of adjuvant IO for UC in patients who are at a high risk of recurrence and positive for ctDNA treated with adjuvant atezolizumab demonstrating improved outcomes compared with observation.	2b

Recommendations	Strength rating
Offer adjuvant cisplatin-based combination chemotherapy to patients with pT3/4 and/or pN+ disease if no neoadjuvant chemotherapy has been given.	Strong
Offer adjuvant nivolumab to selected patients with pT3/4 and/or pN+ disease not eligible for, or who declined, adjuvant cisplatin-based chemotherapy.	Weak

7.7 Metastatic disease

7.7.1 Introduction

The treatment of metastatic UC had remained largely unchanged since pivotal trials published over 20 years ago set the standard of care for first-line treatment with cisplatin-based combinations demonstrating an OS benefit. This longstanding paradigm was challenged in the past years by the introduction of immunotherapy using checkpoint inhibitors and it was finally upended in October 2023 with the presentation of the results of two practice-changing randomised clinical trials (RCTs) demonstrating an overall survival benefit in the first line setting against platinum-based chemotherapy (EV-302/KEYNOTE A39 and Checkmate 901) [487, 488]. These updated guidelines reflect the results of these two trials and the impact for first and later lines management of patients with metastatic bladder cancer.

7.7.2 *First-line systemic therapy for metastatic disease*

In general, patients with untreated metastatic UC can be divided into two broad categories: eligible for combination therapies or ineligible for combination therapies. The distinction between the two groups is currently based on the eligibility criteria for the pivotal trial EV-302/KEYNOTE 39A and is likely to undergo changes in the near future based on results from real-world evidence investigations. Major criteria include ECOG performance status 0-2, GFR ≥ 30 ml/min and adequate organ functions based on eligibility for treatment with Enfortumab vedotin and Pembrolizumab. With regards to platinum-based chemotherapy the definitions to distinguish patients fit for cisplatin, fit for carboplatin und unfit for any platinum-based therapy remains valid as outlined below and summarised in Table 7.2.

7.7.2.1 Definitions: 'Fit for cisplatin, fit for carboplatin, unfit for any platinum-based chemotherapy'

An international survey among BC experts [432] was the basis for a consensus statement on how to classify patients unfit for cisplatin-based chemotherapy. At least one of the following criteria must be present: PS > 1; GFR ≤ 60 mL/min; grade ≥ 2 audiometric hearing loss; grade ≥ 2 peripheral neuropathy or New York Heart Association (NYHA) class III heart failure [433]. Around 50% of patients with BC are not eligible for cisplatin-based chemotherapy [433]. Renal function assessment is of utmost importance for treatment selection. Measuring GFR with radioisotopes (^{99}mTc DTPA or ^{51}Cr-EDTA) is recommended in equivocal cases.

Cisplatin has also been administered in patients with a lower GFR (40–60 mL/min) using different split-dose schedules. The respective studies were mostly small phase I and II trials in different settings (neoadjuvant and advanced disease) demonstrating that the use of split-dose cisplatin is feasible and appears to result in encouraging efficacy [486, 489, 490]. However, no prospective RCT has compared split-dose cisplatin with conventional dosing.

Most patients that are deemed unfit for cisplatin are able to receive carboplatin-based chemotherapy. However, some patients are deemed unfit for any platinum-based chemotherapy, i.e. both cisplatin and carboplatin. Patient are unfit for any platinum-based chemotherapy in case of PS > 2, GFR < 30 mL/min or the combination of PS 2 and GFR < 60 mL/min since the outcome in this patient population is poor regardless of platinum-based treatment or not [491]. Patients with multiple comorbidities may also be poor candidates for platinum-based chemotherapy.

Table 7.2: Definitions of platinum-eligibility for first-line treatment of metastatic urothelial carcinoma

Platinum-eligible		Platinum-ineligible
Cisplatin-eligible	**Carboplatin-eligible**	
ECOG PS 0-1 *and*	ECOG PS 2 *or* GFR 30–60 mL/min	Any of the following:
GFR > 50–60 mL/min *and*	or not fulfilling other cisplatin-eligibility criteria	GFR < 30 mL/min
Audiometric hearing loss grade < 2 *and*		ECOG PS > 2
Peripheral neuropathy grade < 2 *and*		ECOG PS 2 *and* GFR < 60 mL/min
Cardiac insufficiency NYHA class < III		Comorbidites > Grade 2

ECOG = Eastern Cooperative Oncology Group; GFR = glomerular filtration rate; NYHA = New York Heart Association; PS = performance status.

7.7.2.1 First-line chemotherapy in patients fit for combination therapy

7.7.2.1.1 Enfortumab vedotin plus Pembrolizumab

The combination of Enfortumab vedotin (EV) plus pembrolizumab represents the new standard of care for patients who are deemed fit for combination therapies. This is based on EV-302/KEYNOTE 39A, a phase III trial that tested the antibody drug conjugate EV directed against nectin-4 (EV: administered any number of times until progression) in combination with the immune checkpoint inhibitor, pembrolizumab (maximum of 35 cycles) against platinum-based chemotherapy (cisplatin or carboplatin permitted) in combination with gemcitabine (up to 6 cycles) in the first-line advanced unresectable or metastatic urothelial carcinoma. 30% of the patients in the control arm received switch maintenance immunotherapy with avelumab. Both co-primary endpoints, PFS and OS were clearly met with a significant improvement in median PFS of 12.5 vs 6.3 months (HR 0.45 (0.38-0.54) and median OS of 31.5 vs. 16.1 months (HR 0.47 (0.38-0.58), respectively. The overall ORR was 67.7% including 29.1% complete remissions (CR) compared to 44.4% (12.5% CR) with platinum-based chemotherapy (p<0.00001). All pre-specified subgroups benefited equally from EV+pembrolizumab regardless

of cisplatin eligibility, PD-L1 expression or presence of liver metastases. Treatment-related toxicity grade ≥ 3 was reported in 55% for EV/Pembrolizumab versus 70% in the chemotherapy arm. Specific and relevant EV toxicities include skin rash, peripheral neuropathy, ocular disorders and hyperglycemia. Toxicity of EV/Pembrolizumab needs to be managed proactively and attentively to avoid severe sequelae. The administration of EV/Pembrolizumab requires adequate knowledge and care from a specialised interprofessional team [487].

The combination of EV and pembrolizumab as the first-line treatment in 45 cisplatin-ineligible patients with locally-advanced/metastatic UC was also investigated in EV-103, phase 1b/2 study, and demonstrated a confirmed objective response rate after a median of nine cycles of 73.3% with a complete response rate of 15.6% [492]. The median duration of response and median OS were 25.6 months and 26.1 months, respectively. The most common treatment-related AEs were peripheral sensory neuropathy (55.6%), fatigue (51.1%), and alopecia (48.9%) [492]. A second cohort within the same study randomly assigned previously untreated cisplatin-ineligible patients to EV alone or EV with pembrolizumab [493]. The ORR was 64.5% (95% CI, 52.7 to 75.1) and 45.2% (95% CI, 33.5 to 57.3) for patients treated with EV+ pembrolizumab (N = 76) and EV monotherapy (N = 73), respectively. The median DOR was not reached for the combination and was 13.2 months for monotherapy. Based on these results enfortumab vedotin plus pembrolizumab has been granted FDA accelerated approval for patients with locally advanced or metastatic UC who are ineligible for cisplatin-containing chemotherapy.

7.7.2.1.2 Paitents eligible for combination therapy but not eligible for EV or EV not available

In spite of the very recent results of EV-302/KEYNOTE 39A study, EV will not be available in different countries. Moreover, some patients might not be eligible for or refuse treatment with EV including patients with uncontrolled diabetes, peripheral neuropathy grade ≥ 2 and pre-existing significant skin disorders. Platinum-based chemotherapy with integration of checkpoint inhibitors represents the preferred options in such patients. The general presumptions for cisplatin- and carboplatin-based therapy remain unchanged in this case and are outlined below.

7.7.2.1.2.1 Patients fit for cisplatin

Cisplatin-containing combination chemotherapy was the standard of care since the late 1980s demonstrating an OS of 12 to 14 months in different series (for a review see [494]). Methotrexate, vinblastine, adriamycin plus cisplatin and GC achieved survival of 14.8 and 13.8 months, respectively [495]. Overall response rates were 46% for MVAC and 49% for GC. The lower toxicity of GC [200] compared to standard MVAC has resulted in GC becoming the standard regimen.

Dose-dense MVAC combined with granulocyte colony-stimulating factor (G-CSF) is less toxic and more efficacious than standard MVAC in terms of, complete response (CR), and 2-year OS. However, there is no significant difference in median survival between the two regimens [496, 497]. Further intensification of treatment using paclitaxel, cisplatin and gemcitabine (PCG) triplet regimen did not result in a significant improvement in OS in the intention-to-treat (ITT) population of a phase III RCT, comparing PCG to GC [498]. Similarly, the addition of the angiogenesis inhibitor bevacizumab to GC did not result in OS improvement [499].

The disease sites have an impact on long-term survival. In LN-only disease, 20.9% of patients were alive at five years compared to only 6.8% of patients with visceral metastases [495]. In the trials with long-term follow-up, approximately 10-15% of patients with metastatic UC were alive at 5 years and longer, suggesting a sustained benefit from cisplatin-based chemotherapy in a minority of patients [495, 497].

Carboplatin-containing chemotherapy, without the inclusion of immunotherapy, is not considered to be equivalent to cisplatin-based combinations, and should not be considered interchangeable or standard in patients fit for cisplatin. A comparative analysis of four randomised phase II trials of carboplatin vs. cisplatin combination chemotherapy demonstrated lower CR rates and shorter OS for the carboplatin arms [500]. A retrospective study highlighted the importance of applying cisplatin in cisplatin-eligible patients in order to maintain benefit [501].

Switch maintenance with immunotherapy after platinum-based chemotherapy

A randomised phase II trial evaluated switch maintenance treatment with pembrolizumab in patients achieving at least stable disease on platinum-based first-line chemotherapy. The primary endpoint of PFS was met (5.4 months vs. 3.0 months, HR: 0.65, p = 0.04) [502].

The JAVELIN Bladder 100 study investigated the impact of switch maintenance with the PD-L1 inhibitor avelumab after initial treatment with platinum-gemcitabine chemotherapy. Patients achieving at least stable disease or better after 4–6 cycles of platinum-gemcitabine were randomised to avelumab or best supportive care (BSC). Overall survival was the primary endpoint which improved to 21.4 months with avelumab compared to 14.3 months with BSC (HR: 0.69, 95% CI: 0.56–0.86; p < 0.001). Of patients who discontinued BSC and received subsequent treatment 53% received immunotherapy. Immune-related AEs occurred in 29% of all patients and 7% experienced grade 3 complications [503]. Patient-reported ouctomes from JAVELIN Bladder 100 demonstrated no detrimental effect on quality of life [504].

Maintenance IO with avelumab was until recently standard of care for all patients with at least stable disease on first-line platinum-based chemotherapy.

If patients are fit for cisplatin, the results of CheckMate 901 should be considered [488]. This trial tested the addition of nivolumab in combination with gemcitabine/cisplatin (GC) and followed by nivolumab maintenance (until progression or maximum of 24 months) compared to GC alone. Of note, only 9% in the control arm received switch maintenance therapy with avelumab. The co-primary endpoints, PFS and OS were reached with a median PFS of 7.9 vs 7.6 months (HR 0.72, 95%CI 0.59-0.88) and a median OS of 21.7 vs. 18.9 months (HR 0.78, 95%CI 0.63-0.96). The response rate was improved with GC plus Nivolumab (57.6% vs 43.1.%). A complete remission (CR) was achieved in 21.7% of patients with Nivolumab plus GC with a duration of 37.1 months. Nivolumab plus GC had higher treatment related grade ≥3 toxicity (62% vs 52%). This combination represents an alternative to GC followed by maintenance therapy with avelumab in patients not eligible for EV or if EV is not available.

7.7.2.1.2.2 Patients fit for carboplatin (but unfit for cisplatin)

Up to 50% of patients are not fit for cisplatin-containing chemotherapy but most may be candidates for carboplatin [433]. A randomised phase II/III trial in this setting was conducted by the EORTC and compared two carboplatin-containing regimens (methotrexate/carboplatin/vinblastine [M-CAVI] and gemcitabine/carboplatin [GemCarbo]) in patients unfit for cisplatin. The EORTC definitions for eligibility were GFR < 60 mL/min and/or PS 2. Severe acute toxicity was 13.6% with GemCarbo vs. 23% with M-CAVI, while the ORR was 42% for GemCarbo and 30% for M-CAVI, respectively [491]. Based on these results the combination of carboplatin and gemcitabine should be considered a standard of care in this patient group. Importantly, both EV-302/KEYNOTE 39A and JAVELIN Bladder 100 included patients fit for carboplatin, while CheckMate 901 included patients fit for cisplatin only.

Combinations of gemcitabine and paclitaxel have been studied as first-line treatment and produced response rates between 38% and 60% but has never been tested in RCTs [505-507]. A randomised phase II trial assessed the efficacy and tolerability profile of two vinflunine-based regimens (vinflunine/gemcitabine vs. vinflunine/carboplatin). Both regimens showed equal ORR and OS with less haematologic toxicity for the combination of vinflunine/gemcitabine [508]. Non-platinum combination chemotherapy is nevertheless not recommended for first-line use in platinum-eligible patients.

The use of single-agent chemotherapy has been associated with varying response rates. Responses with single agents are usually short, complete responses are rare, and no long-term DFS/OS has been reported. It is not recommended for first-line treatment of metastatic UC.

7.7.2.2 First line therapy in patients not eligible for combination therapy

Limited data exist regarding the optimal treatment for this patient population which is characterised by severely impaired PS (PS > 2) and/or severely impaired renal function (GFR < 30 mL/min) or inadequate organ function. Historically, the outcome in this patient group has been poor. Best supportive care has often been chosen instead of systemic therapy. Most trials evaluating alternative treatment options to cisplatinum-based chemotherapy did not focus specifically on this patient population, making data interpretation difficult. The FDA (but not EMA) has approved pembrolizumab as a first-line treatment for patients not fit to receive any platinum-based chemotherapy regardless of PD-L1 status based on the results of one single-arm phase II trial [509].

Based on the results of two single arm phase II trials trials [509, 510] the checkpoint inhibitors pembrolizumab and atezolizumab have been approved by EMA for first-line treatment in cisplatin- unfit patients in case of positive PD-L1 status. PD-L1 positivity for use of pembrolizumab is defined by immunohistochemistry as a CPS of ≥ 10 using the Dako 22C33 platform and for atezolizumab as positivity of ≥ 5% tumour-infiltrating immune cells using Ventana SP142.

Pembrolizumab was tested in 370 patients with advanced or metastatic UC ineligible for cisplatin, showing an ORR of 29% and CR in 7% of patients [509, 511]. Atezolizumab was evaluated in the same patient population in a phase II trial (n = 119) showing an ORR of 23% with 9% of patients achieving CR [510].

First-line avelumab was evaluated in patients with PD-L1 positive, metastatic or locally advanced disease and demonstrated a median OS of 10.0 months (95% CI: 5.5-14.5 months) with 43% of patients alive at 1 year. A complete response was achieved in 8.5% of patients, and 15.5% had a partial response [512].

A phase 2 randomised trial (BAYOU) evaluating durvalumab with olaparib or placebo in platinum-ineligible patients with metastatic UC demonstrated no PFS or OS benefit for the addition of olaparib; however, in a secondary analysis of patients with homologous recombination repair gene mutations, PFS was improved with the addition of olaparib as compared to placebo (median PFS was 5.6 months (95% CI, 1.9 to 8.1) versus 1.8 months (95% CI, 1.7 to 2.2), (HR, 0.18; 95% CI, 0.06 to 0.47) [513].

The trials IMvigor 130, Keynote 361 and DANUBE all included an experimental arm with immunotherapy alone using atezolizumab, pembrolizumab and durvalumab, respectively [514-516]. No benefit in terms of PFS or OS for the use of single-agent immunotherapy compared to platinum-based chemotherapy was found. The combination of carboplatin/gemcitabine therefore is still considered the preferred first-line treatment choice for patients planned to receive chemotherapy who are ineligible for cisplatin.

7.7.2.3 Results of other trials integrating immunotherapy in the first line setting without OS benefit

In 2020, the results of three phase III trials were published investigating the use of immunotherapy in the first-line setting for platinum-eligible patients. The first trial to report was IMvigor130 investigating the combination of the PD-L1 inhibitor atezolizumab plus platinum-gemcitabine chemotherapy vs. chemotherapy plus placebo vs. atezolizumab alone [514]. The primary endpoint of PFS benefit for the combination vs. chemotherapy alone in the ITT group was reached (8.2 months vs. 6.3 months [HR: 0.82, 95% CI: 0.70–0.96; one-sided, p = 0.007]) while OS was not significant at the interim analysis after a median follow-up of 11.8 months. The small PFS benefit in the absence of an OS benefit has raised questions of its clinical significance.

The KEYNOTE 361 study had a very similar design using the PD-1 inhibitor pembrolizumab plus platinum-gemcitabine vs. chemotherapy plus placebo vs. pembrolizumab alone. The results of the primary endpoints of PFS and OS for the comparison of pembrolizumab plus chemotherapy vs. chemotherapy plus placebo in the ITT population showed no benefit for the combination [515].

DANUBE compared the immunotherapy combination (IO-IO) of CTLA-4 inhibitor tremelimumab and PD-L1 inhibitor durvalumab with chemotherapy alone or durvalumab alone [516]. The co-primary endpoint of improved OS for the IO-IO combination vs. chemotherapy was not reached in the ITT group nor was the OS improved for durvalumab monotherapy vs. chemotherapy in the PD-L1-positive population.

In conclusion, unlike CheckMate 901, these three trials do not support the use of combination of the PD-1/L1 checkpoint inhibitors plus platinum-based chemotherapy or the IO-IO combination as first-line treatment.

*7.7.3 **Further-line systemic therapy for metastatic disease***

7.7.3.1 Introduction

Due to the results of the EV-302/KEYNOTE A39 trial and the expected paradigm shift in first-line therapy with establishment of the EV plus Pembrolizumab combination, as well as the CheckMate 901 trial with the combination of cisplatin, gemcitabine and nivolumab, selecting subsequent therapy lines in patients who fail during or progress after first-line treatment poses a significant challenge. Depending on the choice of first-line therapy the following options exist.

7.7.3.2 Chemotherapy

In patients eligible for combination therapy having received EV plus pembrolizumab, platinum-based chemotherapy with gemcitabine plus cisplatin or carboplatin may be considered, however, data is limited for this new post EV plus pembrolizumab clinical disease state and toxicities, e.g. neuropathy from prior therapy must be taken into consideration in determining a treatment plan. For patients already having received platinum-based chemotherapy with or without immunotherapy further -line chemotherapy data are highly variable and mainly derive from small single-arm phase II trials apart from one single phase III RCT. A reasonable strategy has been to re-challenge former platinum-sensitive patients if progression occurred at least six to twelve months after first-line platinum-based combination chemotherapy. A retrospective analysis of 296 patients within the RISC cohort (Retrospective International Study of Cancers of the Urothelium) revealed that subsequent platinum-based combination chemotherapy achieved a somewhat higher disease control rate (57.4% vs. 44.8%, p.= 0.041) and OS (7.9 vs. 5.5 months, p = 0.035) compared to subsequent non-platinum-based chemotherapy [517]. Second-line response rates of single-agent treatment with paclitaxel (weekly), docetaxel, gemcitabine, nab-paclitaxel, oxaliplatin, ifosfamide, topotecan, pemetrexed, lapatinib, gefitinib and bortezomib have ranged between 0% and 28% in small phase II trials [518, 519].

The paclitaxel/gemcitabine combination has shown good response rates in small single-arm studies but no adequate phase III RCT has been conducted [520, 521]. Vinflunine was tested in a phase III RCT and compared against BSC in patients progressing after first-line treatment with platinum-based chemotherapy [522]. The results showed a very modest ORR (8.6%), a clinical benefit with a favourable safety profile and a survival benefit, which was however only statistically significant in the eligible patient population (not in the ITT population). A randomised phase III trial evaluated the addition of the angiogenesis inhibitor ramucirumab to docetaxel chemotherapy vs. docetaxel alone, which resulted in improved PFS (4.1 vs. 2.8 months) and higher response rates (24.5% vs. 14%) but no OS benefit was achieved [523, 524].

7.7.3.3 Immunotherapy for platinum-pre-treated patients without previous immunotherapy

The immune checkpoint inhibitors pembrolizumab, nivolumab, atezolizumab, avelumab, and durvalumab have demonstrated similar efficacy and safety in patients progressing during, or after, previous platinum-based chemotherapy in phase I, II and III trials.

Pembrolizumab demonstrated a significant OS Improvement as second-line treatment in a phase III RCT leading to EMA and FDA approval. Patients (n = 542) were randomised to receive either pembrolizumab monotherapy or chemotherapy (paclitaxel, docetaxel or vinflunine). The median OS with pembrolizumab was 10.3 months (95% CI: 8.0–11.8) vs. 7.4 months (95% CI: 6.1–8.3) with chemotherapy (HR 0.73, 95% CI: 0.59–0.91, p = 0.002) independent of PD-L1 expression levels [511, 525].

Atezolizumab was the first checkpoint inhibitor approved by the FDA for metastatic UC based on the results of phase I and II trials [236, 526], however, the indication has subsequently been withdrawn. The phase III RCT (IMvigor211) included 931 patients comparing atezolizumab with second-line chemotherapy (paclitaxel, docetaxel or vinflunine) did not meet its primary endpoint of improved OS for patients with high PD-L1 expression with 11.1 months (atezolizumab) vs. 10.6 (chemotherapy) months (stratified HR: 0.87, 95% CI: 0.63–1.21, p = 0.41) [470].

The PD-1 inhibitor nivolumab was approved by the FDA based on the results of a single-arm phase II trial (CheckMate 275), enrolling 270 platinum pre-treated patients. The primary endpoint of ORR was 19.6%, and OS was 8.74 months for the entire group [527]. The TITAN-TCC study evaluated the safety and activity of nivolumab induction plus high-dose ipilumumab (3 mg/kg) boosts in non-responders (stable or progressive disease) in the second-line treatment of 83 patients with metatsatic UC. Fifty (60%) received at least one boost with an investigator-assessed response rate of 33% (CR: 7%), demonstrating promising outcomes with this strategy compared to the rate reported in CheckMate 275 [528].

7.7.3.4 Side-effect profile of immunotherapy

Checkpoint inhibitors including PD-1 or PD-L1 antibodies and CTLA-4 antibodies have a distinct side-effect profile associated with their mechanism of action leading to enhanced immune system activity. These AEs can affect any organ in the body leading to mild, moderate or severe side effects. The most common organs affected are the skin, GI tract, liver, lung, thyroid, adrenal and pituitary gland. Other systems that may be affected include musculoskeletal, renal, nervous, haematologic, ocular and cardiovascular system. Any change during immunotherapy treatment should raise suspicion about a possible relation to the treatment. The nature of immune-related AEs has been very well characterised and published [529]. The timely and appropriate treatment of immune-related side effects is crucial to achieve optimal benefit from the treatment while maintaining safety. Clear guidelines for side-effect management have been published [530]. Immunotherapy treatment should be applied and supervised by trained clinicians only to ensure early side effect recognition and treatment. In case of interruption of immunotherapy, re-challenge will require close monitoring for AEs [531].

7.7.4 ***Integration of other agents***

7.7.4.1 Antibody drug conjugates Enfortumab vedotin monotherapy

The first antibody drug conjugate to report encouraging data in patients previously treated with platinum-based chemotherapy and checkpoint inhibition was EV. The phase-II single-arm study EV-201 in 125 patients showed a confirmed objective response rate of 44%, including 12% complete responses [532]. This data led to accelerated FDA and EMA approval for EV in locally-advanced or metastatic UC patients who previously received a PD-1 or PD-L1 inhibitor and platinum-containing chemotherapy, as well as for cisplatin-ineligible patients who received one or more prior lines of therapy [533, 534]. Another cohort of the same EV-201 trial demonstrated similar promising results in 91 patients that were cisplatin-ineligible and had received prior IO [535]. A phase III RCT (n = 608) comparing EV with single-agent chemotherapy after prior platinum chemotherapy and checkpoint inhibitor immunotherapy demonstrated significant survival benefit of almost 4 months (12.88 months vs. 8.97 months; HR 0.7, 95% CI: 0.56–0.89) [536]. The most common treatment-related AEs included alopecia (45%), peripheral

neuropathy (34%), fatigue (31%, 7.4% ≥ grade 3), decreased appetite (31%), diarrhoea (24%), nausea (23%) and skin rash (16%, 7.4% ≥ grade 3).

7.7.4.2 Antibody drug conjugate Sacituzumab govetican

Another new and also promising antibody drug conjugate is sacituzumab govitecan, consisting of a humanised monoclonal antibody targeting trophoblast cell surface antigen 2 (Trop-2) conjugated to SN-38, the active metabolite of irinotecan. Sacituzumab govitecan was tested in 113 platinum and immunotherapy pre-treated metastatic UC (mUC) patients [532] and achieved an ORR of 27% and a total of 77% had a decrease in measurable disease, median PFS was 5.4 months and median OS 10.9 months [537]. Side effects consisted of haematological toxicities (neutropenia 34% ≥ grade 3; febrile neutropenia 10% ≥ grade 3), fatigue (52%), alopecia (47%), nausea (60%), diarrhea (65%, 10% ≥ grade 3) and decreased appetite (36%) [537]. Sacituzumab govitecan has received accelerated FDA approval for metastatic UC with prior platinum and IO pre-treatment. Several trials using sacituzumab govitecan as monotherapy or in combination are ongoing.

7.7.4.3 FGFR inhibition

Genomic profiling of UC has revealed common potentially actionable genomic alterations including alterations in FGFR [538]. Erdafitinib is a pan-FGFR tyrosine kinase inhibitor and the first FDA-approved targeted therapy for mUC with susceptible FGFR2/3 alterations following platinum-containing chemotherapy. The phase II trial of erdafitinib included 99 patients whose tumour harboured an FGFR3 mutation or FGFR2/3 fusion and who had disease progression following chemotherapy [234]. The confirmed ORR was 40% and an additional 39% of patients had stable disease. A total of 22 patients had previously received immunotherapy with only one patient achieving a response, yet the response rate for erdafitinib for this subgroup was 59%. At a median follow-up of 24 months, the median PFS was 5.5 months (95% CI: 4.0–6.0) and the median OS was 11.3 months (95% CI: 9.7–15.2) [234]. Treatment-related AEs of ≥ grade 3 occurred in 46% of patients. Common AEs of ≥ grade 3 were hyponatraemia (11%), stomatitis (10%), and asthenia (7%) and 13 patients discontinued erdafitinib due to AEs, including retinal pigment epithelial detachment, hand-foot syndrome, dry mouth, and skin/nail events. In a long-term follow up, the efficacy and safety profile remained similar with no new safety signals with longer follow-up [539].

In the recent THOR cohort 1 trial, a phase 3 trial of erdafitinib as compared with chemotherapy (docetaxel or vinflunine) in patients with metastatic UC with susceptible FGFR3/2 alterations who had progression after one or two previous treatments that included an anti–PD-1 or anti–PD-L1 demonstrated an improvement in OS with erdafitinib as compared to chemotherapy (12.1 months vs. 7.8 months; HR 0.64 (0.47 to 0.88); P=0.005). Median PFS was also longer with erdafitinib than with chemotherapy (5.6 vs. 2.7 months; (HR 0.58 (0.44 -0.78) [540]. Treatment-related toxicity grade ≥ 3 was similar in the two groups. The most common treatment-related adverse events of grade 3 or higher were palmar–plantar erythrodysesthesia syndrome (9.6%), stomatitis (8.1%), onycholysis (5.9%), and hyperphosphatemia (5.2%) in the erdafitinib group.

Data on cohort 2 with 351 patients, anti-PD-(l1) naïve and progressing after one prior treatment line compared Erdafitinib with pembrolizumab. No difference in the primary endpoint OS was detected (10.9 versus 11.1 months, HR 1.18 (0.92-1.51) [541]. Overall response rate was 40.0% and 21.6% and median duration of response was 4.3 and 14.4 months for erdafitinib and pembrolizumab, respectively. 64.7% and 50.9% of patients in the erdafitinib and pembrolizumab arms had ≥ 1 grade 3-4 adverse events.

In addition to erdafitinib, several other FGFR inhibitors are being evaluated including infigratinib which has demonstrated promising activity [235]. A phase 2/3 trial of the pan-FGFR inhibitor, rogaratinib versus chemotherapy in patients with locally advanced or metastatic UC with FGFR1-3 mRNA overexpression demonstrated similar outcomes as compared to chemotherapy [542]. The increased identification of FGFR3 mutations/fusion has led to several ongoing trials with different agents and combinations in different disease settings.

*7.7.5 **Current status of predictive biomarkers***

The most important advance in recent years has been the recognition of alterations in FGFR3 including mutations and gene fusions as a predictive marker for response to FGFR inhibitors [234]. It is recommended to screen mUC patients ideally at diagnosis of metastatic disease for FGFR3 alterations to plan optimal treatment including trials.

Many efforts have focused on markers for predicting response to immune checkpoint inhibition. Programmed death-ligand 1 expression by immunohistochemistry has been evaluated in many studies with mixed and, so far, inconclusive results. This may in part be related to the use of different antibodies and various scoring systems evaluating different compartments i.e., tumour cells, immune cells, or both. A major limitation of PD-L1 staining relates to the significant proportion of PD-L1-negative patients that respond to immune

checkpoint blockade. The predictive value of PD-L1 was not confirmed in large phase III trials evaluating the integration of immunotherapy in the first-line setting for mUC [514-516]. At present, the only indication for PD-L1 testing in mUC is dictated by current EMA approvals and relates to the potential use of immune checkpoint inhibitors as first-line monotherapy in patients unfit for cisplatin-containing chemotherapy.

Another biomarker that has been evaluated for predicting response to immunotherapy is high TMB [238]. Neoantigen burden and TMB have been associated with response to immune checkpoint blockade in several malignancies. High TMB has been associated with response to immune checkpoint inhibitors in metastatic UC in small single-arm trials [236, 239] but was not confirmed so far in RCTs. Other markers that have been evaluated in predicting response to immune checkpoint inhibitors include molecular subtypes, CD8 expression by immunohistochemistry and other immune gene cell signatures. Recent work has focused on the importance of stroma including the role of TGFs in predicting response to immune checkpoint blockade [242, 243].

In conclusion, apart from FGFR3 alterations, there are currently no further validated predictive molecular markers that are routinely used in clinical practice.

*7.7.6 **Special situations***

7.7.6.1 Impact of prior neoadjuvant/adjuvant therapy on treatment sequence

Peri-operative systemic treatment is increasingly used in UC including cisplatin-based chemotherapy in the neoadjuvant setting for BC and adjuvant platinum-based chemotherapy for upper tract UC [543]. Many ongoing phase III trials investigate the use of immunotherapy in this setting as well (see Section 7.6.2). So far, one trial has reported a significant DFS benefit for adjuvant treatment with nivolumab compared with placebo whereas one trial reported no significant benefit using atezolizumab vs. placebo in the same setting whilst another trial reported negative findings [481, 484]. It is expected that an increased number of patients with metastatic UC will have received pre-treatment with platinum and/or immunotherapy agents. No prospective trials have investigated the treatment of such patients. The choice of treatment in these patients depends on the applied peri-operative treatment and the time until relapse. If at least 12 months have passed since the end of peri-operative treatment the same systemic treatment as in treatment-naive patients is recommended.

7.7.6.2 Systemic treatment of metastatic disease with histology other than pure urothelial carcinoma

Pure UC represents the predominant histology in over 90% of patients with mUC. subtypes (e.g. micropapillary, nested, sarcomatoid) and divergent differentiation (e.g., SCC, adenocarcinoma) can be found in addition to pure UC in up to 33% of patients. Such patients were often excluded from large phase II and phase III trials and therefore the knowledge about the best management of such patients is limited. The respective literature was reviewed recently [66] and an expert Delphi survey and consensus conference provided guidance [82]. In case of predominant pure UC it is recommended to treat patients with mixed histology the same way as patients with a pure UC histology. Patients with predominant non-urothelial differentiation such as small cell neuroendocrine carcinoma, urachal adenocarcinoma, SCC and adenocarcinoma should be treated individually.

*7.7.7 **Treatment of patients with bone metastases***

The prevalence of metastatic bone disease (MBD) in patients with advanced/metastatic UC is 30–40% [544]. Interestingly, a recent report described several observations related to age- and sex-related differences in the distribution of metastases in patients with metastatic BC and demonstrated that bone was the most common metastatic site in men with other differences noted according to patient age and sex [545]. Skeletal complications due to MBD have a detrimental effect on pain and QoL and are also associated with increased mortality [546]. Bisphosphonates such as zoledronic acid reduce and delay skeletal-related events (SREs) due to bone metastases by inhibiting bone resorption, as shown in a small pilot study [547]. Denosumab, a fully human monoclonal antibody that binds to and neutralises RANKL (receptor activator of nuclear factor κB ligand), was shown to be non-inferior to zoledronic acid in preventing or delaying SREs in patients with solid tumours and advanced MBD, including patients with UC [548]. Patients with MBD, irrespective of the cancer type, should be considered for bone-targeted treatment [546].

Patients treated with zoledronic acid or denosumab should be informed about possible side effects including osteonecrosis of the jaw and hypocalcaemia. Supplementation with calcium and vitamin D is mandatory. Dosing regimens of zoledronic acid should follow regulatory recommendations and have to be adjusted according to pre-existing medical conditions, especially renal function [549]. For denosumab, no dose adjustments are required for variations in renal function.

7.7.8 Summary: treatment algorithm for metastatic urothelial cancer update 2024

Figure 7.2 summarises the treatment algorithm for metastatic BC based on the evidence discussed in the text above. Patients with treatment-naive mUC can be divided into two broad categories: eligible for combination therapies or ineligible for combination therapies. The distinction between the two groups is currently based on the eligibility criteria for the pivotal trial EV-302/KEYNOTE 39A. Criteria include ECOG performance status 0-2, GFR ≥30ml/min and adequate organ functions with eligibility for treatment with EV and Pembrolizumab.

The combination of EV plus the checkpoint inhibitor pembrolizumab represents the new standard of care for patients who are deemed fit for combination therapies. In patients that might not be eligible for or refuse treatment with EV including patients with uncontrolled diabetes, peripheral neuropathy grade ≥2 and pre-existing significant skin disorders, platinum-based chemotherapy with integration of immune checkpoint inhibitors represents the preferred options.

With regards to platinum-based chemotherapy, the definitions are grouped according to platinum-eligibility based on clear definitions. In platinum-based chemotherapy, cisplatin is to be preferred to carboplatin. Patients who are cisplatin-ineligible but carboplatin-eligible should receive gemcitabine- carboplatin combination chemotherapy. In case of positive PD-L1 status, treatment with checkpoint inhibitors (atezolizumab or pembrolizumab) could be an alternative option.

Patients unfit for both cisplatin and carboplatin (platinum-unfit) can be considered for immunotherapy (FDA approved irrespective of PD-L1 status, EMA approved only for PD-L1 positive patients) or receive BSC.

In cases of disease stabilization or better on platinum-based chemotherapy switch, maintenance treatment with IO (avelumab) is recommended. Alternatively, patients can be followed closely and receive second-line immunotherapy at the time of progression (pembrolizumab).

It is recommended to determine FGFR mutation status before deciding about further-line treatment. Patients with FGFR3 mutations are candidates for FGFR inhibitor treatment.

Enfortumab vedotin therapy is standard in case of progression after platinum chemotherapy and IO, however based on EV-302/KEYNOTE 39A, the majority of patients will be candidates for EV plus pembrolizumab in the first-line setting. The optimal sequence of novel agents and potential combinations are the subject of many ongoing trials. It is generally recommended to treat patients within ongoing clinical trials whenever possible.

7.7.9 Summary of evidence and recommendations for metastatic disease

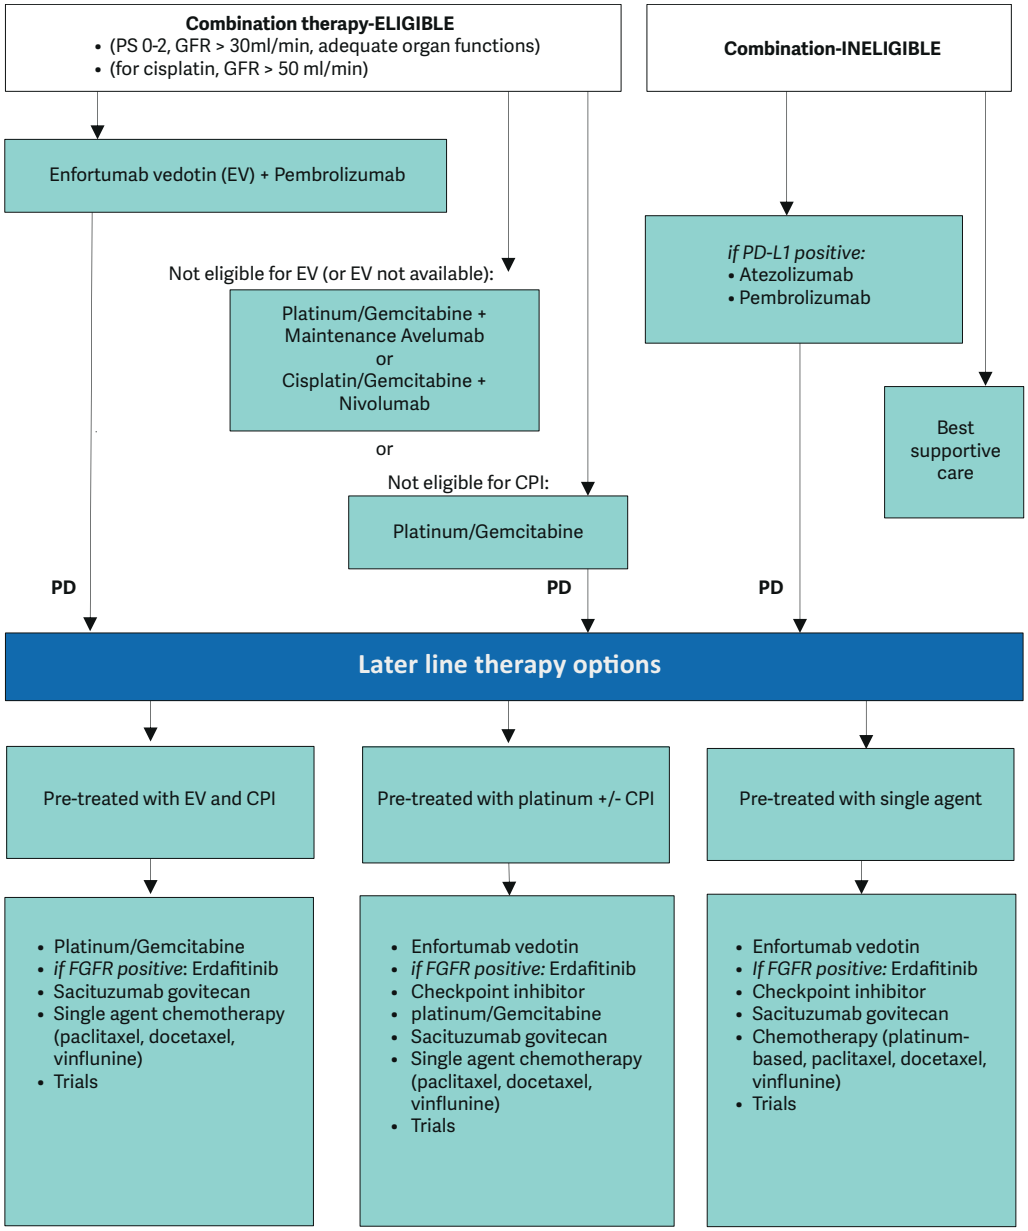
Summary of evidence	LE
Enfortumab vedotin in combination with pembrolizumab in the first-line setting demonstrated significant survival benefit as compared to chemotherapy.	1
The combination of cisplatin and gemcitabine plus Nivolumab in the first-line setting demonstrated significant survival benefit as compared to chemotherapy alone.	1b
In a first-line setting, PS and the presence or absence of visceral metastases are independent prognostic factors for survival.	1b
In a second-line setting, negative prognostic factors are: liver metastasis, PS ≥ 1 and low haemoglobin (< 10 g/dL).	1b
Cisplatin-containing combination chemotherapy can achieve median survival of up to 14 months, with long-term DFS reported in ~15% of patients with nodal disease and good PS.	1b
Single-agent chemotherapy provides low response rates of usually short duration.	2a
Carboplatin combination chemotherapy is less effective than cisplatin-based chemotherapy in terms of complete response and survival.	2a
There is no defined standard therapy for platinum chemotherapy-unfit patients with advanced or metastatic UC.	2b
Post-chemotherapy surgery after partial or complete response may contribute to long-term DFS in highly selected patients.	3
Zoledronic acid and denosumab have been approved for supportive treatment in case of bone metastases of all cancer types including UC, as they reduce and delay skeletal related events.	1b

PD-1 inhibitor pembrolizumab has been approved for patients that have progressed during or after previous platinum-based chemotherapy based on the results of a phase III trial.	1b
Enfortumab vedotin after prior platinum chemotherapy and checkpoint inhibitor immunotherapy has demonstrated a significant survival benefit as compared to chemotherapy.	1b
PD-1 inhibitor atezolizumab is approved for patients with advanced or metastatic UC unfit for cisplatin-based chemotherapy in case of high PD-L1 expression defined as tumour-infiltrating immune cells covering ≥ 5% of the tumour area using the SP142 assay.	1b
PD-1 inhibitor pembrolizumab is approved for patients with advanced or metastatic UC unfit for any platinum-based chemotherapy in case of high PD-L1 expression defined as CPS of ≥ 10 using the Dako 22C33 platform (EMA; FDA approval independent of PD-L1 status).	1b
The combination of chemotherapy plus pembrolizumab or atezolizumab and the combination of durvalumab and tremelimumab have not demonstrated OS survival benefit compared to platinum-based chemotherapy alone.	1b
Switch maintenance with the PD-L1 inhibitor avelumab has demonstrated significant OS benefit in patients achieving at least stable disease on first-line platinum-based chemotherapy.	1b

Recommendations	**Strength rating**
First-line treatment if eligible for combination therapy	
Use antibody drug conjugate enfortumab vedotin (EV) in combination with checkpoint inhibitor (CPI) pembrolizumab.	Strong
If contraindications for EV or EV not available: Offer platinum-containing combination chemotherapy (cisplatin or carboplatin plus gemcitabine) followed by maintenance treatment with CPI avelumab in patients with at least stable disease on chemotherapy.	Strong
If contraindications for EV (or EV not available) and cisplatin-eligible: Consider cisplatin/gemcitabine in combination with CPI nivolumab.	Strong
If contraindications for checkpoint inhibitor therapy: Use platinum-containing combination chemotherapy (Cisplatin or carboplatin plus gemcitabine).	Strong
First-line treatment if not eligible for combination therapy	
Consider single agent CPI pembrolizumab or atezolizumab in case of high PD-1 expression. (for definitions see text).	Weak
Second-line treatment	
After prior EV + CPI	
Offer platinum-containing combination chemotherapy (cisplatin or carboplatin plus gemcitabine).	Weak
If actionable FGFR alterations: offer erdafitinib.	Weak
Consider antibody drug conjugate sacituzumab govitecan.	Weak
Consider single agent chemotherapy (docetaxel, paclitaxel, vinflunine).	Weak
After prior platinum-based chemotherapy +/- CPI	
Offer antibody drug conjugate enfortumab vedotin.	Strong
If actionable FGFR alterations: offer erdafitinib.	Strong
If no prior CPI: offer pembrolizumab.	Strong
Consider antibody drug conjugate sacituzumab govitecan.	Weak
Consider single agent chemotherapy (docetaxel, paclitaxel, vinflunine).	Weak
Further treatment after EV, CPI, platinum-based therapy	
General statement: Offer treatment in clinical trials. Consider best supportive care (BSC) alone if patient is not a candidate for further cancer-specific systemic therapy.	Strong
If actionable FGFR alterations: offer Erdafitinib.	Weak

BSC = best supportive care; CPI = checkpoint inhibitor; EV = enfortumab vedotin; GC = gemcitabine plus cisplatin; FGFR = fibroblast growth factor receptor

Figure 7.2: Flow chart for the management of metastatic urothelial cancer*



**EV = enfortumab vedotin; FGFR = fibroblast growth factor receptor; GFR = glomerular filtration rate; PS = performance status; CPI=checkpoint inhibitor; PD-L1= programmed deathligand 1; PD= programmed death*

7.8 Quality of life

7.8.1 Introduction

The evaluation of HRQoL considers physical, psychological, emotional and social functioning. In patients with MIBC, HRQoL is affected, particularly in the physical and social functioning domains [550, 551].

Several questionnaires have been validated for assessing HRQoL in patients with BC, including FACT-G [552], EORTC QLQ-C30/BLM30 [553], SF-36 [554] and the Bladder Cancer Index (BCI) [555]. In spite of these validated questionnaires, there is heterogeneity in the measurements used to assess sexual health. A health questionnaire that covers the entire range of sexual health in bladder cancer patients is currently lacking [556].

Regardless of the which questionnaire is used, assessment of the baseline and post-treatment HRQoL is important. Questionnaires are helpful tools in clinical decision making, but, in addition, data support the prognostic value of baseline HRQoL [557]. In a large population-based study of patients with MIBC and no prior psychiatric history, 31% of all patients with MIBC were diagnosed with a new mental health disorder after their bladder cancer diagnosis [558].

7.8.2 ***Neoadjuvant chemotherapy***

Two RCTs including patiens undergoing NAC have published their HRQoL data [459, 559]. Huddart *et al.*, analysed the subset of patients within the BC2001 trial who underwent NAC prior to (chemo)radiation. Using the FACT-BL questionnaire, no detrimental impact of NAC on HRQoL was observed [459]. Kitamura *et al.*, reported on 64 patients included in the JCOG0209 study who underwent NAC (MVAC vs. MVAC and RC). An overall decline on HRQoL was reported directly following NAC using the FACT-BL questionnaire. However, no difference in HRQoL was observed after the consolidating RC.

7.8.3 ***Radical cystectomy and urinary diversion***

Two systematic reviews and meta-analyses focused on HRQoL after RC and urinary diversion [366, 560].

Yang *et al.*, compared HRQoL of incontinent and continent urinary diversions (all types) including 29 studies (n = 3,754) of which 9 had a prospective design (one of which was randomised) [366]. Only three studies reported HRQoL data both pre- and post-operatively. All these three studies reported an initial deterioration in overall HRQoL but general health, functional and emotional domains at 12 months post-surgery were equal or better than baseline. Overall, no difference in HRQoL between continent and incontinent urinary diversion was reported although an ileal conduit may confer a small physical health benefit [560].

Cerruto *et al.*, reported HRQoL comparing ileal conduit with orthotopic neobladder reconstruction [560]. A pooled analysis was performed including 18 studies (n = 1,553) of which the vast majority were retrospective studies. Although this study was hampered by methodological limitations, no statistical significant difference in overall HRQoL was found.

Altogether, there appears to be no superior type of urinary diversion in terms of overall HRQoL but it is rather a result of proper patient selection. An older and isolated patient is probably better served with an ileal conduit, whereas a younger patient with a higher level of interest in body image and sexuality is better off with an orthotopic diversion. The patient's choice is the key to the selection of reconstruction method [366].

A number of RCTs comparing ORC with RARC (with either intra- or extracorporeal urinary diversion) have reported their HRQoL data [358, 561-563]. All studies reported no statistical significant difference in HRQoL outcomes between surgical techniques.

7.8.4 ***Adjuvant therapy***

HRQoL data was reported in the phase 3 Checkmate 274 RCT where patients were randomised for adjuvant nivolumab or placebo after radical surgery for bladder cancer or UTUC. Patients were not pre-treated with NAC. No clinically meaningful detoration in HRQoL was observed during nivolumab treatment (based on the EORTC QLQ-C30/VAS questionnaire) [483].

7.8.5 ***Bladder-sparing trimodality therapy***

The only HRQoL data in bladder sparing treatment collected in a RCT setting was published by Huddart *et al.* [459]. The primary endpoint was the change in the Bladder Cancer Subscale (BLCS), as part of the FACT-BL questionnaire, at one year post-treatment. Questionnaire return rate at one and five years was 70% and 60%, respectively. A reduction in HRQoL was seen in the majority of the domains immediately following RT, however, in most patients the HRQoL scores returned to baseline 6 months after RT and maintained at this level for five years. Approximately 33% of patients reported persistent lower Bladder Cancer Subscale scores after five years. Addition of chemotherapy did not affect the HRQoL outcomes. Also see section 7.5.4 for further discussion of QoL after TMT.

7.8.6 ***Non-curative or metastatic bladder cancer***

In patients with primary non-curative or metastastic disease HRQoL is reduced because of associated micturition problems, bleeding, pain and therefore disturbance of social and sexual life [564]. Beneficial impact of palliative surgery [565], RT [566], and/or chemotherapy on bladder-related symptoms have been described [567].

A HRQoL analysis was performed in platinum-refractory patients who were randomised to pembrolizumab vs. another line of chemotherapy (KEYNOTE-45 trial) [568]. It was reported that patients treated with pembrolizumab had stable or improved global health status/QoL, whereas those treated with investigators' choice of chemotherapy experienced declines in global health [568].

Recently, HRQoL data was presented from cohort 1 of the EV-201 study including 125 patients treated with enfortumab vedotin after failing previous treatment with platinum chemotherapy and anti–PD-1/L1 therapy [569]. Patients who remained on enfortumab vedotin treatment showed no detoriation in HRQoL. In patients with bone metastases at baseline, pain control and possibly pain reduction was observed.

7.8.7 Summary of evidence and recommendations for health-related quality of life

Summary of evidence	LE
Compared to non-cancer controls, the diagnosis and treatment of BC has a negative impact on HRQoL.	2a
There is no distinct difference in overall QoL between patients with continent or incontinent diversion.	1b
In patients with MIBC treated with RC, overall HRQoL declines immediately after treatment and recovers to baseline at 12 months post-operatively in most patients.	1b
In patients with MIBC treated with RT, overall HRQoL declines immediately after treatment, and recovers to baseline at 6 months post-treatment.	1b
HRQoL data are comparable for RARC (with either intracorporeal or extracorporeal urinary diversion) and ORC.	1b
In patients with MIBC treated with RT, concomitant chemotherapy or neo-adjuvant chemotherapy has no significant impact on HRQoL.	1b
Adjuvant treatment with nivolumab does not result in a clinically meaningful decrease in HRQoL compared to placebo.	1b
In patients with platinum-refractory advanced UC, pembrolizumab may be superior in terms of HRQoL compared to another line of chemotherapy.	1b

Recommendations	Strength rating
Use validated questionnaires to assess health-related quality of life in patients with muscle-invasive bladder cancer, both at baseline and post-treatment.	Strong
Discuss the type of urinary diversion taking into account a patient preference, existing comorbidities, tumour variables and coping abilities.	Strong

8. FOLLOW-UP

8.1 Follow-up in muscle invasive bladder cancer

An appropriate schedule for disease monitoring should be based on natural timing of recurrence; probability and site of recurrence; functional monitoring after urinary diversion and the potential available management options [570].

Nomograms on CSS following RC have been developed and externally validated, but their wider use cannot be recommended until further data become available [571, 572].

Current surveillance protocols are based on patterns of recurrence drawn from retrospective series only. Combining this data is not possible since most retrospective studies use different follow-up regimens and imaging techniques. Additionally, reports of asymptomatic recurrences diagnosed during routine oncological follow-up and results from retrospective studies are contradictory [573-575]. From the Volkmer B, *et al.*, series of 1,270 RC patients, no differences in OS were observed between asymptomatic and symptomatic recurrences [574]. Conversely, in the Giannarini, *et al.*, series of 479 patients; those with recurrences detected during routine follow-up (especially in the lungs) and with secondary urothelial tumours as the site of recurrence, had a slightly higher survival [573]. Boorjian, *et al.*, included 1,599 RC patients in their series, with 77% symptomatic recurrences. On multivariate analysis, patients who were symptomatic at recurrence had a 60% increased risk of death as compared to asymptomatic patients [575].

However, at this time, no data from prospective trials demonstrating the potential benefit of early detection of recurrent disease and its impact on OS are available [576].

8.2 Site of recurrence

8.2.1 Local recurrence

Local recurrence takes place in the soft tissues of the original surgical site or in LNs. Contemporary cystectomy has a 5–15% probability of pelvic recurrence which usually occurs during the first 24 months, most often within 6 to 18 months after surgery. However, late recurrences can occur up to five years after RC. Risk factors described are pathological stage, LNs, positive margins, extent of LND and peri-operative chemotherapy [577].

Patients generally have a poor prognosis after pelvic recurrence. Even with treatment, median survival ranges from four to eight months following diagnosis. Definitive therapy can prolong survival, but mostly provides significant palliation of symptoms. Trimodality management generally involves a combination of chemotherapy, radiation and surgery [576].

*8.2.2 **Distant recurrence***

Distant recurrence is seen in up to 50% of patients treated with RC for MIBC. As with local recurrence, pathological stage and nodal involvement are risk factors [578]. Systemic recurrence is more common in locally-advanced disease (pT3/4), ranging from 32 to 62%, and in patients with LN involvement (range 52–70%) [579].

The most likely sites for distant recurrence are LNs, lungs, liver and bone. Nearly 90% of distant recurrences appear within the first three years after RC, mainly in the first two years, although late recurrence has been described after more than 10 years. Median survival of patients with progressive disease treated with platinum-based chemotherapy is 9–26 months [580-582]. However, longer survival (28–33% at 5 years) has been reported in patients with minimal metastatic disease undergoing TMT management, including metastasectomy [324, 583].

*8.2.3 **Urothelial recurrences***

After RC, the incidence of new urethral tumours was 4.4% (1.3–13.7%). Risk factors for secondary urethral tumours are urethral malignancy in the prostatic urethra/prostate (in men) and bladder neck (in women). Orthotopic neobladder was associated with a significant lower risk of urethral tumours after RC (OR: 0.44) [584].

There is limited data, and agreement, about urethral follow-up, with some authors recommending routine surveillance with urethral wash and urine cytology and others doubting the need for routine urethral surveillance. However, there is a significant survival advantage in men with urethral recurrence diagnosed asymptomatically vs. symptomatically, so follow-up of the male urethra is indicated in patients at risk of urethral recurrence [576]. Treatment is influenced by local stage and grade of urethral occurrence. In urethral CIS, BCG instillations have success rates of 83% [585]. In invasive disease, urethrectomy should be performed if the urethra is the only site of disease; in case of distant disease, systemic chemotherapy is indicated [3].

Upper urinary tract UCs occur in 4–10% of cases and represent the most common sites of late recurrence (3-year DFS following RC) [586]. Median OS is 10–55 months, and 60–67% of patients die of metastatic disease [576]. A meta-analysis found that 38% of UTUC recurrence was diagnosed by follow-up investigations, whereas in the remaining 62%, diagnosis was based on symptoms. When urine cytology was used during surveillance, the rate of primary detection was 7% vs. 29.6% with UUT imaging. The meta-analysis concluded that patients with non-invasive cancer are twice as likely to have UTUC as patients with invasive disease [587]. Multifocality increases the risk of recurrence by three-fold, while positive ureteral or urethral margins increase the risk by seven-fold. Radical nephroureterectomy can prolong survival [588].

8.3 Time schedule for surveillance

Although, based on low level evidence only, some follow-up schedules have been suggested, guided by the principle that recurrences tend to occur within the first years following initial treatment. A schedule suggested by the EAU Guidelines Panel includes a CT scan (every 6 months) until the third year, followed by annual imaging thereafter. Patients with multifocal disease, NMIBC with CIS or positive ureteral margins are at higher risk of developing UTUC, which can develop late (> 3 years). In those cases, monitoring of the UUT is mandatory during follow-up. Computed tomography is to be used for imaging of the UUT [587].

The exact time to stop follow-up is not well known and recently a risk-adapted schedule has been proposed, based on the interaction between recurrence risk and competing health factors that could lead to individualised recommendations and may increase recurrence detection. Elderly and very low-risk patients (those with NMIBC or pT0 disease at final cystectomy report) showed a higher competing risk of non-BC mortality when compared with their level of BC recurrence risk. On the other hand, patients with locally-advanced disease or LN involvement are at a higher risk of recurrence for more than 20 years [589]. However, this model has not been validated, does not differentiate between pure UC or variant histologies, and does not incorporate several risk factors related to non-BC mortality. Subtype tumours (including urothelial subtypes, non-urothelial subtypes, and mixed subtypes) might be associated with a greater recurrence risk than pure UC. Recently, a different follow-up scheme for patients with subtype tumours has been proposed [590]. In case of pT0 patients with previous subtype in TURB or in those in the age range between 60 and 79 years, the follow-up should be longer than in pure UC since the risk of recurrence persists over time. Similar to pure UC, patients older than 80 years with subtype tumours might not need oncologic surveillance given the higher risk of non-BC mortality compared to the risk of recurrence whereas patients younger than 60 years should be offered extended surveillance (> 10

years) since the risk of recurrence will exceed that of non-BC mortality [590]. Future prospective studies are needed to answer the question whether a more intense follow- up for subtypes should be considered.

Furthermore, the prognostic implications of the different sites of recurrence should be considered. Local and systemic recurrences have a poor prognosis and early detection of the disease will not influence survival [591]. Despite this, the rationale for a risk-adapted schedule for BC surveillance appears to be promising and deserves further investigation.

Since data for follow-up strategies are sparse, a number of key questions were included in a recently held consensus project [81, 82]. Outcomes for all statements for which consensus was achieved are listed in Section 8.6.

8.4 Follow-up of functional outcomes and complications

Apart from oncological surveillance, patients with a urinary diversion need functional follow-up. Complications related to urinary diversion are detected in 45% of patients during the first five years of follow-up. In a series of 131 patients, this rate increased to 94% in those surviving > 15 years [592].

General functional complications are diverse and include: vitamin B12 deficiency, metabolic acidosis, worsening of renal function, urinary infections, urolithiasis and ureteroenteric stricture [593]. Benign ureteroenteric strictures may occur in up to 20% of patients [593]. Based on SEER data, cystectomy was found to be associated with a 21% increased risk of fractures compared to no RC due to chronic metabolic acidosis and subsequent long-term bone loss [591]. Since low vitamin B12 levels have been reported in 17% of patients with bowel diversion, in case of cystectomy and bowel diversion, vitamin B12 levels should be measured annually [81, 82, 594]. In a series of 3,360 patients who underwent RC for MIBC, 29% progressed to advanced chronic kidney disease within 12 months [595].

In a retrospective study comparing various forms of intestinal diversion, ileal conduits had fewer late complications than continent abdominal pouches or orthotopic neobladders [594]. The main long-term complications in ileal conduit patients are stomal complications in up to 24% and functional and/or morphological changes of the UUT in up to 30% of patients [594, 596, 597]. At 15 years of follow-up, 50% of patients developed UUT changes and 38% developed urolithiasis [598].

The main specific complications in patients with a neobladder are continence problems and emptying dysfunction [576]. Clifford *et al.*, prospectively evaluated continence outcomes in male patients undergoing orthotopic neobladder diversion [599]. Day-time continence increased from 59% at less than three months post-operatively to 92% after 12 to 18 months. Night-time continence increased from 28% at less than three months post-operatively to 51% after 18 to 36 months. Also of interest is the urinary bother in females with an orthotopic neobladder. Bartsch and co-workers reported day-time and night-time continence rates of 70.4% and 64.8%, respectively, in 56 female neobladder patients. Emptying disfunction is especially common in women: approximately two-thirds need to catheterise their neobladder, while almost 45% do not void spontaneously at all [600]. There seems to be a correlation between voiding patterns and nerve preservation; in 66 women bilateral preservation of autonomic nerves decreased the need for catheterisation to between 3.4–18.7% (CI: 95%) [601].

In a single-centre series of 259 male patients, long-term follow-up after orthotopic bladder substitution (median 121 months [range 60–267]), showed that excellent long-term functional outcomes can be achieved in high-volume centres with dedicated teams [602].

8.5 Summary of evidence and recommendations for specific recurrence sites

Site of recurrence	Summary of evidence	Recommendation	Strength rating
Local recurrence	Poor prognosis. Treatment should be individualised depending on the local extent of tumour.	Offer radiotherapy, chemotherapy and possibly surgery as options for treatment, either alone or in combination.	Strong
Distant recurrence	Poor prognosis.	Offer chemotherapy as the first option, and consider metastasectomy or radiotherapy in case of unique metastasis site.	Strong
Upper urinary tract recurrence	Risk factors are multifocal disease, NMIBC/CIS or positive ureteral margins.	See EAU Guidelines on Upper Urinary Tract Urothelial Carcinomas [1].	Strong
Secondary urethral tumour	Staging and treatment should be done as for primary urethral tumour.	See EAU Guidelines on Primary Urethral Carcinoma [3].	Strong

8.6 EAU-ESMO consensus statements on the management of advanced- and variant bladder cancer [81, 82]*

Consensus statement
After radical cystectomy with curative intent, regular follow-up is needed.
After radical cystectomy with curative intent, follow-up for the detection of second cancers in the urothelium is recommended.
After radical cystectomy with curative intent, follow-up of the urethra with cytology and/or cystoscopy is recommended in selected patients (e.g., multifocality, carcinoma *in situ* and tumour in the prostatic urethra).
After trimodality treatment with curative intent, follow-up for the detection of relapse is recommended every 3–4 months initially; then after 3 years, every 6 months in the majority of patients.
After trimodality treatment with curative intent, regular cystoscopic evaluation of the bladder wall is needed.
After trimodality treatment with curative intent, follow-up imaging with CT of thorax and abdomen to assess distant recurrence or recurrence outside the bladder is needed.
In patients with a partial or complete response after chemotherapy for metastatic urothelial cancer, regular follow-up is needed. Imaging studies may be done according to signs/symptoms.
In patients treated with radical cystectomy with curative intent and who have a neobladder, management of acid bases household includes regular measurements of pH and sodium bicarbonate substitution according to the measured value.
To detect relapse after radical cystectomy with curative intent, a CT of the thorax and abdomen is recommended up to five years post-operatively.
Vitamin B12 levels have to be measured annually in the follow-up of patients treated with radical cystectomy and bowel diversion with curative intent.

**Only statements which met the a priori consensus threshold across all three stakeholder groups are listed (defined as ≥ 70% agreement and ≤ 15% disagreement, or vice versa).*
CT = computed tomography.

10. CONFLICT OF INTEREST

All members of the Muscle-invasive and Metastatic Bladder Cancer Guidelines Working Group have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publicly accessible through the European Association of Urology website: https://uroweb.org/guidelines/muscle-invasive-and-metastatic-bladder-cancer/panel.

This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

11. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Paris 2024. ISBN 978-94-92671-23-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, The Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aim and scope

This overview represents the updated European Association of Urology (EAU) Guidelines for the management of upper urinary tract urothelial carcinoma (UTUC). Separate EAU guidelines are available addressing non-muscle-invasive bladder cancer [1], muscle-invasive and metastatic bladder cancer (MIBC) [2], and primary urethral carcinoma [3].

It must be emphasised that clinical guidelines present the best evidence available to the experts, but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and references/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The European Association of Urology (EAU) Guidelines Panel on NMIBC consists of an international multidisciplinary group of clinicians, including urologists, uro-oncologists, a radiologist, a pathologist, and a patient representative. Members of this panel have been selected based on their expertise and to represent the professionals treating patients suspected of harbouring urothelial carcinoma (UC). All involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU website Uroweb: https://uroweb.org/guidelines/upper-urinary-tract-urothelial-cell-carcinoma/panel/.

1.3 Available publications

A quick reference document, the Pocket Guidelines is available online and in print. This is an abridged version which may require consultation together with the full text version. Several scientific publications are available, the most recent scientific summary was published in 2021 [4]. All documents are accessible through the EAU website: https://uroweb.org/guideline/upper-urinary-tract-urothelial-cell-carcinoma/.

1.4 Publication history & summary of changes

The first EAU Guidelines on UTUC were first published in 2011. Standard procedure for EAU Guidelines includes an annual assessment of newly published literature in the field to guide future updates. The 2024 UTUC Guidelines presents an update of the 2023 version.

1.4.1 Summary of changes

For the 2024 UTUC Guidelines, new and relevant evidence was identified, collated and appraised through a structured assessment of the literature for all sections of the Guidelines. Key changes include the addition of:

- New text and guidelines updates in section 3.2.2 on the genetic risk factors and the implications of identifying lynch syndrome's related UTUCs, and in section 3.4 on the molecular background of UTUCs;
- new text updates in section 6.1.2.2 on tumour location, multifocality, size and hydronephrosis;
- updates in section 6.2 on the risk stratification for clinical decision making, both in text and evidence;
- key updates to the text, evidence and guidelines in section 7.3.2 on the management of distant metastases.

2. METHODS

2.1 Data identification

For the 2023 UTUC Guidelines, new and relevant evidence has been identified, collated, and appraised through a structured assessment of the literature. The search was restricted to articles published between May 4th 2022 and May 1st 2023. Databases searched included Pubmed, Ovid, EMBASE and both the Cochrane Central Register of Controlled Trials and the Cochrane Database of Systematic Reviews. After deduplication, a total of 333 unique records were identified, retrieved, and screened for relevance.

Excluded from the search were basic research studies, case series, reports, and editorial comments. The publications identified were mainly retrospective, including some large multicentre studies. Owing to the scarcity of randomised data, articles were selected based on the following criteria: evolution of concepts, intermediate- and long-term clinical outcomes, study quality, and relevance. Older studies were only included if they were historically relevant.

A detailed search strategy is available online: https://uroweb.org/guideline/upper-urinary-tract-urothelial-cell-carcinoma/?type=appendicespublications.

Recommendations within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [5];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact and certainty of patient values and preferences on the intervention.

Strong recommendations typically indicate a high degree of evidence quality and / or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [6].

Additional methodology information and a list of associations endorsing the EAU Guidelines can be found in the online: https://uroweb.org/eau-guidelines/methodology-policies.

2.2 Review

The UTUC Guidelines was subject to peer-reviewed prior to publication in 2023.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Urothelial carcinoma (UC) is the second most common urological malignancy in developed countries [7]. They can be localised in the lower (bladder and urethra) and/or the upper (pyelocaliceal cavities and ureter) urinary tract. Bladder cancer (BC) accounts for 90–95% of UCs whilst upper tract urothelial carcinomas (UTUC) account for only 5–10% of UCs with an estimated annual incidence in Western countries of almost two cases per 100,000 inhabitants [1]. This rate has risen in the past few decades likely as a result of improved detection and the aging population [8, 9].

The peak incidence is in individuals aged 70–90 years and UTUC is twice as common in men [10]. A retrospective international registry including data from 2,380 patients diagnosed between 2014 and 2019 (101 centres from 29 countries) confirmed that UTUC patients were predominantly male (70.5%) and 53.3% were past or present smokers. The majority of patients (53%) were diagnosed after they presented with symptoms, mainly visible haematuria [11]. This was confirmed by a meta-analysis pooling 44 studies that showed a pooled UTUC incidence rate of 0.75% in patients with visible haematuria and 0.17% for those with non-visible haematuria [12]. In addition, approximately two-thirds of patients who present with UTUCs have muscle-invasive disease at diagnosis compared to 15–25% of patients diagnosed with *de novo* BC [13]. The higher incidence of muscle-invasive disease in UTUC vs. BC has been confirmed in population-based studies from Germany and England suggesting that muscle-invasive UTUC represents approximately half of incident cases in recent years [14, 15]. Approximately 9% of patients present with metastasis [8, 16-18].

Pyelocaliceal tumours are approximately twice as common as ureteral tumours and multifocal tumours are found in approximately 10–20% of cases [19]. The presence of concomitant carcinoma *in situ* of the upper tract is between 11% and 36% [8]. In 17% of cases, concurrent BC is present [20] whilst a prior history of BC is found in 41% of American men but in only 4% of Chinese men [21]. This, along with genetic and epigenetic factors, may explain why Asian patients present with more advanced and higher-grade disease compared to other ethnic groups [8].

Following treatment, recurrence in the bladder occurs in 29% of UTUC patients, depending on patient-, tumour- and treatment-specific characteristics [22] compared to a 2–5% recurrence rate in the contralateral upper tract [23].

Upper tract UC and BC exhibit significant differences in the prevalence of common genomic alterations. In individual patients with a history of both tumours, BC and UTUC are often clonally related. Genomic characterisation of UTUC provides information regarding the risk of bladder recurrence and can identify tumours associated with Lynch syndrome [24].

Regarding UTUC occurring in patients with BC, of 82 patients treated with intravesical bacillus Calmette-Guérin (BCG) for high-risk BC who had regular upper tract imaging between years 1 and 3, 13% developed UTUC, all of which were asymptomatic [25], whilst in another series of 307 patients without routine upper tract imaging the incidence of UTUC after BC was 25% [26]. A multicentre cohort study (n = 402) with a 50 month follow-up demonstrated a UTUC incidence of 7.5% in NMIBC patients receiving BCG with predictors being intravesical recurrence and non-papillary tumour at transurethral resection of the bladder (TURB) [27]. Following radical cystectomy for MIBC, 3–5% of patients develop a metachronous UTUC [28, 29].

3.2 Risk factors

*3.2.1 **Environmental risk factors***

A number of environmental risk factors have been implicated in the development of UTUC [19, 30]. Published evidence in support of a causative role for these factors is not strong, with the exception of smoking and aristolochic acid. Tobacco exposure increases the relative risk of developing UTUC by 2.5 to 7.0 fold [31-33]. A large population-based study assessing familial clustering in relatives of UC patients, including 229,251 relatives of case subjects and 1,197,552 relatives of matched control subjects, has demonstrated genetic or environmental roots independent of smoking-related behaviours. With more than 9% of the cohort being UTUC patients, clustering was not seen for UTUC. This suggests that the familial clustering of UC is specific to the lower urinary tract (i.e., BC) [34].

Aristolochic acid, a nitrophenanthrene carboxylic acid produced by aristolochia plants, which are used worldwide for different health-related issues, especially in China and Taiwan [35], exerts negative effects on the urinary system. Aristolochic acid irreversibly injures renal proximal tubules resulting in chronic tubulointerstitial disease, while the mutagenic properties of this carcinogen can lead to UTUC [35-37]. Aristolochic acid has been linked to BC, renal cell carcinoma, hepatocellular carcinoma, and intrahepatic cholangiocarcinoma [38]. Two routes of exposure to aristolochic acid are known: (i) environmental contamination of agricultural products by aristolochia plants, as reported for Balkan endemic nephropathy [39]; and (ii) ingestion of aristolochia-based herbal remedies [40, 41]. Following bioactivation, aristolochic acid reacts with genomic DNA to form aristolactam-deoxyadenosine adducts [42]; these lesions persist for decades in target tissues, serving as robust biomarkers of exposure [43]. These adducts generate a unique mutational spectrum, characterised by A>T transversions located predominately on the non-transcribed strand of DNA [38, 44]. However, it is estimated that less than 10% of individuals exposed to aristolochic acid develop UTUC [37].

Two retrospective series demonstrated that aristolochic acid-associated UTUC is more common in females [45, 46]. However, females with aristolochic acid UTUC have a better prognosis than their male counterparts. Consumption of arsenic in drinking water and aristolochia-based herbal remedies together appears to have an additive carcinogenic effect [47]. In Taiwan and Chile, the presence of arsenic in drinking water has been tentatively linked to UTUC [48, 49].

In addition, alcohol consumption may be associated with development of UTUC. A large case-control study (1,569 cases and 506,797 controls) has evidenced a significantly higher risk of UTUC in ever-drinkers compared to never-drinkers (OR: 1.23; 95% CI: 1.08–1.40, p = 0.001). Compared to never-drinkers, the risk threshold for UTUC was > 15 g of alcohol/day. A dose-response has been observed [50].

*3.2.2 **Genetic risk factors***

Lynch syndrome is characterised by a predisposition to early onset colorectal cancer and several extra-colonic malignancies related to pathogenic germline mutations in one allele of the mismatch repair (MMR) genes MLH1, MSH2, MSH6 or PMS2. After colorectal and endometrial cancers, UTUC is the 3rd most common malignancy in the Lynch syndrome spectrum [51]. Identifying Lynch Syndrome's related UTUCs has important clinical implications for both the patient and their relatives given the high risk of developing subsequent multiple different malignancies in the carrier and the strong hereditary predisposition of this condition. Germline mutations in MMR genes are found in 9% of patients with UTUC compared to 1% of patients with BC [52].

From a genetic perspective, the majority of tumours develop in MSH2 and MSH6 mutation carriers [53]. The carcinogenesis is related to the somatic mutation of the second allele of the germline-mutated MMR gene. This will result in a deficient MMR (dMMR) system related to the loss of the expression of the corresponding protein MLH1, MSH2, MSH6 or PMS2 in immunochemistry, which can be responsible for a microsatellite instability identified using the PCR method.

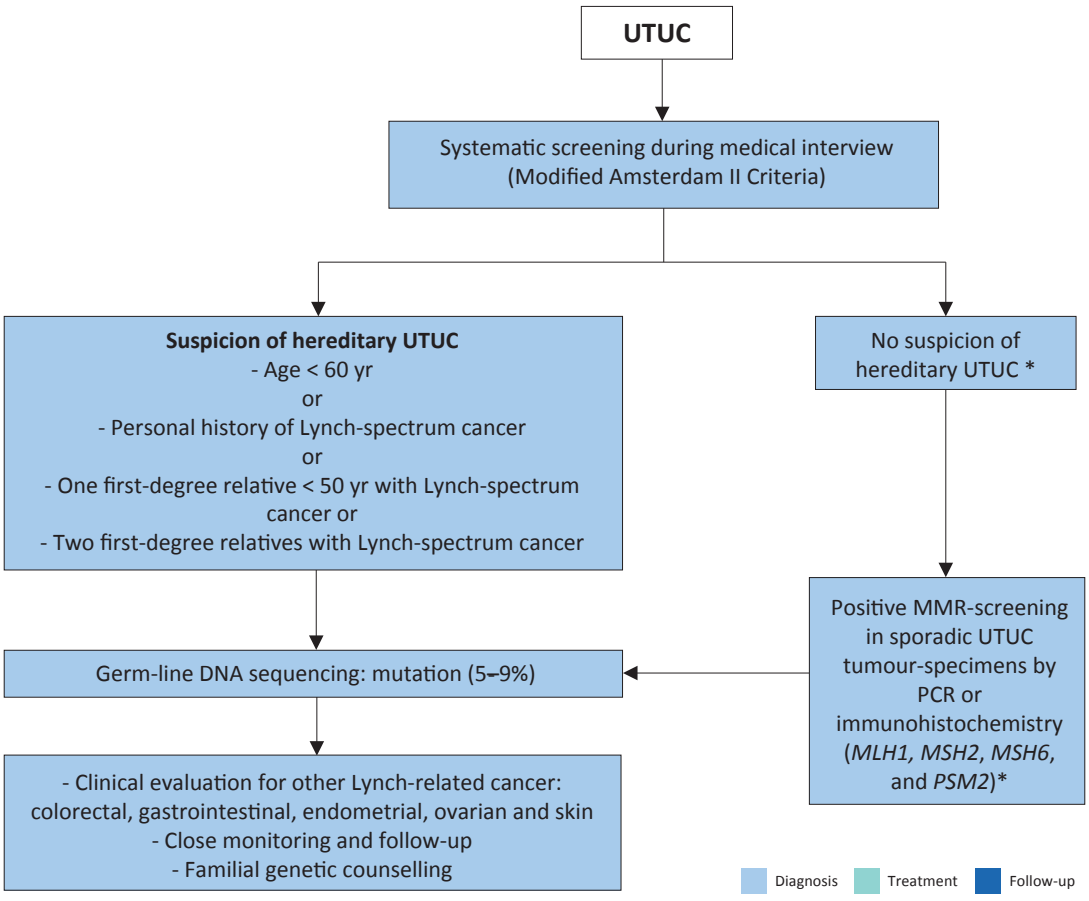
From a clinical perspective, although the PREMM5 model has been developed to estimate the cumulative probability of an individual to carry a germline mutation related to the Lynch syndrome [54], the Amsterdam II criteria remains predominantly used to identify families that are at increased risk of Lynch syndrome [55]. The latter include:

1. At least three relatives with a Lynch-associated cancer (colorectal, endometrium, small bowel or UTUC);
2. A first degree relative to the other two;
3. At least two successive affected generations;
4. At least one relative diagnosed before the age 50;
5. Exclusion of familial adenomatous polyposis in the colorectal cancer cases;
6. Pathological confirmation of the diagnosis.

A study of 115 consecutive UTUC patients reported that 13.9% screened positive for potential Lynch syndrome using the Amsterdam II criteria and 5.2% had confirmed Lynch syndrome [56].

Another UTUC-specific study has suggested that an age <60 at initial diagnosis and a personal history of any other Lynch-related malignancy could be both associated with an increased risk of Lynch syndrome in these patients [57]. A simplified screening tool for UTUC patients has been proposed including these two criteria associated with two others deriving from the Amsterdam II criteria and including one-first degree relative with Lynch-related cancer diagnosed before 50 and two first-degree relatives with Lynch-related cancer regardless of age [58]. Using this simplified screening tool, the proportion of UTUC patients with a suspicion of Lynch-related disease could be more than 20% [58]. Importantly, patients with UTUC who are identified at high risk for Lynch syndrome based on clinical criteria should undergo germline DNA sequencing and family counselling [59, 60] (Figure 3.1). Nonetheless, given the limited diagnostic performance of clinical criteria, UTUC patients without suspicion for genetic predisposing factors could be tested for MSI or dMMR using PCR or immunochemistry, respectively. As for any clinical suspicion of hereditary UTUC, those with positive test should also undergo germline DNA sequencing and family counselling [52, 61-64] (Figure 3.1).

Figure 3.1: Selection of patients with UTUC for Lynch syndrome screening during the first medical interview



**These patients may benefit from MMR deficiency screening using PCR or IHC. Positive result should prompt subsequent testing for germline DNA sequencing mutations.*
MMR = mismatch repair; mismatch repair genes = MLH1, MSH2, MSH6, and PSM2; UTUC = upper urinary tract urothelial carcinoma.

Other germline mutations in MSH2, BRCA2, BRCA1 and BRIP1 has been shown to significantly increase the risk of developing UTUC in Chinese patients [65]. Differences in the exposure and susceptibility to carcinogens such as smoking may explain the differences in susceptibility to genetic predisposing mutations to overt disease. Some genetic polymorphisms are associated with an increased risk of cancer or faster disease progression that introduces variability in the inter-individual susceptibility to the risk factors previously mentioned. Upper urinary tract UCs may also share some risk factors and described molecular pathways with bladder UC [24]. So far, two UTUC-specific polymorphisms have been reported [66].

3.2.3 History of bladder cancer

A history of BC is associated with a higher risk of developing UTUCs (see Section 3.1). Patients requiring ureteral stenting at the time of TURB, including prior to radical cystectomy, have been shown to have a higher risk for upper tract recurrence [67, 68].

3.3 Histology and classification

3.3.1 Histological types

Upper urinary tract tumours are almost always UCs with pure non-urothelial histology being rare [69, 70]. However, histological subtypes are present in approximately 25% of UTUCs [71, 72]. Pure squamous cell carcinoma of the urinary tract is often assumed to be associated with chronic inflammatory diseases and infections arising from urolithiasis [73, 74]. Urothelial carcinoma with divergent squamous differentiation (i.e., squamous subtype) is present in approximately 15% of cases [73]. Keratinising squamous metaplasia of urothelium is a risk factor for squamous cell cancers and therefore mandates surveillance. Upper urinary tract UCs with different subtypes are high- grade and have a worse prognosis compared to pure UC [72, 75, 76]. Other subtypes, although rare, include sarcomatoid with inverted growth also being is frequent in the UUT [76, 77].

Collecting duct carcinomas, which may seem to share similar characteristics with UCs, display a unique transcriptomic signature similar to renal cancer, with a putative cell of origin in the distal convoluted tubules. Therefore, collecting duct carcinomas are considered as renal tumours [78].

3.4 Molecular background of UTUCs

A number of studies focusing on molecular classification have been able to demonstrate genetically distinct groups of UTUC by evaluating DNA, RNA and protein expression. The most common genomic alterations included FGFR3, chromatin remodelling genes (i.e., KMT2D and KDM6A), TP53/MDM2, and other typical tumour suppressors/oncogenes such as CDKN2A or RAS [79]. Low-grade tumours are enriched for activating FGFR3 mutations (> 90% tumours) and depleted of TP53/MDM2 mutations, whereas high-grade tumours often show mutations in TP53 signalling [80]. It has also been shown that UTUC has a T-cell depleted immune contexture and activated FGFR3 signalling [81]. Five different molecular subtypes with different gene expression, tumour location and outcome have been identified, but, as yet, it is unclear whether these subtypes will respond differently to treatment and therefore, these subtypes have limited use in daily practice [82].

3.5 Summary of evidence and recommendations for epidemiology, aetiology, and histology

Summary of evidence	LE
Aristolochic acid and smoking exposure increases the risk for UTUC.	2a
Patients with Lynch syndrome are at risk for UTUC.	2a

Recommendations	Strength rating
Evaluate patient and family history to screen patients for Lynch syndrome using modified Amsterdam II criteria.	Strong
Perform germline DNA sequencing in patients with clinical suspicion of hereditary UTUC.	Weak
Offer testing for MMR proteins or microsatellite instability in patients without clinical suspicion of hereditary UTUC.	Weak

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Classification

The classification and morphology of UTUC and BC are similar [1]. However because of the difficulty in adequate sample acquisition, it is often difficult to distinguish between non-invasive papillary tumours [83], flat lesions (carcinoma *in situ* [CIS]), and invasive carcinoma in biopsies. Therefore, histological grade is often used for clinical decision making as it is strongly associated with pathological stage [84].

4.2 Tumour Node Metastasis staging

The tumour, node, metastasis (TNM) classification is shown in Table 1 [85]. The regional lymph nodes (LNs) are the hilar and retroperitoneal nodes and, for the mid- and distal ureter, the pelvic nodes. Laterality does not affect N classification.

4.3 Tumour grade

In 2004 and 2016, the WHO and the International Society of Urological Pathology published a new histological classification of UCs which provides a different patient stratification between individual categories compared to the older 1973 WHO classification [86, 87]. In 2022, an update of the 2004/2016 WHO grading classification was published without major changes [88]. These guidelines are still based on both the 1973 and 2004/2016 WHO classifications since most published data use the 1973 classification [83].

Table 1: TNM classification 2017 for upper tract urothelial cell carcinoma [85]

T - Primary tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Ta	Non-invasive papillary carcinoma
Tis	Carcinoma *in situ*
T1	Tumour invades subepithelial connective tissue
T2	Tumour invades muscularis
T3	(Renal pelvis) Tumour invades beyond muscularis into peripelvic fat or renal parenchyma (Ureter) Tumour invades beyond muscularis into periureteric fat
T4	Tumour invades adjacent organs or through the kidney into perinephric fat
N - Regional lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node 2 cm or less in the greatest dimension
N2	Metastasis in a single lymph node more than 2 cm, or multiple lymph nodes
M - Distant metastasis	
M0	No distant metastasis
M1	Distant metastasis

TNM = Tumour, Node, Metastasis (classification).

5. DIAGNOSIS

5.1 Symptoms

The diagnosis of UTUC may be incidental or symptom related. Flank pain, due to clot or tumour tissue obstruction can occur in 20–32% of cases [11]. Systemic symptoms (including anorexia, weight loss, malaise, fatigue, fever, night sweats, and cough) in patients with UTUC should prompt evaluation for metastases associated with a worse prognosis [11]. Symptoms at diagnosis are associated with indicate a worse prognosis [89].

5.2 Imaging

*5.2.1 **Computed tomography***

Computed tomography (CT) urography has the highest diagnostic accuracy of the available imaging techniques [90]. A meta-analysis of 13 studies comprising 1,233 patients revealed a pooled sensitivity of CT urography for UTUC of 92% (CI: 0.85–0.96) and a pooled specificity of 95% (CI: 0.88–0.98) [91].

Rapid acquisition of thin sections allows high-resolution isotropic images that can be viewed in multiple planes to assist with diagnosis without loss of resolution. Epithelial "flat lesions" without mass effect or urothelial thickening are generally not visible with CT.

The presence of enlarged LNs on CT is highly predictive of metastases in UTUC [92, 93].

*5.2.2 **Magnetic resonance urography***

Magnetic resonance (MR) urography is indicated in patients who cannot undergo CT urography, usually when radiation or iodinated contrast media are contraindicated [94]. The sensitivity of MR urography is 75% after contrast injection for tumours < 2 cm [94]. Computed tomography urography is more sensitive and specific for the diagnosis and staging of UTUC compared to MR urography [95].

*5.2.3 **^{18}F-Fluorodeoxglucose positron emission tomography/computed tomography***

A retrospective multicentre publication on the use of 18F-Fluorodeoxglucose positron emission tomography/computed tomography (FDG-PET/CT) for the detection of nodal metastasis in 117 surgically-treated UTUC patients reported promising sensitivity and specificity of 82% and 84%, respectively. Suspicious LNs on FDG-PET/CT were associated with worse recurrence-free survival [96]. These results warrant further validation and comparison with MR and CT. FDG-PET can also be used to assess (nodal and distant) metastases in patients unfit for iodinated contrast media due to renal impairment or allergy.

5.3 Cystoscopy

Urethrocystoscopy is an integral part of UTUC work-up to rule out concomitant BC [8, 20].

5.4 Cytology and urinary markers

Abnormal cytology may indicate high-grade UTUC when bladder cystoscopy is normal, and in the absence of CIS in the bladder and prostatic urethra [1, 97]. Voided urine cytology is less sensitive for UTUC than selectively obtained cytology from the affected upper tract [98]. In a recent study, barbotage cytology detected up to 91% of cancers [99]. Barbotage cytology taken from the renal cavities and ureteral lumina is preferred before application of a contrast agent for retrograde ureteropyelography as it may cause deterioration of cytological specimens [97, 99]. Retrograde ureteropyelography remains an option to detect UTUCs [84, 100, 101]. The sensitivity of fluorescence *in situ* hybridisation (FISH) for molecular abnormalities characteristic of UTUCs is approximately 72–84% [102, 103]. In a systematic review, including 25 studies on cytology and urinary markers, cytology and FISH were most commonly used [104]. FISH had comparable specificity (80-100%) and a higher sensitivity (35-86%) compared to cytology (11-71%). However, considering the wide ranges in sensitivity and specificity for both cytology and FISH, the authors concluded that these test were suboptimal to rule out cancer/UTUC. A prospective study in 79 patients with suspicion of UTUC using upper tract urine collected just before URS, reported sensitivities for Xpert Bladder, FISH, Bladder Epicheck and cytology of 100%, 87%, 64% and 42% , respectively. Specificities were 4%, 82%, 79% and 94%, respectively [105]. FISH, Bladder Epicheck and cytology could be helpful as an ancillary tool to detect UTUC; however, further confirmation in well-designed prospective comparative trials is needed.

5.5 Diagnostic ureteroscopy

Flexible ureteroscopy (URS) is used when necessary to confirm the diagnosis of UTUC by visualising the ureter, renal pelvis and collecting system and perform a biopsy of suspicious lesions. It is also essential for meticulous tumour mapping before considering kidney-sparing options for UTUC. Presence, appearance, multifocality and size of the tumour can be determined using URS. In addition, ureteroscopic biopsies can determine tumour

grade in more than 90% of cases with a low false-negative rate, regardless of sample size [106]. However, undergrading occurs with ureteroscopic diagnostic biopsy compared to nephroureterectomy specimens [107], making second-look URS necessary, as part of follow-up if kidney-sparing treatment is chosen [84, 108, 109] .

Ureteroscopy also facilitates selective ureteral sampling for cytology [101, 110, 111]. Stage assessment using ureteroscopic biopsy can be inaccurate, hence, combining ureteroscopic biopsy grade, imaging findings, and urinary cytology may help in the decision-making process between radical nephroureterectomy (RNU) and kidney-sparing therapy [111, 112]. In a meta-analysis comparing URS vs. no URS prior to RNU, 8 out of 12 studies found an increased risk for intravesical recurrence in those undergoing URS [113]. Performing a biopsy at URS was also identified as a risk factor for intravesical recurrence [113]. A second systematic review of 16 studies showed that URS alone was not significantly related to intravesical recurrence; whereas URS with a biopsy significantly increased the risk for subsequent intravesical recurrence albeit without an impact on overall survival and non-urothelial recurrence [114]. This underlines the need for a study evaluating whether an immediate intravesical instillation of chemotherapy in patients who underwent URS plus biopsy, or laser treatment, for UTUC can lower the intravesical recurrence rate after RNU (see section 7.2.4.2).

Technical developments in flexible ureteroscopes and the use of novel imaging techniques may improve visualisation and diagnosis of flat lesions [115]. Narrow-band imaging is a promising technique, but results are preliminary [116]. Optical coherence tomography and confocal laser endomicroscopy (Cellvizio®) have been used *in vivo* to evaluate tumour grade and/or for staging purposes, with a promising correlation with definitive histology in high-grade UTUC [117, 118].

5.6 Summary of evidence and recommendations for the diagnosis of UTUC

Summary of evidence	LE
The diagnosis and staging of UTUC is best done with computed tomography urography and URS.	2a
Selective urinary cytology has high sensitivity in high-grade tumours, including carcinoma *in situ*.	3
Urethrocystoscopy can detect concomitant BC.	2a

Recommendations	Strength rating
Perform a urethrocystoscopy to rule out bladder tumour.	Strong
Perform chest, abdominal and pelvis with computed tomography (CT) urography for diagnosis and staging.	Strong
Use diagnostic ureteroscopy (URS) if imaging and voided urine cytology are not sufficient for the diagnosis and/or risk-stratification of patients suspected to have UTUC.	Strong
Magnetic resonance urography or ^{18}F-Fluorodeoxglucose positron emission tomography/CT may be used when CT is contra-indicated.	Weak

6. PROGNOSIS

6.1 Prognostic factors

Many prognostic factors have been identified and can be used to risk-stratify patients in order to decide on the most appropriate local treatment (radical vs. kidney-sparing) and discuss peri-operative systemic therapy. Factors can be divided into patient-related factors and tumour-related factors.

*6.1.1 **Patient-related factors***

6.1.1.1 Age and gender

Older age at the time of RNU is independently associated with decreased cancer-specific survival (CSS) [119, 120]. Gender has no impact on prognosis of UTUC [121].

6.1.1.2 Ethnicity

A multicentre study of international patients from various academic centres did not show any difference in outcomes between races [122]. In contrast, U.S. population-based studies have indicated that African-American patients have worse outcomes than other ethnicities. The cause of this difference is unclear, possibly being related to access to care and/or biological patterns. Another study has demonstrated differences between Chinese and American patients at presentation in terms of risk factors, disease characteristics and predictors of adverse oncologic outcomes [21].

6.1.1.3 Genetic pre-disposition

Patients who test positive for Lynch syndrome, are significantly younger and exhibit a higher prevalence of UTUC with for ureteral location [123]. No impact on prognosis has been shown to date.

6.1.1.4 Tobacco consumption

Being a smoker at diagnosis increases the risk for disease recurrence, mortality [124, 125] and intravesical recurrence after RNU [126]. Smoking cessation over ten years improves outcomes to the level of non-smokers [125, 127].

6.1.1.5 Surgical delay

A delay between diagnosis of an invasive tumour and its removal may increase the risk of disease progression. Once a decision regarding RNU has been made, the procedure should be carried out within twelve weeks, whereas a treatment delay below four weeks has been suggested for the subgroup of patients with ureteral UTUC [128-132].

6.1.1.6 Other factors

High comorbidity and performance indices scores (e.g. American Society of Anesthesiologists [ASA], performance status [PS], and Charlson Comorbidity Index) are also associated with worse survival outcomes across disease stages [133-136].

A higher ASA score confers worse CSS after RNU [137], as does poor PS [138]. Obesity and higher body mass index adversely affect cancer-specific outcomes in patients treated with RNU [139], with potential differences between races [140]. Several blood-based biomarkers have been associated with locally-advanced disease and cancer-specific mortality such as high pre-treatment-derived neutrophil- lymphocyte ratio [141-144], low albumin [143-145], high C-reactive protein [143] or modified Glasgow score [146], high De Ritis ratio (aspartate transaminase/alanine transaminase) [147], altered renal function [143, 148] and high fibrinogen [143, 148].

*6.1.2 **Tumour-related factors***

6.1.2.1 Tumour stage and grade

The main prognostic factors are tumour stage and grade [111, 120, 149, 150]. Upper urinary tract UCs that invade the muscle have a poor prognosis. In a large Dutch series of UTUC, 5-year CSS was 86% for non- muscle-invasive tumours, 70% for muscle-invasive organ-confined tumours and 44% for locally-advanced tumours [18]. A contemporary SEER analysis of RNUs for high-risk disease showed that 5-year CSS was 86% for T1N0, 77% for T2N0, 63% for T3N0 and 39% for T4N0/T any N1–3 [151]. pT3 sub staging (pT3a vs. pT3b) might be relevant [152]; however, high quality validation is lacking.

6.1.2.2 Tumour location, multifocality, size and hydronephrosis

6.1.2.2.1 Multifocality

Approximately 7-42% of UTUC patients have been reported to have multifocal tumours [153-157]. Patients with multifocal tumours are more likely to harbour advanced tumour stage and a worse prognosis despite treatment with RNU [153-157]. However, multifocal tumours can also have a good prognosis and be present in the setting of otherwise low-risk UTUC.

It is important to note that the definition of multifocality varies among studies. Some studies consider the number of lesions [156], while others focus on tumour location (i.e., both renal pelvis and ureter) [153-155, 157].

Taken together, tumour multifocality alone is insufficient for risk stratification, and a combination of factors is needed to determine whether kidney-sparing surgery is a safe option. Patients should be categorised as high-risk UTUC not only when tumour multifocality is present but when it is accompanied by high risk factors (see Figure 6.1).

6.1.2.2.2 Hydroureteronephrosis

Hydroureteronephrosis has been linked to advanced disease and poor prognosis in patients treated with RNU [92, 158, 159]. A recent meta-analysis of 22 studies involving 7,542 patients found pre-operative hydroureteronephrosis to be significantly associated with ureteral tumour location, advanced tumour stage, and lymph node metastasis [160]. In addition, pre-operative hydroureteronephrosis was independently associated with worse overall, cancer-specific, and disease-free survival, but not intravesical recurrence [160].

It is important to note that some low-risk UTUC patients may exhibit hydroureteronephrosis with for example a pTa low-grade tumour obstructing the ureter. Taken together, just like tumour multifocality, the presence of hydroureteronephrosis alone is insufficient for risk stratification, and a combination of factors is needed to determine whether kidney-sparing surgery is a safe option. Patients should be categorised as high-risk UTUC not only when pre-operative hydroureteronephrosis is present but if it is accompanied by other high risk factors (see Figure 6.1).

6.1.2.2.3 Tumour size

Increasing tumour size is linked to a higher risk of muscle-invasive and non-organ-confined disease in both ureteral and renal pelvis UTUC cases [161]. A recent meta-analysis of 32,292 patients confirmed that larger tumours are significantly associated with worse overall, cancer-specific, and disease-free survival, as well as intravesical recurrence [161]. In renal pelvis UTUC, where the median tumour size ranges from 3.5 to 4.0 cm, each 1 cm increase in tumour size elevates the risk of harbouring muscle-invasive disease at RNU by 1.25-fold [162]. A recent multi-institutional study with 932 patients suggested that a 2 cm tumour size serves as the optimal threshold for identifying high-risk patients (> pT2 UTUC) [163]. However, measuring tumour size lacks standardisation, leading to inter-assessor variability.

Taken together, just like tumour multifocality and hydroureteronephrosis, tumour size alone is insufficient for risk stratification, and a combination of factors is needed to determine whether kidney-sparing surgery is a safe option. Therefore, similar to tumour multifocality and hydroureteronephrosis, tumour size alone should not dictate therapeutic decisions. Patients should be categorised as high-risk UTUC not only when tumour size exceeds 2 cm but if it is accompanied by other high risk factors (see Figure 6.1).

6.1.2.3 Pathological subtypes

Pathological subtypes are associated with worse CSS and overall survival (OS) [72]. Most studied subtypes are micropapillary [75], squamous [164] and sarcomatoid [75], all of which are consistently associated with locally-advanced disease and worse outcome [73]. Patients harbouring pathological subtypes should be proposed RNU after a shared-decision process due to the higher risk of progression.

6.1.2.4 Lymph node involvement

Patients with nodal metastasis experience poor survival after surgery [165]. Lymph node density (cut-off 30%) and extranodal extension are powerful predictors of survival outcomes in N+ UTUC [166-168]. Lymph node dissection (LND) performed at the time of RNU allows for optimal tumour staging, although its curative role remains controversial [167, 169-172].

6.1.2.5 Lymphovascular invasion

Lymphovascular invasion (LVI) is present in approximately 20% of invasive UTUCs and is an independent predictor of survival [173-175]. Lymphovascular invasion status should be specifically reported in the pathological reports of all UTUC specimens [176, 177].

6.1.2.6 Surgical margins

Positive soft tissue surgical margin is associated with a higher risk of disease recurrence after RNU. Pathologists should look for and report positive margins at the level of ureteral transection, bladder cuff, and around the tumour [178].

6.1.2.7 Other pathological factors

Extensive tumour necrosis (> 10% of the tumour area) is an independent prognostic predictor in patients who undergo RNU [179]. Where neoadjuvant treatment was given, pathological downstaging is associated with better OS [180, 181]. The architecture of UTUC, as determined from pathological examination of RNU specimens, is also a strong prognosticator with sessile growth pattern being associated with worse outcome [182-184]. Concomitant CIS in organ-confined UTUC and a history of bladder CIS are associated with a higher risk of recurrence and cancer-specific mortality [185, 186]. Macroscopic infiltration or invasion of peri-pelvic adipose

tissue confers a higher risk of disease recurrence after RNU compared to microscopic infiltration of renal parenchyma [71, 187].

6.1.3 Molecular markers

Because of the rarity of UTUC, the main limitations of molecular studies are their retrospective design and, for most studies, small sample size. None of the investigated markers have been validated to support their introduction in daily clinical decision making [79, 143].

6.2 Risk stratification for clinical decision making

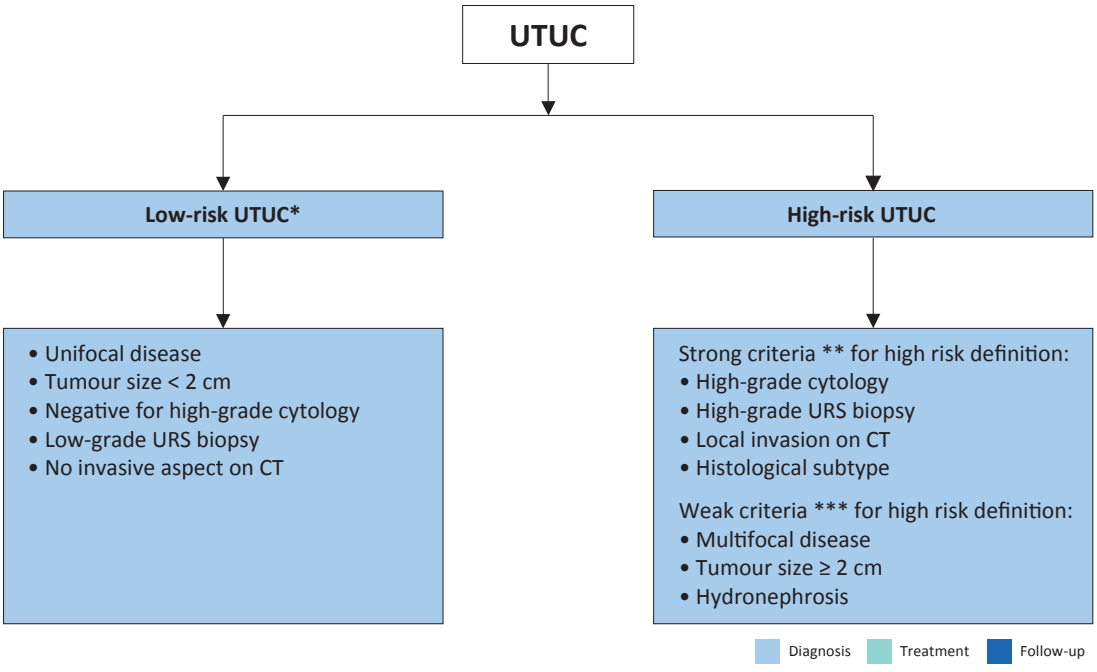
As tumour stage is difficult to assess clinically in UTUC, it is useful to stratify patients according to the low- and high risk of progression in order to identify those who are likely to benefit from kidney-sparing treatment and those who should be treated by radical nephroureterectomy [188, 189]. The factors to consider for the risk stratification are presented in Figure 6.1.

The level of evidence to consider individually size, multifocality and hydronephrosis as a surrogate for high-risk of progression remains low. Therefore, in the presence of low-grade disease associated with these factors, a shared decision-making process with the patient is important to discuss the therapeutic strategy (kidney-sparing strategy or RNU).

Pre-RNU models aiming at predicting which patient has > pT2 /non-organ-confined disease have been published [190-194]. Several risk stratification models have been assessed with the main aim to identify better patients eligible for kidney-sparing surgery [188, 189, 195-197].

Prognostic nomograms based on pre-operative factors and post-operative pathological characteristics are also available [169, 192, 198-203] and may be used when counselling patients regarding follow-up and administration of peri-operative chemotherapy. Nevertheless, despite a moderate to good discrimination accuracy, severe heterogeneity discourages its use in systematic ways.

Figure 6.1: Risk stratification of non-metastatic UTUC according to the risk of progression to a> pT2 /non-organ-confined disease



CT = computed tomography; URS = ureteroscopy; UTUC = upper urinary tract urothelial carcinoma.
** All these factors need to be present.*
***Any of these factors need to be present.*
****In the presence of low-grade tumour these factors are not strong predictors of invasive disease.*

6.3 Bladder recurrence

A meta-analysis of available data has identified significant predictors of bladder recurrence after RNU [22]. Three categories of predictors for increased risk of bladder recurrence were identified:

1. Patient-specific factors such as male gender, previous BC, smoking and pre-operative chronic kidney disease.
2. Tumour-specific factors such as positive pre-operative urinary cytology, tumour grade, ureteral location, multifocality, tumour diameter, invasive pT stage, and necrosis [204, 205].
3. Treatment-specific factors such as laparoscopic approach, extravesical bladder cuff removal, and positive surgical margins [22].

In addition, the use of diagnostic URS has been associated with a higher risk of developing bladder recurrence after RNU [206, 207]. Based on low-level evidence only, a single dose of intravesical chemotherapy after diagnostic/therapeutic ureteroscopy of non-metastatic UTUC has been suggested to lower the rate of intravesical recurrence, similarly to that after RNU [22].

6.4 Summary of evidence and recommendation for the prognosis of UTUC

Summary of evidence	LE
Important prognostic factors for risk stratification include tumour size, stage, grade, multifocality, hydronephrosis and different histological subtypes.	3
Models are available to predict pT2/non-organ confined disease and prognosis after RNU.	3
Patient, tumour, and treatment-related factors impact risk of bladder recurrence after both kidney-sparing management and RNU.	3
Currently, no molecular biomarkers are validated for clinical use.	3

Recommendation	Strength rating
Use prognostic factors to risk-stratify patients for therapeutic guidance.	Strong

7. DISEASE MANAGEMENT

All patients with suspicion of UTUC on imaging should be discussed in a multidisciplinary team prior to the initiation of treatment.

7.1 Localised low-risk disease

7.1.1 General considerations on kidney-sparing surgery

Kidney-sparing surgery for low-risk UTUC reduces the morbidity associated with radical nephroureterectomy (e.g., loss of kidney function), without compromising oncological outcomes [208]. In low-risk cancers, it is the preferred approach as survival is similar to that after RNU [208]. This option should therefore be discussed in all low-risk cases, irrespective of the status of the contralateral kidney, in a shared-decision making process with the patient. Recommendations for kidney-sparing management of UTUC are listed in Section 7.1.7.

7.1.2 Ureteroscopy

Endoscopic ablation should be considered in patients with clinically low-risk cancer [209, 210]. A flexible ureteroscope is useful in the management of pelvicalyceal tumours [211]. The patient should be informed of the need and be willing and able to comply with an early second-look URS [212] and stringent surveillance; complete tumour resection or destruction is necessary [212]. Nevertheless, a risk of disease progression remains with endoscopic management due to the suboptimal performance of imaging and biopsy for risk stratification and tumour biology [213]. A systematic review reported comparable survival outcomes after endoscopic treatment to radical nephroureterectomy at the cost of higher local recurrence rates and repeated interventions, but also with some uncertainties about long-term renal preservation after endoscopic treatment [214].

*7.1.3 **Percutaneous access***

Percutaneous management can be considered for low-risk UTUC in the renal pelvis [209, 215]. This may also be offered for low-risk tumours in the lower caliceal system that are inaccessible or difficult to manage by flexible URS. However, this approach is being used less due to the availability of improved endoscopic tools such as distal-tip deflection of recent ureteroscopes [210, 215]. Moreover, a risk of tumour seeding remains with percutaneous access [215].

*7.1.4 **Ureteral resection***

Segmental ureteral resection with adequate margins provides sufficient pathological specimens for staging and grading while preserving the ipsilateral kidney. Segmental resection of the proximal two-thirds of ureter is associated with higher failure rates than for the distal ureter [216, 217].

Distal ureterectomy with ureteroneocystostomy is indicated for low-risk tumours in the distal ureter that cannot be completely removed endoscopically [199, 216, 218]. A total ureterectomy with an ileal-ureteral substitution or renal autotransplantation with pyelocystostomy is technically feasible, but only in selected cases when a renal-sparing procedure is mandatory and the tumour is low risk [219, 220].

*7.1.5 **Chemo-ablation***

A single-arm phase III trial including 71 patients with biopsy-proven low-grade UTUC less than 15 mm showed that the use of mitomycin-containing reverse thermal gel (UGN-101) instillations (6 weekly induction) in a chemoablation setting via retrograde catheter to the renal pelvis and calyces was associated with a complete response rate in a total of 41 patients (58%) [221]. The most frequently reported all-cause adverse events (AEs) were: ureteric stenosis in 31 (44%), urinary tract infection in 23 (32%), haematuria in 22 (31%), flank pain in 21 (30%), nausea in 17 (24%) and 19/31 (61%) reported ureteric stenosis requiring treatment. Among the 41 patients with complete response, 29 received at least one maintenance instillation (median of 6), 23/41 (56%) remained disease free at one year [221].

*7.1.6 **Adjuvant instillations***

7.1.6.1 Upper urinary tract

The antegrade instillation of BCG or mitomycin C in the upper urinary tract via percutaneous nephrostomy after complete tumour eradication has been studied for CIS after kidney-sparing management [186, 222]. Retrograde instillation through a single-J open-ended ureteric stent is also used. Before both the antegrade and retrograde approach a nephro-ureterogram needs to rule out ureteric obstruction or leakage, asses that there is no infection and ensure a low pressure system to avoid pyelovenous influx during instillation/perfusion. The reflux obtained from a double-J stent has been used but this approach is suboptimal because the drug often does not reach the renal pelvis [223-226].

A systematic review and meta-analysis assessing the oncologic outcomes of patients with papillary UTUC or CIS of the upper tract treated with kidney-sparing surgery and adjuvant endocavitary treatment analysed the effect of adjuvant therapies (i.e., chemotherapeutic agents and/or immunotherapy with BCG) after kidney-sparing surgery for papillary non-invasive (Ta–T1) UTUCs and BCG for the treatment of upper tract CIS, finding no difference between the method of drug administration (antegrade vs. retrograde vs. combined approach) in terms of recurrence, progression, CSS, and OS; however, all included studies were underpowered and highly heterogeneous. Furthermore, the recurrence rates following adjuvant instillations are comparable to those reported in the literature in untreated patients, questioning their efficacy [227]. The analyses were based on retrospective small studies suffering from publication and reporting bias.

Recent evidence suggests that early single adjuvant intracavitary upper tract instillation of mitomycin C in patients with low-grade UTUC might reduce the risk of local recurrence [228]. The authors report limited complications related to the instillations but propose a retrograde pyelography before instillations are commenced to exclude contrast extravasation. This concept will need further evaluation in a randomised context [228].

7.1.6.2 Bladder

There are currently no data to support the use of bladder instillation of chemotherapy after kidney-sparing surgery as available RCTs included only patients who received RNU.

*7.1.7 **Recommendation for kidney-sparing management of localised low-risk UTUC***

Recommendation	Strength rating
Offer kidney-sparing management as primary treatment option to patients with low-risk tumours.	Strong

7.2 Localised high-risk disease

*7.2.1 **Radical nephroureterectomy***

7.2.1.1 Surgical approach

7.2.1.1.1 Open radical nephroureterectomy

Open RNU with bladder cuff excision is the standard treatment of high-risk UTUC, regardless of tumour location [13]. Radical nephroureterectomy must be performed according to oncological principles preventing tumour seeding [13]. Section 7.2.5 lists the recommendations for RNU.

7.2.1.1.2 Minimal invasive radical nephroureterectomy

Retroperitoneal metastatic dissemination and metastasis along the trocar pathway following manipulation of large tumours in a pneumoperitoneal environment may occur [229, 230]. Several precautions may lower the risk of tumour spillage:

1. avoid entering the urinary tract, except when performing a bladder cuff excision and only after prior clipping of the ureter and complete drainage of the bladder;
2. avoid direct contact between instruments and the tumour;
3. perform the procedure in a closed system. Avoid morcellation of the tumour and use an endobag for tumour extraction;
4. the kidney and ureter must be removed *en bloc* with the bladder cuff;
5. in invasive or large (T3/T4 and/or N+/M+) tumours an open approach is favoured, as the oncological outcomes may be better compared to minimally-invasive RNU [231, 232].

Laparoscopic RNU is safe in experienced hands when adhering to strict oncological principles. There is a tendency towards equivalent oncological outcomes after laparoscopic vs. open RNU [230, 233-236]. One prospective randomised study has shown that laparoscopic RNU is inferior to open RNU for non-organ- confined UTUC. However, this was a small trial (n = 80) [232]. Oncological outcomes after RNU have not changed significantly over the past three decades despite staging and surgical refinements [237]. In a population-based data set, a hospital volume of > 6 patients per year treated with RNU showed improvement of short-term outcomes (30- and 90-day mortality) and overall long-term survival [238]. A robot-assisted laparoscopic approach can be considered allowing comparable peri operative benefit as standard laparoscopic surgery [239-241], with data suggesting oncologic equivalence with the other approaches [242-244]; however, the risk of intravesical recurrence may be increased with both laparoscopic and robotic RNU compared to the open approach [245].

7.2.1.1.3 Bladder cuff management

Resection of the distal ureter and its orifice is performed because there is a considerable risk of tumour recurrence in this area and in the bladder [22, 216, 246-248]. Several techniques have been considered to simplify distal ureter resection, including the pluck technique, stripping, transurethral resection of the intramural ureter, and intussusception. None of these techniques has convincingly been shown to be equal to complete bladder cuff excision [23, 246].

7.2.1.1.4 Lymph node dissection

The use of a LND template is likely to have a greater impact on patient survival than the number of removed LNs [249]. Template-based and completeness of LND improves CSS in patients with muscle-invasive disease and reduces the risk of local recurrence [250]. Even in clinically [251] and pathologically [252] node-negative patients, LND improves survival. The risk of LN metastasis increases with advancing tumour stage [170]. Lymph node dissection appears to be unnecessary in cases of TaT1 UTUC because of the low risk of LN metastasis [253-256], however, tumour staging is inaccurate pre-operatively; therefore a template-based LND should be offered to all patients who are scheduled for RNU for high-risk UTUC. The templates for LND have been described [250, 257, 258].

*7.2.2 **Distal ureterectomy***

Distal ureterectomy for high-risk UTUC in the distal ureter only seems to be associated with similar oncological outcomes as RNU [208, 259]. This procedure can be performed with concomitant LN dissection. However,

given the low level of evidence, this approach should only be currently used in highly selected cases where the benefits may be greater than the potential risks.

*7.2.3 **Kidney-sparing surgery for imperative indications***

Kidney-sparing surgery, including ureteroscopy or segmental ureterectomy, can be considered on a case-by- case basis for patients with high-risk UTUC with imperative indications such as solitary kidney, bilateral UTUC, severe chronic kidney disease or any other comorbidity compromising the use of RNU. However, there is a greater risk of progression after kidney-sparing surgery for high- vs. low-risk UTUC with a direct impact on survival [208].

*7.2.4 **Peri-operative chemotherapy***

7.2.4.1 Neoadjuvant treatments

7.2.4.1.1 Chemotherapy

The primary advantage of neoadjuvant chemotherapy (NAC) is the ability to give cisplatin-based regimens when patients still have maximal renal function. Several retrospective studies evaluating the role of NAC have shown evidence of pathological downstaging and complete response rates at RNU [180, 260-263] with a direct impact on OS [194]. Furthermore, NAC has been shown to result in lower disease recurrence- and mortality rates compared to RNU alone, without compromising the use of definitive surgical treatment with a potential OS benefit [262, 264-266].

No RCTs have been published yet but prospective data from phase II trials showed that NAC based on cisplatin combination therapy was associated with a 14 - 19% pathological complete response rate in high-grade and/or cT2-T4N0M0 UTUC [267, 268]. In addition, final pathological stage was < ypT1 in more than 60% of included patients with acceptable toxicity profile. In a systematic review and meta-analysis comprising more than 800 patients, NAC has shown a pathologic partial response of 43% and a downstaging in 33% of patients, resulting in an OS and CSS survival benefit compared with RNU alone [269]. However, it is important to note that the evidence in the meta-analysis is not conclusive, given the significant bias and heterogeneity of the available data and the lack of distinction between truly neoadjuvant and downstaging chemotherapy.

7.2.4.1.2 Immunotherapy

Only a small phase II study including 10 patients with high-risk UTUC evaluated the efficacy of pembrolizumab in the neoadjuvant setting [270]. However, no pathological response was observed and one treatment-related death was reported. Thus, there is currently no evidence to support the use of neoadjuvant immunotherapy for high-risk UTUC.

7.2.4.2 Adjuvant treatments

7.2.4.2.1 Bladder instillations

The rate of bladder recurrence after RNU for UTUC is 22–47% [189, 246]. Two prospective randomised trials [271, 272] and two meta-analyses [273, 274] have demonstrated that a single post-operative dose of intravesical chemotherapy (mitomycin C, pirarubicin) 2–10 days after surgery reduces the risk of bladder tumour recurrence within the first years post-RNU in patients without a history of BC. Prior to instillation, a cystogram can be considered in case of concerns about drug extravasation. All studies showed a very low risk of adverse events. Intravesical chemotherapy has also been safely given at the time of RNU prior to bladder cuff opening, removing the need for a post- operative cystogram, but with low level data for efficacy [275].

Based on current evidence it is unlikely that additional instillations beyond one peri-operative instillation of chemotherapy further substantially reduce the risk of intravesical recurrence [276]. Whilst there is no direct evidence supporting the use of intravesical chemotherapy instillation of chemotherapy after kidney-sparing surgery, single- dose chemotherapy might also be effective in that setting as well. Management is outlined in Figures 7.1 and 7.2. One low-level evidence study suggested that bladder irrigation might reduce the risk of bladder recurrence after RNU [277].

7.2.4.2.2 Systemic Chemotherapy

A phase III multicentre prospective RCT (n = 261) evaluating the benefit of four cycles of adjuvant gemcitabine-platinum combination chemotherapy initiated within 90 days after RNU vs. surveillance has reported a significant improvement in disease-free survival (DFS) in patients with pT2–pT4, N (any) or positive (pT any, N1–3) M0 UTUC (3 year DFS 71% vs 50%; 5 year DFS 63% vs 46%. HR 0.54 ; CI 0.36-0.79; 3 & 5 year MFS 19 % improvement HR 0.55 CI 0.0.36-0.77) [278]. Patients were stratified to gemcitabine/cisplatin or gemcitabine/carboplatin chemotherapy based on GFR alone with benefit seen irrespective of chemotherapy type. There was a non-significant trend towards improved OS (12% at 3 years) but as the study had met its primary endpoint of 3

year DFS, it closed early, leaving it underpowered for the secondary endpoint of OS. The main potential limitation of using adjuvant chemotherapy is the concern that renal function may deteriorate after RNU precluding cisplatin use in patients who could benefit from this [279, 280]. A review of peri-operative predictors of decline in renal function after RNU showed three month GFR levels of around 50 mls/min [281]. With split dose and hydration cisplatin may be considered in patients with a GFR down to 45 mL/min. Table 2 outlines the eligibility criteria for platinum chemotherapy.

In a retrospective study histological subtypes of UTUC exhibit different survival rates and adjuvant chemotherapy was only associated with an OS benefit in patients with pure UC [282]. However, whilst histological subtypes of UTUC exhibit different survival rates in retrospective studies, adjuvant chemotherapy should be considered where UC is the dominant pathology.

Table 2: Definitions of platinum-eligibility for systemic treatment of urothelial carcinoma. [2]

Platinum-eligible		**Platinum-ineligible**
Cisplatin-eligible	**Carboplatin*-eligible**	
ECOG PS 0-1 ***and*** GFR > 50–60 mL/min ***and*** Audiometric hearing loss grade < 2 ***and*** Peripheral neuropathy grade < 2 ***and*** Cardiac insufficiency NYHA class < III	ECOG PS 2 *or* GFR 30–60 mL/min ***or*** not fulfilling other cisplatin-eligibility criteria	Any of the following: • GFR < 30mL/min • ECOG PS > 2 • ECOG PS 2 *and* GFR < 60mL/min • Comorbidites > Grade 2

**** Carboplatin is not indicated for neoadjuvant treatment***

7.2.4.2.3 Immunotherapy

In a phase III, multicentre, double-blind RCT involving patients with high-risk muscle-invasive UC who had undergone radical surgery (pT3, pT4a, or pN+), adjuvant nivolumab improved DFS compared to placebo in the intention-to-treat population (20.8 vs. 10.8 months) and among patients with a programmed death-ligand 1 (PD-L1) expression level of 1% or more [283]. The patient population predominantly consisted of BC patients post-radical cystectomy, with an additional smaller cohort of patients with UTUC post-RNU. The median recurrence-free survival outside the urothelial tract in the entire intention-to-treat population was 22.9 months for nivolumab and 13.7 months for placebo. Treatment-related adverse events > grade 3 occurred in 17.9% of the nivolumab group and 7.2% of the placebo group. On subgroup analysis, patients with UTUC included in this study did not seem to benefit from adjuvant nivolumab, which requires further follow-up and analysis. Nonetheless, the European Medicines Agency (EMA) approved nivolumab as monotherapy for the adjuvant treatment of patients with muscle-invasive UC with tumour cell PD-L1 expression > 1%, who are at high risk of recurrence after radical surgery and who decline or are unfit for adjuvant chemotherapy [284].

A network meta-analysis suggests superior oncological benefit for adjuvant platinum-based chemotherapy over immune checkpoint inhibitors in patients treated with radical surgery for UTUC [285].

7.2.4.2.4 Radiotherapy

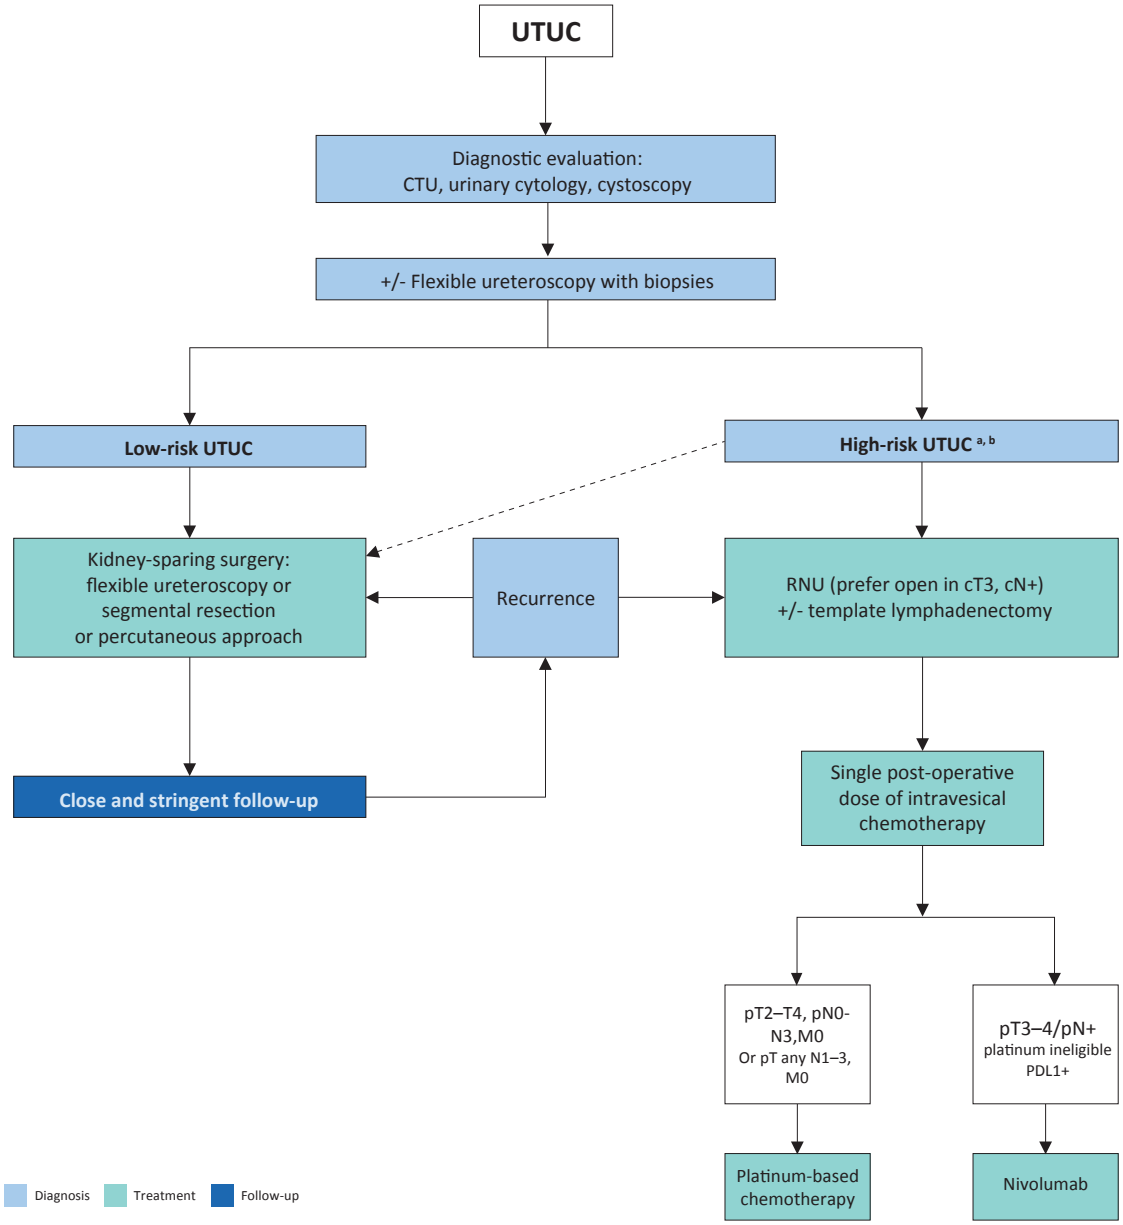
Adjuvant radiation therapy has been suggested to control loco-regional disease after surgical removal. The data remains controversial and insufficient for conclusions [286-289]. Moreover, its added value to chemotherapy remains questionable [288].

7.2.5 *Summary of evidence and recommendations for the management of high-risk non-metastatic UTUC*

Summary of evidence	LE
Radical nephroureterectomy is the standard treatment for high-risk UTUC, regardless of tumour location.	2a
Open, laparoscopic and robotic approaches have similar oncological outcomes for organ-confined UTUC.	2a
Failure to completely remove the bladder cuff increases the risk of BC recurrence.	3
Lymphadenectomy improves survival in muscle-invasive UTUC.	3
Post-operative platinum-based adjuvant chemotherapy improves disease-free survival.	1b
Single post-operative intravesical instillation of chemotherapy lowers the BC recurrence rate.	1b

Recommendations	Strength rating
Perform radical nephroureterectomy (RNU) in patients with high-risk non-metastatic upper tract urothelial carcinoma (UTUC).	Strong
Perform open RNU in non-organ confined UTUC.	Weak
Perform a template-based lymphadenectomy in patients with high-risk non-metastatic UTUC.	Weak
Offer adjuvant platinum-based chemotherapy after RNU to eligible patients with pT2–T4 and/or pN+ disease.	Strong
Deliver a post-operative bladder instillation of chemotherapy to lower the intravesical recurrence rate in patients without a history of BC.	Strong
Discuss adjuvant nivolumab with patients unfit for, or who declined, platinum-based adjuvant chemotherapy for > pT3 and/or pN+ disease after previous RNU alone or > ypT2 and/or ypN+ disease after previous neoadjuvant chemotherapy, followed by RNU.	Weak
Offer distal ureterectomy to selected patients with high-risk tumours limited to the distal ureter.	Weak
Discuss kidney-sparing management to high-risk patients with imperative indication on a case- by-case basis, in a shared-decision making process with the patient despite the higher risk of disease progression.	Strong

Figure 7.1: Proposed flowchart for the management of UTUC



a: In patients with solitary kidney consider a more conservative approach.
b: In low-grade patients without invasive features consider a more conservative approach.
CTU = computed tomography urography; RNU = radical nephroureterectomy; UTUC = upper urinary tract urothelial carcinoma.

Figure 7.2: Surgical treatment according to location and risk status

b: In low-grade patients without invasive features consider a more conservative approach.
1 = first treatment option; 2 = secondary treatment option.
**In case not amendable to endoscopic management.*
LND = lymph node dissection; RNU = radical nephroureterectomy; URS = ureteroscopy; UTUC = upper urinary tract urothelial carcinoma.

7.3 Metastatic disease

*7.3.1 **Clinical loco-regional lymph node metastases***

Evidence is lacking regarding the optimal management of clinical node-positive disease. Patients with clinically N+ UTUC should be offered downstaging first-line platinum-based chemotherapy. In patients whose cancer responds or who have stable disease, maintenance avelumab can be offered, especially in cN2 disease [290]. Depending on the extent of the nodal disease (i.e., cN1/N2) surgical resection with LN dissection can be discussed in a multidisciplinary team and with the patient when responding on after initial systemic therapy. In patients whose cancer progress, second-line treatment can be offered, similar to metastatic disease [291, 292].

*7.3.2 **Distant metastases***

7.3.2.1 Systemic treatments - First-line setting

7.3.2.1.1 Enfortumab vedotin + pembrolizumab combination therapy

For more than 23 years despite multiple attempts with new agents and/or combinations of treatments, platinum-based chemotherapy remained standard of care for previously untreated advanced or metastatic urothelial cancer. In October 2023, the landscape changed dramatically with the EV302 phase III randomised multi-centre study. This compared the combination of the nectin 4 directed antibody-drug conjugate enfortumab vedotin with the check point inhibitor pembrolizumab, (EV+P) with platinum based combination chemotherapy (gemcitabine-cisplatin or gemcitabine -carboplatin. See table 2 for definition of cisplatin eligibility).

This study showed significant improvement in both PFS (HR 0.45 (0.38-0.54) and OS (HR 0.47 (0.38-0.58) with RR of 68% (versus 44%) and CR 29% . OS benefit was seen across sub groups regardless of cisplatin eligibility. The most common grade 3 or above TRAE of special interest included skin reactions (15.5%) , peripheral neuropathy (6.8%) and hyperglycaemia (6.1%). The proportion of UTUC patients in this study is not yet known.

Sequencing of treatment after Ev+Pembro is currently unclear and later line treatments will depend upon what agents the patient has previously received (Figure 7.3).

7.3.2.1.2 Patients ineligible for EV+Pembro and fit for cisplatin-based combination chemotherapy

Upper tract UC and urothelial BC both respond to systemic platinum-based chemotherapy. Eligibility to platinum-based chemotherapy in the metastatic setting is based on the same criteria outlined in Table 2. A retrospective analysis of three RCTs showed that primary tumour location in the lower- or upper urinary tract had no impact on progression-free survival (PFS) or OS in patients with locally-advanced or metastatic UC treated with platinum-based combination chemotherapy [293]. Therefore, cisplatin-containing combination chemotherapy is the standard treatment for advanced or metastatic UTUC ineligible for EV + Pembro [2]. A number of cisplatin-containing chemotherapy regimens have proven efficacy although gemcitabine and cisplatin are the most widely used. The use of cisplatin-based chemotherapy is widely considered in patients with eGFR > 45 mL/min [293].

The efficacy of immunotherapy using PD1 or PD-L1 inhibitors has been evaluated in the first-line setting for the treatment of cisplatin/carboplatin-fit patients with metastatic UC, including those with UTUC [294]. First-line immune checkpoint inhibitors or the combination of platinum-based chemotherapy with immune checkpoint inhibitors have not previously resulted in positive significant survival advantages were thus not previously recommended [295-297]. These studies included both cisplatin and carboplatin combinations.

A phase III RCT in advanced/metastatic urothelial cancer has now shown an overall benefit from the addition of nivolumab to chemotherapy (gemcitabine-cisplatin). Median OS was improved (21.7 months v 18.9 months HR 0.78 (0.63-0.96) as well as median PFS (7.9 months versus 7.6 months HR 0.72 (0.59-0.88). Objective RR were 57.6% compared with 43.1 % for chemotherapy alone [298]. Although there is no sub-group analysis based on tumour position in this study, 12.6% of patients had UTUC.

7.3.2.1.3 Patients ineligible for Ev+Pembro and unfit for cisplatin-based combination chemotherapy

Carboplatin-based chemotherapy is recommended in patients unfit for cisplatin [2]. Carboplatin with gemcitabine is the preferred regimen [299], irrespective of PDL-1 status. In a recent critical re-analysis of RCTs comparing OS after cisplatin vs. carboplatin-based regimens in advanced UC, cisplatin conferred a minor OS benefit compared to carboplatin [300].

7.3.2.1.4 Maintenance therapy after first-line platinum-based chemotherapy

Maintenance avelumab is recommended in patients with complete/partial response or stable disease after 4–6 cycles of platinum-based chemotherapy, given in the first line setting only. Data from a phase III RCT showed that the use of avelumab maintenance therapy after 4 to 6 cycles of gemcitabine plus cisplatin or carboplatin (started within 10 weeks of completion of first-line platinum-based chemotherapy) significantly prolonged

OS as compared to best supportive care alone in those patients with advanced or metastatic UC who did not experience disease progression during, or responded to, first-line chemotherapy (HR: 0.69; 95% CI: 0.56–0.86) [290, 301]. An increase in median OS from 14 to 21 months was observed with avelumab. Although no subgroup analysis based on tumour location was available in this study, almost 30% of the included patients had UTUC. Similarly, in a phase II study comprising 108 patients with metastatic UC achieving at least stable disease on first-line platinum-based chemotherapy, maintenance pembrolizumab improved PFS compared to placebo (5.4 vs. 3.0 months) [302].

7.3.2.1.5 Patients unfit for any combination therapy

Pembrolizumab or atezolizumab are alternative choices for patients who are PD-L1 positive and not eligible/fit for platinum-based chemotherapy. In a single-arm phase II trial (n = 370) of cisplatin-ineligible UC, pembrolizumab monotherapy was associated with an objective response rate of 26% in 69 metastatic UTUC patients [303]. In the overall cohort, a PD-L1 expression of 10% was associated with a greater response rate to pembrolizumab. Treatment-related toxicity was in line with previous studies. In a single-arm phase II trial (n = 119) of cisplatin-ineligible UC, atezolizumab monotherapy was associated with an objective response rate of 39% in 33 (28%) metastatic UTUC patients [304]. Median OS in the overall cohort was 15.9 months and treatment-related toxicity was in line with previous studies [296].

7.3.2.2 Systemic treatments - later line setting

Subsequent treatments depend on the type of treatment given in the first line setting.

7.3.2.2.1 Platinum based chemotherapy

Platinum based chemotherapy should be the second line treatment of choice if not received in the first line setting. No data supports the use of maintenance avelumab outside of the first line setting.

7.3.2.2.2 Immunotherapy

A phase III RCT including 542 patients who received prior platinum-based chemotherapy for advanced UC showed that pembrolizumab decreased the risk of death compared to second-line chemotherapy (the investigator's choice of paclitaxel, docetaxel, or vinflunine); median OS: 10.3 months for pembrolizumab and 7.4 months for chemotherapy (HR: 0.73; 95% CI: 0.59–0.91) [305]. Responses were more frequent and durable for pembrolizumab compared to chemotherapy (21% vs. 11%). In the UTUC subgroup (n = 75/13.8%), the OS benefit seemed larger (50%).

The IMVigor211 trial explored atezolizumab in PD-L1-positive tumours in patients with tumours which relapsed after platinum-based chemotherapy; it failed to show a significant OS advantage of atezolizumab compared to second-line chemotherapy [306].

Other immunotherapies such as nivolumab [307], avelumab [308, 309] and durvalumab [310] have shown objective response rates ranging from 17.8% [310] to 19.6% [307] and median OS ranging from 7.7 months to 18.2 months in patients with platinum-resistant metastatic UC. These results were obtained from single-arm phase I or II trials only and the number of UTUC patients included in these studies was only specified for avelumab (n = 7/15.9%) without any subgroup analysis based on primary tumour location [309].

The immunotherapy combination of nivolumab plus ipilimumab has shown significant anti-tumour activity with objective response rate up to 38% in a phase I/II multicentre trial including 78 patients with metastatic UC experiencing disease progression after platinum-based chemotherapy [311]. Although UTUC patients were included in this trial, no subgroup analysis was available. Other immunotherapy combinations may be effective in the second-line setting but data are currently limited [312].

7.3.2.2.3 Novel agents

Fibroblast growth factor receptors (FGFR) inhibition

Erdafitinib, a pan-FGFR tyrosine kinase inhibitor of FGFR1–4, was associated with a 40% radiological response rate according to the Response Evaluation Criteria in Solid Tumours (RECIST) in a phase II trial of 99 patients with locally-advanced or metastatic UC who progressed after first-line chemotherapy and harboured a FGFR DNA genomic alterations (FGFR2/3 fusions or FGFR3 mutations) [313]. This study included 23 UTUC patients with visceral metastases showing a 43% radiological response rate. The subsequent phase III Thor trial randomised 266 patients with advanced UC who had had similar mutations and had experienced disease progression after 1-2 lines of previous treatment, to treatment with either erdafitinib or investigators choice of chemotherapy (vinfunine or docetaxel). Significant improvements in median OS, (4.3 months; HR 0.64;CI 0.47-0.88), PFS 2.9 months (58; CI 0.44-0.78) and a 36% risk reduction in death were observed. 33.5 % of patient in this study had UTUC [314]. As the rate of activating alterations of FGFR3 is higher in UTUC than in bladder cancer [315] a potentially greater impact

of FGR3 targeting agents is anticipated. UTUC patients should be tested for FGFR alterations (FGFR2/3 mutations or FGFR3 fusions) prior to erdafitinib treatment.

Antibody drug conjugates (ADC)

A phase II study enrolled 89 patients (of whom 43% had UTUC) with cisplatin-unfit metastatic UC experiencing disease progression after therapy with PD-1 or PD-L1 inhibitors. All patients received the antibody–drug conjugate enfortumab vedotin. The objective radiological response rate (RECIST) was 52% of which 20% of patients achieved complete response [316]. In a phase III trial of enfortumab vedotin for the treatment of patients with locally- advanced or metastatic UC who had previously received platinum-containing chemotherapy and had disease progression during or after treatment with a PD-1 or PD-L1 inhibitor, enfortumab vedotin significantly prolonged survival as compared to standard chemotherapy (median OS 12.88 vs. 8.97 months) [317].

In an open-label phase II trial a total of 108 patients with metastatic UC who progressed after platinum- based chemotherapy and checkpoint inhibitors were treated with the antibody-drug conjugate sacituzumab govitecan. The objective radiological response rate was 27%, with median duration of response of 7.2 months, median PFS of 5.4 months and median OS of 10.9 months. However, the proportion of patients with UTUC was not mentioned in the publication [318].

A pre-planned subgroup analysis from the phase III RANGE trial assessed the impact on outcomes and safety of ramucirumab added to docetaxel after disease progression on both platinum-based chemotherapy and immune checkpoint inhibitors [319]. Median PFS was 3.15 months on ramucirumab/docetaxel vs. 2.73 months on placebo/docetaxel (HR: 0.786; 95% CI: 0.404–1.528, p = 0.4877). This trend for ramucirumab benefit occurred despite the ramucirumab arm having a higher percentage of patients with poorer prognosis. However, these findings need confirmation by further studies, as this analysis is limited by patient numbers and an imbalance in the treatment arms.

7.3.2.3 Surgery

7.3.2.3.1 Radical nephroureterectomy

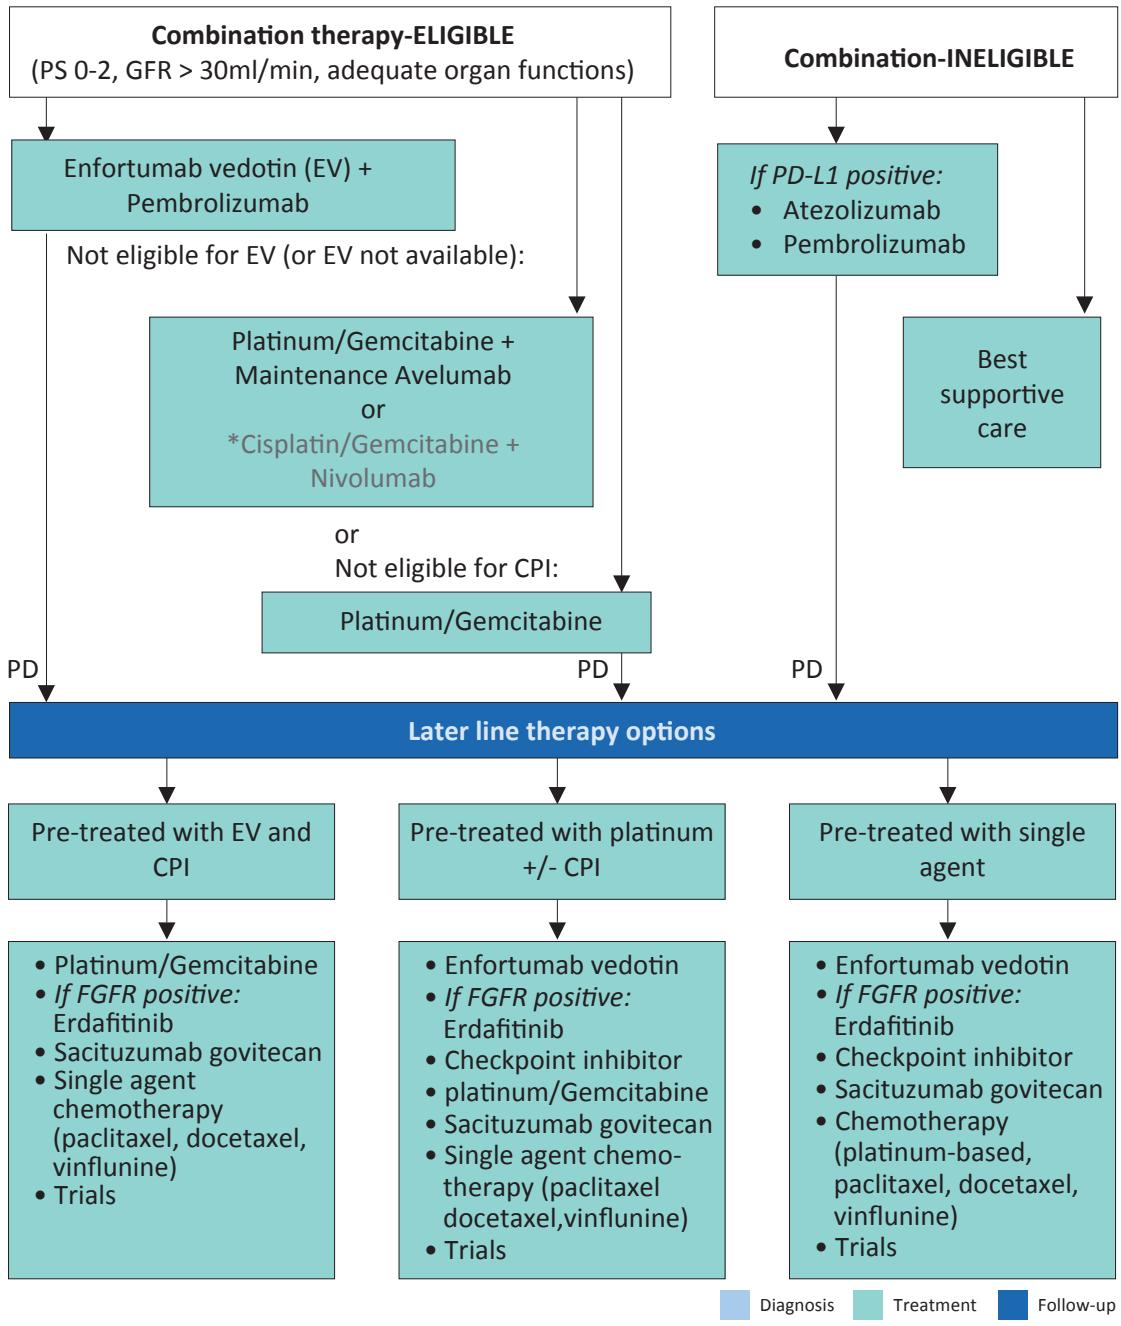
Data regarding RNU in the metastatic setting are lacking with mainly retrospective observational studies [320-322].

Although evidence remains very limited, RNU may be associated with CSS [321, 323, 324] and OS benefit in selected patients, especially those fit enough to receive cisplatin-based chemotherapy [320, 321]. It is noteworthy that these benefits may be limited to those patients with only one metastatic site [321]. Nonetheless, given the high risk of bias of the observational studies addressing RNU for metastatic UTUC, indications for RNU in this setting should mainly be reserved for palliative patients, aimed at controlling symptomatic disease [26, 124].

7.3.2.3.2 Metastasectomy

There is no UTUC-specific study supporting the role of metastasectomy in patients with advanced disease. Reports suggesting that resection of metastatic lesions could be safe and oncologically beneficial in selected patients should be interpreted with caution [325-329]. In the absence of data from RCTs, patients should be evaluated on an individual basis and the decision to perform a metastasectomy (surgically) should be made following a shared decision-making process with the patient.

Figure 7.3 Flowchart for the management of metastatic upper tract urothelial carcinoma



**In view of lack of subgroup analysis data for UTUC*
EV = enfortumab vedotin; FGFR = fibroblast growth factor receptor; GFR = glomerular filtration rate; PS = performance status; CPI=checkpoint inhibitor; PD-L1= programmed death-ligand 1; PD= programmed death

7.3.3 Summary of evidence and recommendations for the treatment of metastatic UTUC

Summary of evidence	LE
Enfortmab vedotin + Pembrolizumab offers an overall survival benefit compared to gemcitabine-cisplatin in the 1st line setting.	1b
Cisplatin-based combination chemotherapy can improve median survival.	2
Cisplatin-containing combination chemotherapy is the standard of care in advanced or metastatic patients fit enough to tolerate cisplatin and who are ineligible for Enfortumab + Pembrolizumab.	1b
Cisplatin-containing combination chemotherapy in combination with nivolumab offers a survival advantage compared with chemotherapy alone in the 1st line setting.	1b

Carboplatin-based combination chemotherapy offers a survival benefit in cisplatin unfit patients.	1b
Non-platinum combination chemotherapy has not been tested against standard chemotherapy in patients who are fit or unfit for cisplatin combination chemotherapy.	4
Maintenance avelumab is associated with an OS advantage compared with best supportive care in patients who did not have disease progression after 4 to 6 cycles of gemcitabine plus either cisplatin or carboplatin.	1b
PD-1 inhibitor pembrolizumab has been approved for patients who have experienced disease progression during or after previous platinum-based chemotherapy and did not receive previous immune therapy based on the results of a phase III trial.	1b
PD-1 inhibitor nivolumab has been approved for patients that have experienced disease progression during or after previous platinum-based chemotherapy and did not receive previous immune therapy based on the results of a phase II trial.	2a
PD-1 inhibitor pembrolizumab has been approved for patients with advanced or metastatic UC unfit for platinum-based first-line chemotherapy based on the results of a phase II trial but use of pembrolizumab is restricted to PD-L1 positive patients.	2a
PD-L1 inhibitor atezolizumab has been approved for patients with advanced or metastatic UC unfit for platinum-based first-line chemotherapy based on the results of a phase II trial, but use of atezolizumab is restricted to PD-L1 positive patients.	2a
Erdafitinib was associated with improved overall survival in platinum-refractory patients with locally-advanced or metastatic UC and FGFR DNA genomic alterations (FGFR2/3 mutations or FGFR3 fusions).	1b
Enfortumab vedotin was associated with OS benefit in patients who had previously received platinum-containing chemotherapy and experienced disease progression during or after treatment with a PD-1 or PD-L1 inhibitor.	1b
Palliative nephroureterectomy can improve quality of life by controlling symptomatic disease.	3
RNU can confer a survival benefit in highly selected patients with metastatic UC e.g., after response to platinum-based combination chemotherapy with limited metastatic burden.	4

Recommendations	**Strength rating**
Offer Enfortumab vedotin in combination with pembrolizumab as first line treatment to patients with advanced/metastatic disease.	Strong
First-line treatment for platinum-eligible patients who are unsuitable/ineligible for Enfortumab + Pembrolizumab	
Offer platinum combination chemotherapy to platinum-eligible patients.	Strong
Offer cisplatin based chemotherapy with gemcitabine-cisplatin + nivolumab in cisplatin eligible patients.	Weak
Offer cisplatin-based chemotherapy with gemcitabine/cisplatin or HD-MVAC to cisplatin-eligible patients.	Strong
Offer gemcitabine/carboplatin chemotherapy to cisplatin-ineligible patients.	Strong
Offer maintenance avelumab to patients who did not have disease progression after 4 to 6 cycles of platinum-based combination chemotherapy.	Strong
First-line treatment in patients ineligible for any combination therapy	
Offer checkpoint inhibitors pembrolizumab or atezolizumab to patients with PD-L1 positive tumours.	Weak
Later lines of treatment	
Offer platinum based combination chemotherapy as second line treatment of choice if not received in the first line setting.	Strong
Offer checkpoint inhibitor (pembrolizumab) to patients with disease progression during or after platinum-based combination chemotherapy for metastatic disease who did not receive maintenance avelumab.	Strong
Offer enfortumab vedotin to patients previously treated with platinum-containing chemotherapy and who had disease progression during or after treatment with a PD-1 or PD-L1 inhibitor.	Strong

Test UTUC patients for FGFR alterations (FGFR2/3 mutations or FGFR3 fusions) prior to erdafitinib treatment.	Strong
Offer erdafitinib as an alternative subsequent-line therapy to patients: • previously treated with platinum-containing chemotherapy; • who had disease progression during or after treatment with a PD-1 or PD-L1 inhibitor; • who harbour FGFR DNA genomic alterations (FGFR2/3 mutations or FGFR3 fusions).	Strong
Only offer vinflunine to patients with metastatic disease as second-line treatment if immunotherapy or combination chemotherapy is not feasible. Alternatively, offer vinflunine as third- or subsequent-line treatment.	Strong
Offer nephroureterectomy as a palliative treatment to symptomatic patients with resectable locally-advanced tumours.	Weak

DNA = deoxyribonucleic acid; FGFR = fibroblast growth factor receptors; HD-MVAC = high-dose intensity methotrexate, vinblastine, adriamycin plus cisplatin; PD-L1 = programmed death ligand 1.

8. FOLLOW-UP

The aims for follow-up after treatment for UTUC are to comply with patient rehabilitation needs, to detect recurrent or new primary tumours within the urothelium, and to detect regional and distant metastases. Bladder recurrence is not considered a distant recurrence. Unfortunately, the heterogeneity of available studies on disease-recurrence in UTUC is significant, and recommendations on follow-up have a low level of evidence at best.

After previous RNU for low-risk tumours bladder follow-up should adopt the NMIBC follow-up protocol for low-risk disease , a cystoscopy at three months post-operatively, a subsequent cystoscopy 9 months later and yearly cystoscopies for 5 years [330]. Screening for metastases during follow-up is not mandatory. Due to the low risk of contralateral upper tract recurrence routine imaging should be discussed on an individual basis [331].

When RNU has been performed for high-risk tumours, stringent follow-up is mandatory to detect metachronous bladder tumours (probability increases over time [332]), local recurrence, and distant metastases. The risk of bladder recurrences and other-site recurrences decreases 4 years after RNU, suggesting that less vigorous annual cystoscopies and cross-sectional imaging including CT urographies thereafter may apply [333]. For high risk, please consult the recommendations.

After kidney-sparing management for low-risk UTUC, and where no subsequent upstaging or upgrading occurred after the early second-look ureteroscopy after 6-8 weeks [212] or was found in the resection specimen after segmental ureteric resection, cystoscopy and CT-urography should be carried out at 3 and 6 months, and then yearly for 5 years. The risk for bladder recurrences beyond 5 years is limited (6%) [334].

In patients treated with kidney-sparing for high-risk tumours, the indication (imperative vs. non-imperative) affects the surveillance regimen by the consequences of recurrent disease. Still, the ipsilateral UUT requires careful and long-term follow-up due to the high risk of disease recurrence [211, 335, 336] and progression following RNU, even beyond 5 years [337].

Surveillance regimens are based on CT urography, cystoscopy and urinary cytology [332, 338]. There are, however, several unanswered questions related to the optimal follow-up of patients treated for both low-risk and high-risk UTUC, of which some are:

- The added value of new urinary markers compared to cytology in voided urine samples [339].
- The effect of the Paris System on sensitivity and specificity of voided and selective urinary cytology during follow-up of UTUC, especially in high-risk tumours [340].
- If adjuvant upper tract instillations have been administered after endourologic kidney-sparing management, will that allow for less vigorous follow-up?
- The role of ureteroscopies of the ipsilateral upper urinary tract during follow-up after endourologic kidney-sparing treatment vs. CT urography and voided urinary cytology.

Additionally, it is not known how patients with Lynch syndrome, without and with UTUC, should be screened of followed long-term given the inadequacy of surveillance based on urinalysis for nonvisible haematuria [341] and urine cytology [342], particularly in those individuals who are MSH2 mutation carriers [53] and those who already have developed a UTUC. Section 8.1 presents the summary of evidence and recommendations for follow-up of UTUC.

8.1 Summary of evidence and recommendations for the follow-up of UTUC

Summary of evidence	LE
Follow up should be based on risk stratification and the type of treatment.	3

Recommendations	Strength rating
After radical nephroureterectomy	
Low-risk tumours	
Perform cystoscopy at three months. If negative, perform subsequent cystoscopy 9 months later and then yearly, for 5 years.	Weak
High-risk tumours	
Perform cystoscopy and urinary cytology at 3 months. If negative, repeat subsequent cystoscopy and cytology every 3 months for a period of 2 years, and every 6 months thereafter until 5 years, and then yearly.	Weak
Perform computed tomography (CT) urography and chest CT every 6 months for 2 years, and then yearly.	Weak
After kidney-sparing management	
Low-risk tumours	
Perform cystoscopy and CT urography at 3 and 6 months, and then yearly for 5 years.	Weak
Perform ureteroscopy (URS) at 3 months if no second-look ureteroscopy was performed.	Weak
High-risk tumours	
Perform second-look URS and cytology in 6 weeks. If no residual tumour follow similar follow-up principles as for high-risk disease treated with radical nephroureterectomy.	Weak

10. CONFLICT OF INTEREST

All members of the Non-Muscle-Invasive Bladder Cancer Guidelines working panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is available on the European Association of Urology website: http://uroweb.org/guideline/upper-urinary-tract-urothelial-cell-carcinoma/.

This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

11. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Paris 2024. ISBN 978-94-92671-23-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, The Netherlands: http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aims and scope

The Prostate Cancer (PCa) Guidelines Panel have prepared this guidelines document to assist medical professionals in the evidence-based management of PCa.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The PCa Guidelines Panel consists of an international multidisciplinary group of urologists, radiation oncologists, medical oncologists, radiologists, pathologists, a geriatrician and a patient representative.

All imaging sections in the text have been developed jointly with the European Society of Urogenital Radiology (ESUR) and the European Association of Nuclear Medicine (EANM). Representatives of the ESUR and the EANM in the PCa Guidelines Panel are (in alphabetical order): Dr. A. Farolfi, Dr. D. Oprea-Lager, Prof.Dr. O. Rouvière and Dr. I.G. Schoots.

All radiotherapy (RT) sections have been developed jointly with the European Society for Radiotherapy & Oncology (ESTRO). Representatives of ESTRO in the PCa Guidelines Panel are (in alphabetical order): Prof.Dr. G. De Meerleer, Prof.Dr. A.M. Henry, and Prof.Dr. T. Wiegel.

The International Society of Urological Pathology is represented by Prof.Dr. A. van Leenders.

Dr. E. Briers, expert Patient Advocate Hasselt-Belgium representing the patient voice as delegated by the European Prostate Cancer Coalition/Europa UOMO.

All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website Uroweb: https://uroweb.org/guideline/prostate-cancer/.

1.3 Available publications

A quick reference document (Pocket guidelines) is available. This is an abridged version which may require consultation together with the full text version. Several scientific publications are available [1, 2] as are a number of translations of all versions of the PCa Guidelines. All documents can be accessed on the EAU website: http://uroweb.org/guideline/prostate-cancer/.

1.4 Publication history and summary of changes

1.4.1 Publication history

The EAU PCa Guidelines were first published in 2001. This 2024 document presents an update of the 2023 EAU-EANM-ESTRO-ESUR-ISUP-SIOG PCa Guidelines publication.

1.4.2 Summary of changes

The literature for the complete document has been assessed and all chapters of the 2024 PCa Guidelines have been updated. New data have been included in the following sections, resulting in new sections, and new and revised recommendations:

- An update in section 4.4 regarding the 2016 Cambridge Prognostic Groups.
- Restructure of section 5 – Diagnostic Evaluation to separate biopsy indication, biopsy strategy and biopsy approach.
- Incorporation of new text and references throughout section 5 including a new subsection 5.3.4 on tissue samples for homologous recombination repair (HRR)-testing and 5.3.5.7 on Intra-operative assessment of surgical margin status. Update on Table 5.6, Table 5.7, Figure 5.2 and a new section in section 5.5.4 on perilesional biopsy.
- New text additions throughout section 6 with special attention to section 6.1 treatment modalities and new summary of evidence in section 6.2.5 on active surveillance strategy as well as 6.4.2 on controversies in the definitions of clinically relevant PSA relapse. Substantial text additions to section 6.7.6.6 on combinations with PARP inhibitors
- New recommendation in section 6.3.2.5 Guidelines for the treatment of intermediate-risk disease regarding active surveillance and radiotherapeutic treatment.
- New recommendations in section 6.3.3.4 Guidelines for radical and palliative treatment of high-risk localised disease and for Pelvic lymph node dissection (PLND) and radiotherapeutic treatment
- New recommendations in section 6.7.13 on the Guidelines for systemic treatments of castrate-

resistant disease.
- Small amendments to Figure 6.4 and Figure 6.5
- New subsection 8.2.1 on active surveillance and 8.2.5.8 on osteonecrosis during bisfosfonates or denosumab as well as substantial addition of text to section 8.3.1 and 8.3.2

2. METHODS

2.1 Data identification

For the 2024 PCa Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature. A number of comprehensive searches were performd, covering all sections of the PCa Guidelines. The search was limited to English language publications. Databases searched included Medline, EMBASE and the Cochrane Libraries, covering a time frame between April 1st 2022 and May 1st 2023. A total of 3233 unique records were identified, retrieved and screened for relevance. A detailed search strategy is available online: https://uroweb.org/guideline/prostate-cancer/?type=appendices-publications.

Changes in recommendations were generally only considered on the basis of high-level evidence (i.e. systematic reviews (SR) with meta-analysis, randomised controlled trials (RCTs), and prospective comparative studies) published in the English language. Additional information can be found in the general Methodology section of this print and online at the EAU website: https://uroweb.org/guidelines/policies-and-methodological-documents/.

Recommendation within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:
:

1. the overall quality of the evidence which exists for the recommendation [3];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact and certainty of patient values and preferences on the intervention.

Strong recommendations typically indicate a high degree of evidence quality and/or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [4]. The strength rating forms will be available online.

A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address. In addition, the International Society of Geriatric Oncology (SIOG), the European Society for Radiotherapy & Oncology (ESTRO), the European Society for Urogenital Radiology (ESUR), the European Association of Nuclear Medicine (EANM) and the International Society of Urological Pathology (ISUP) have endorsed the PCa Guidelines.

2.2 Review

Publications ensuing from SRs have all been peer-reviewed.

2.3 Future goals

Results of ongoing and new SRs will be included in the 2025 update of the PCa Guidelines:

- A SR assessing the performance of risk stratification tools incorporating imaging, biomarkers, biopsy involvement and/or magnetic resonance imaging (MRI)-targeted biopsies, compared to the classical risk classifications (d'Amico, EAU, the Cancer of the Prostate Risk Assessment (CAPRA) and the National Comprehensive Cancer Network (NCCN)) recommended in current guidelines for predicting biochemical recurrence, metastasis or death after local treatment for prostate cancer. Are the new stratification tools preferred above the classical risk classifications?
- A SR assessing the outcomes of brachytherapy (BT) boost combined with external beam RT for PCa.
- Care pathways for the various stages of PCa management have been developed. These pathways will, in due time, inform treatment flowcharts and an interactive app.

3. EPIDEMIOLOGY AND AETIOLOGY

3.1 Epidemiology

Prostate cancer (PCa) is the second most commonly diagnosed cancer in men, with an estimated 1.4 million diagnoses and 375,000 deaths worldwide in 2020 [5, 6]. In Europe, it is the most frequently diagnosed cancer in men and the third cancer-related cause of death in men [7].

A SR of autopsy studies reported a prevalence of PCa at age < 30 years of 5% (95% confidence interval [CI]: 3–8%), increasing by an odds ratio (OR) of 1.7 (1.6–1.8) per decade, to a prevalence of 59% (48–71%) by age > 79 years [8]. There is variation in the frequency of autopsy-detected PCa between men with different ethnical backgrounds and geographical areas (e.g., 83% in white US males vs. 41% in Japan at age 71–80) [9].

Regarding incidence of PCa diagnosis, the variation is even more pronounced between different geographical areas, driven by rate of prostate-specific antigen (PSA) testing and influenced by (inter)national organisations recommendations on screening (see Section 5.1) [10]. It is highest in Australia/New Zealand and Northern America (age-standardised rates [ASR] per 100,000 of 111.6 and 97.2, respectively), and in Western and Northern Europe (ASRs of 94.9 and 85, respectively). The incidence is low in Eastern and South-Central Asia (ASRs of 10.5 and 4.5, respectively), but rising [11]. Rates in Eastern and Southern Europe were low but have also shown a steady increase [6, 9]. Besides PSA testing, incidence is also dependent on the age of the population, geography and ethnicity.

There is relatively less variation in mortality rates worldwide, although rates are generally high in populations of African descent (e.g., Caribbean: ASR of 29 and Sub-Saharan Africa: ASRs ranging between nineteen and fourteen), intermediate in the USA and very low in Asia (South-Central Asia: ASR of 2.9) [6, 12]. Mortality due to PCa has decreased in most Western nations but the magnitude of the reduction varies between countries [5].

3.2 Aetiology

*3.2.1 **Family history/hereditary prostate cancer***

Family history and ethnic background are associated with an increased PCa incidence suggesting a genetic predisposition [13, 14]. Men of African ancestry in the Western world demonstrate more unfavourable outcomes due to a combination of biological, environmental, social, and health care factors [15]. They are more likely to be diagnosed with more advanced disease [16] and upgrade after prostatectomy was more frequent as compared to Caucasian men (49% vs. 26%) [17]. Racial disparities in development of, prevention of, and therapies for PCa may exist. Indeed, a multi-ancestry polygenic risk score of 278 risk variants published by Chen et. al. showed a strong association with PCa risk in men with African ancestry and might be used to identify susceptibility in this high-risk population [18]. It should be kept in mind that many PCa studies include either small percentages of men from other origin than Caucasians or focus on highly specific other groups [19].

However, only a small subpopulation of men with PCa have true hereditary disease (≥ 3 cases in the same family, PCa in three successive generations, or ≥ two men diagnosed with PCa < 55 yrs). Hereditary PCa (HPCa) is associated with a six-to-seven-year earlier disease onset but the disease aggressiveness and clinical course does not seem to differ in other ways [13, 20]. In a large USA population database, HPCa (reported by 2.18% of participants) showed a relative risk (RR) of 2.30 for diagnosis of any PCa, 3.93 for early-onset PCa, 2.21 for lethal PCa, and 2.32 for clinically significant PCa (csPCa) [21]. These increased risks with HPCa were higher than for familial PCa (≥two first- or second-degree relatives with PCa on the same side of the pedigree), or familial syndromes such as hereditary breast- and ovarian cancer and Lynch syndrome. With the father as well as two brothers affected, the probability of high-risk PCa at age 65 was 11.4% (vs. a population risk of 1.4%), and for any PCa 43.9% vs. 4.8%, in a Swedish population-based study [22].

3.2.1.1 Germline mutations and prostate cancer

Genome-wide association studies have identified more than 100 common susceptibility loci contributing to the risk for (aggressive) PCa [23, 24]. The frequency and distribution of positive germline variants in 3,607 unselected PCa patients showed that 620 (17.2%) contained a pathogenic mutation [25]. Whilst in men with PCa disease undergoing multigene testing across the USA, it was found that 15.6% of men with PCa have pathogenic variants identified in genes tested ([Breast Cancer genes] *BRCA1, BRCA2, HOXB13, MLH1, MSH2, PMS2, MSH6, EPCAM, ATM, CHEK2, NBN,* and *TP53*), and 10.9% of men have germline pathogenic variants in DNA repair genes (see Table 3.1) [26]. Pathogenic variants were most commonly identified in *BRCA2* (4.5%), *CHEK2* (2.2%), *ATM* (1.8%), and *BRCA1* (1.1%) [26].

Among men with metastatic PCa, an incidence of 11.8% was found for germline mutations in genes mediating DNA-repair processes [27] and 16.2% of patients diagnosed with metastatic castrate-resistant PCa (mCRPC) [28]. Targeted genomic analysis of genes associated with an increased risk of PCa could offer options to identify families at high risk [29, 30].

A prospective cohort study of male *BRCA1* and *BRCA2* carriers confirmed *BRCA2* association with aggressive PCa [31]. An analysis of the outcomes of 2,019 patients with PCa (18 *BRCA1* carriers, 61 *BRCA2* carriers, and 1,940 non-carriers) showed that PCa with germline *BRCA1/2* mutations were more frequently associated with ISUP grade group ≥ 4, T3/T4 stage, nodal involvement, and metastases at diagnosis than PCa in non-carriers [32]. *BRCA*-susceptibility gene mutation carriers were also reported to have worse outcome when compared to non-carriers after local therapy [33]. In a retrospective study of 313 patients who died of PCa and 486 patients with low-risk localised PCa, the combined *BRCA1/2* and *ATM* mutation carrier rate was significantly higher in lethal PCa patients (6.07%) than in localised PCa patients (1.44%) [34]. The rate of PCa among *BRCA1* carriers was more than twice as high (8.6% vs. 3.8%) compared to the general population, in contrast to findings of the prospective IMPACT study (Identification of Men with a Genetic Predisposition to Prostate Cancer (see Chapter 5) [35].

Table 3.1: Germline mutations in DNA repair genes associated with increased risk of prostate cancer

Gene	Location	Prostate cancer risk	Findings
BRCA2	13q12.3	- RR 2.5 to 4.6 [39, 40] - PCa at 55 years or under: RR: 8–23 [36, 37]	• up to 12 % of men with metastatic PCa harbour germline mutations in 16 genes (including *BRCA2* [5.3%]) [27] • 2% of men with early-onset PCa harbour germline mutations in the *BRCA2* gene [36] • *BRCA2* germline alteration is an independent predictor of metastases and worse PCa-specific survival [32, 38]
ATM	11q22.3	RR: 6.3 for metastatic PCa [27]	• higher rates of lethal PCa among mutation carriers [34] • up to 12% of men with metastatic PCa harbour germline mutations in 16 genes (including *ATM* [1.6%]) [27]
CHEK2	22q12.1	OR 3.3 [39, 40]	• up to 12% of men with metastatic PCa harbour germline mutations in 16 genes (including *CHEK2* [1.9%]) [27]
BRCA1	17q21	RR: 1.8–3.8 at 65 years or under [41, 42]	• higher rates of lethal PCa among mutation carriers [34] • up to 12% of men with metastatic PCa harbour germline mutations in 16 genes (including *BRCA1* [0.9%]) [27]
HOXB13	17q21.2	OR 3.4–7.9 [29, 43]	• significantly higher PSA at diagnosis, higher Gleason score and higher incidence of positive surgical margins in the radical prostatectomy specimen than non-carriers [44]
MMR genes *MLH1* *MSH2* *MSH6* *PMS2*	3p21.3 2p21 2p16 7p22.2	RR: 3.7 [45]	• Mutations in *MMR* genes are responsible for Lynch syndrome [46] • *MSH2* mutation carriers are more likely to develop PCa than other *MMR* gene mutation carriers [47]

BRCA2 = breast cancer gene 2; ATM = ataxia telangiectasia mutated; CHEK2 = checkpoint kinase 2; BRCA1 = breast cancer gene 1; GS = Gleason score; HOXB13 = homeobox B13; MMR = mismatch repair; MLH1 = mutL homolog 1; MSH2 = mutS homolog 2; MSH6 = mutS homolog 6; OR = odds ratio; PMS2 = post-meiotic segregation increased 2; PCa = prostate cancer; RP = radical prostatectomy; RR = relative risk; PSA = prostate-specific antigen.

*3.2.2 **Risk factors for prostate cancer***

A wide variety of exogenous/environmental factors have been discussed as being associated with the risk of developing PCa or as being aetiologically important for the progression from latent to clinical PCa [48]. Asians who immigrated to the USA have approximately half the risk of PCa when compared to their US born Asian-descendant counterparts, implying a role for environmental or dietary factors [49]. However, currently there are no known effective preventative dietary or pharmacological interventions.

3.2.2.1 Metabolic syndrome

The single components of metabolic syndrome (MetS) that have been associated with a significantly greater risk of PCa are hypertension (p = 0.035) and waist circumference ≥ 102 cm (p = 0.007), but in contrast, having ≥ 3 components of MetS is associated with a reduced risk (OR: 0.70, 95% CI: 0.60–0.82) [50, 51].

3.2.2.1.1 Obesity

Within the Reduction by Dutasteride of Prostate Cancer Events (REDUCE) study, obesity was associated with lower risk of low-grade PCa (OR: 0.79, p = 0.01), and a higher risk of high-grade PCa (OR: 1.28, p = 0.042), in multivariable analyses [52]. This effect seems mainly explained by environmental determinants of height/body mass index (BMI) rather than genetically elevated height or BMI [53]. A SR showed an association between obesity and increased PC-specific mortality [54].

3.2.2.1.2 Diabetes/metformin

The association between metformin use and PCa is controversial. At population level, metformin users (but not other oral hypoglycaemic agents) were found to be at a decreased risk of PCa diagnosis compared with never users (adjusted OR: 0.84, 95% CI: 0.74–0.96) [55]. In 540 diabetic participants of the REDUCE study, metformin use was not significantly associated with PCa and therefore not advised as a preventive measure (OR: 1.19, p = 0.50).

3.2.2.1.3 Cholesterol/statins

A meta-analysis of fourteen large prospective studies did not show any association between blood total cholesterol, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol levels and the risk of developing either overall PCa or high-grade PCa [51]. Results from the REDUCE study did not show a preventive effect of statins on PCa risk, even though a meta-analysis suggested a lower risk of advanced PCa in statin users [50, 56].

3.2.2.2 Dietary factors

The association between a wide variety of dietary factors and PCa have been studied, but there is a paucity of quality evidence (Table 3.2). To date, the current body of evidence will not support a causal relationship between specific (dietary and otherwise) factors and the development of PCa. Consequently, no effective preventative strategies can be suggested.

Table 3.2: Main dietary factors that have been associated with PCa

Alcohol	High alcohol intake, but also total abstention from alcohol has been associated with a higher risk of PCa and PCa-specific mortality [57]. A meta-analysis shows a dose-response relationship with PCa [58].
Coffee	Coffee consumption may be associated with a reduced risk of PCa; with a pooled RR of 0.91 for the highest category of coffee consumption [59].
Dairy	A weak correlation between high intake of protein from dairy products and the risk of PCa was found [60].
Fat	No association between intake of long-chain omega-3 poly-unsaturated fatty acids and PCa was found [61]. A relation between intake of fried foods and risk of PCa may exist [62].
Tomatoes (lycopenes/ carotenes)	A trend towards a favourable effect of tomato intake (mainly cooked) and lycopenes on PCa incidence has been identified in meta-analyses [68, 69]. Randomised controlled trials comparing lycopene with placebo did not identify a significant decrease in the incidence of PCa [63].
Meat	Meta-analyses show a potential association between red meat, total meat, and processed meat consumption and PCa [64, 65].

Soy (phytoestrogens [isoflavones/ coumestans])	Phytoestrogen intake was significantly associated with a reduced risk of PCa in a meta-analysis [66]. Total soy food intake has been associated with a reduced risk of PCa, but also with an increased risk of advanced disease [67, 68].
Vitamin D	A U-shaped association has been observed, with both low- and high vitamin-D concentrations being associated with an increased risk of PCa, and more strongly for high-grade disease [68, 69].
Vitamin E/Selenium	An inverse association of blood, but mainly nail selenium levels (reflecting long-term exposure) with aggressive PCa have been found [70, 71]. Selenium and Vitamin E supplementation were, however, found not to affect PCa incidence [72].

3.2.2.3 Hormonally active medication

3.2.2.3.1 5-alpha-reductase inhibitors (5-ARIs)

Although it seems that 5-ARIs have the potential of preventing or delaying the development of PCa (decreasing the risk by 25% but only for ISUP grade group 1 cancer), this must be weighed against treatment-related side effects as well as the potential small increased risk of high-grade PCas (although this does not seem to impact PCa mortality) [73, 74]. None of the available 5-ARIs have been approved by the European Medicines Agency (EMA) for chemoprevention.

3.2.2.3.2 Testosterone

Hypogonadal men receiving testosterone supplements do not have an increased risk of developing PCa [75]. A pooled analysis showed that men with very low concentrations of free testosterone (lowest 10%) have a below average risk (OR: 0.77) of PCa [76]. Furthermore, although the evidence is limited, men who are managed expectantly for PCa, or who received radical curative therapy, do not have worse outcomes when receiving testosterone supplementation, despite a theoretical higher risk of progression after correction of the hypogonadal situation [77].

3.2.2.4 Other potential risk factors

A significantly higher rate of ISUP grade group ≥ 2 PCa (hazard ratio [HR]: 4.04) was found in men with inflammatory bowel disease when compared with the general population [78]. Balding was associated with a higher risk of PCa death [79]. Gonorrhoea was significantly associated with an increased incidence of PCa (OR: 1.31, 95% CI: 1.14–1.52) [80]. Occupational exposure may also play a role, based on a meta-analysis which revealed that night-shift work is associated with an increased risk (2.8%, p = 0.030) of PCa [81]. Current cigarette smoking was associated with an increased risk of PCa death (RR: 1.24, 95% CI: 1.18–1.31) and with aggressive tumour features and worse prognosis, even after quitting smoking [82, 83]. A meta-analysis on Cadmium (Cd) found a positive association (magnitude of risk unknown due to heterogeneity) between high Cd exposure and risk of PCa for occupational exposure, but not for non-occupational exposure, potentially due to higher Cd levels during occupational exposure [84]. Men positive for human papillomavirus-16 may be at increased risk [85]. Plasma concentration of the estrogenic insecticide chlordecone is associated with an increase in the risk of PCa (OR: 1.77 for highest tertile of values above the limit of detection) [86]. A number of other factors previously linked to an increased risk of PCa have been disproved including vasectomy [87] and self-reported acne [88]. There are conflicting data about the use of aspirin or nonsteroidal anti-inflammatory drugs and the risk of PCa and mortality [89, 90]. Ultraviolet radiation exposure decreased the risk of PCa (HR: 0.91, 95% CI: 0.88–0.95) [91]. A review found a small but protective association of circumcision status with PCa [92]. Higher ejaculation frequency (≥ 21 times a month vs. 4 to 7 times) has been associated with a 20% lower risk of PCa [93].

*3.2.3 **Summary of evidence for epidemiology and aetiology***

Summary of evidence	**LE**
Prostate cancer is a major health concern in men, with incidence mainly dependent on age and extent of PSA testing.	3
Genetic factors are associated with risk of (aggressive) PCa.	3
A variety of dietary/exogenous/environmental factors have been associated with PCa incidence and prognosis.	3
In hypogonadal men, testosterone supplements do not increase the risk of PCa.	2a
No conclusive data exist which could support specific preventive or dietary measures aimed at reducing the risk of developing PCa.	1a

4. CLASSIFICATION AND STAGING SYSTEMS

4.1 Classification

The objective of a tumour classification system is to combine patients with a similar clinical outcome. This allows for discussion about prognosis with patients, the design of clinical trials on relatively homogeneous populations, the comparison of clinical and pathological data obtained from different hospitals across the world, and the development of recommendations for the treatment of these patient populations. Throughout these Guidelines the Union for International Cancer Control (UICC) 8th edition (2017), the Tumour, Node, Metastasis (TNM) classification for staging of PCa (Table 4.1) [94] and the EAU risk group classification are used [95]. The latter classification is based on the grouping of patients with a similar risk of biochemical recurrence (BCR) after radical prostatectomy (RP) or external beam radiotherapy (EBRT). Changes in the diagnostic pathway, such as imaging (e.g., MRI, Prostate-Specific Membrane Antigen [PSMA] Positron Emission Tomography Computed Tomography [PET/CT] scan) and biopsy (e.g., increasing number of systematic biopsy cores, targeted biopsy) may cause a stage shift in risk classification systems [96].

Although the 2017 American Joint Committee on Cancer (AJCC) staging 8th edition specifically states that clinical staging should be based on digital rectal examination (DRE) only, such an explicit comment is not made by the UICC. Since clinical stage as assessed by DRE only, is included in the EAU (D'Amico) risk group classification, cT-stage should be based on DRE findings and not on imaging. Additional staging information based on imaging should be reported separately. A non-palpable PCa with bilateral positive biopsies and extra-prostatic extension (EPE) on MRI would therefore be categorised as cT1c with a separate report of MRI findings.

Table 4.1: Clinical Tumour Node Metastasis (TNM) classification of PCa [94]

T - Primary Tumour (stage based on digital rectal examination [DRE] only)	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
T1	Clinically inapparent tumour that is **not palpable**
T1a	Tumour incidental histological finding in 5% or less of tissue resected
T1b	Tumour incidental histological finding in more than 5% of tissue resected
T1c	Tumour identified by needle biopsy (e.g. because of elevated prostate-specific antigen [PSA])
T2	Tumour that is palpable and confined within the prostate
T2a	Tumour involves one half of one lobe or less
T2b	Tumour involves more than half of one lobe, but not both lobes
T2c	Tumour involves both lobes
T3	Tumour extends **palpably** through the prostatic capsule
T3a	Extracapsular extension (unilateral or bilateral)
T3b	Tumour invades seminal vesicle(s)
T4	Tumour is fixed or invades adjacent structures other than seminal vesicles: external sphincter, rectum, levator muscles, and/or pelvic wall
N - Regional (pelvic) Lymph Nodes[1]	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
M - Distant Metastasis[2]	
M0	No distant metastasis
M1	Distant metastasis
M1a	Non-regional lymph node(s)
M1b	Bone(s)
M1c	Other site(s)

[1] *Metastasis no larger than 0.2 cm can be designated pNmi.*

[2] *When more than one site of metastasis is present, the most advanced category is used. (p)M1c is the most advanced category.*

Pathological staging (pTNM) is based on histopathological tissue assessment and largely parallels the clinical TNM, except for clinical T1 and T2 substages. Pathological stages pT1a/b/c do not exist and histopathologically confirmed organ-confined PCas after RP are pathological stage pT2. The current UICC no longer recognises pT2 substages [94].

Of note: the EANM recently proposed a molecular imaging TNM ('miTNM') classification, taking into account PSMA PET/CT findings [97]. The prognosis of the miT, miN and miM substages is likely to be better than their T, N and M counterparts due to the 'Will Rogers phenomenon'; the extent of this prognosis shift remains to be assessed as well as its practical interest and impact [98]. This reclassification is not endorsed by the UICC or the AJCC.

4.2 Gleason score and International Society of Urological Pathology 2019 grade

In the original Gleason grading system, 5 Gleason grades (ranging from 1–5) based on histological tumour architecture were distinguished, but in the 2005 and subsequent 2014 ISUP consensus meetings Gleason grades 1 and 2 were eliminated [99, 100]. The 2005 ISUP modified Gleason score (GS) of biopsy-detected PCa comprises the Gleason grade of the most extensive (primary) pattern, plus the second most common (secondary) pattern, if two are present. If only one pattern is present, it needs to be doubled to yield the GS. For three grades, the biopsy GS comprises the most common grade plus the highest grade, irrespective of its extent. In case intraductal carcinoma (IDC) is present intermixed with invasive PCa, it should be incorporated in the GS based on its underlying architectural pattern [101]. In addition to reporting of the carcinoma features for each biopsy side, an overall (or global) GS based on the carcinoma-positive biopsies can be provided. The global GS takes into account the cumulative extent of each grade from all prostate biopsies. The 2014 and 2019 ISUP endorsed a grading system limiting the number of PCa grades, ranging them from 1 to 5 (see Table 4.2) [100, 102].

Table 4.2: International Society of Urological Pathology 2014 grade (group) system

Gleason score	ISUP grade
2-6	1
7 (3+4)	2
7 (4+3)	3
8 (4+4 or 3+5 or 5+3)	4
9-10 (4+5 or 5+4 or 5+5)	5

4.3 Clinically significant prostate cancer

The descriptor 'clinically significant' is widely used to differentiate PCa that may cause morbidity or death in a specific patient from types of PCa that rarely do. This distinction is particularly important as insignificant PCa is common [8]. Unless this distinction is made, such cancers are at high risk of being over-treated, with the treatment itself risking harmful side effects to patients. The over-treatment of insignificant PCas has also been criticised as a major drawback of population-based screening and individual early detection [103]. Although pathological factors are often used to delineate insignificant PCa, the definition of significant vs. insignificant is a balance between tumour and patient factors. High-risk PCa is significant in almost all men, except when life expectancy is limited. Low-risk PCa is insignificant in almost all men.

From a pathological point of view, in large studies of RP specimens with only ISUP grade group 1 disease, EPE (0.3%) [104] and biochemical recurrence (3.5%) were rare, and seminal vesicle (SV) invasion or lymph node (LN) metastasis did not occur at all [105, 106]. International Society of Urological Pathology grade group 1 disease at RP itself can therefore be considered clinically insignificant. Whilst ISUP grade group 1 bears the hallmarks of cancer histologically, ISUP grade group 1 at RP itself does not behave in a clinically malignant fashion [107]. It is important to note that the studies showing absence of metastasis in ISUP grade group 1 were all done on RP specimens; ISUP grade group 1 on biopsy is associated with a low risk of developing metastasis and disease-specific death, due to under-sampling of a higher-grade component. In a contemporary retrospective study of men with cT1-T2 cN0 ISUP grade group 1 PCa at mpMRI-targeted biopsy, 72% had ISUP grade group ≥ 2, 9% ISUP grade group ≥ 3, 25% had pT3a and 4% pT3b at subsequent RP [108]. Finally, modifications in PCa grading has led to a grade shift during the past ten to fifteen years; for instance the introduction of the ISUP 2005 led to 20% of pre-ISUP 2005 GS 6 tumours being upgraded to GS 7 or higher, which has to be taken into account when interpreting older studies [109].

The current standard practice of MRI-targeted and template biopsies has improved diagnostic accuracy [110], however sampling error may still occur such that higher grade cancer could be missed. This should especially be considered in case of high PSA density, high pathological biopsy tumour volume and a visible lesion at MRI, but only ISUP grade group 1 at biopsy [111, 112]. Another complexity in defining insignificant cancer is that ISUP grade group 1 may progress to higher grades over time, becoming clinically significant at a later biopsy [113].

Therefore, although ISUP grade group 1 itself can be described as clinically insignificant, it is important to take into account other factors, including age, imaging prior to biopsy and adequate sampling core number. When combined with low-risk clinical factors (see Table 4.3), ISUP grade group 1 represents low-risk PCa and recommended management options are active surveillance (AS) or watchful waiting (WW) (see Sections 6.2.1.1 & 6.2.1.2). It has been proposed to rename ISUP grade group 1 "tumours" omitting the "cancer" label [114, 115]. At this moment, no broad consensus yet exists for changing this disease taxonomy [116, 117]. Instead, although it is probably insignificant cancer, it should be appropriately observed.

Epidemiological and autopsy data suggest that a proportion of ISUP grade group 2 PCa would remain undetectable during a man's life [118] and therefore may be over-treated. In current guidelines deferred treatment may be offered to select patients with intermediate-risk PCa [119], but clear evidence is lacking for appropriate selection criteria [120].

Recent papers have defined clinically significant cancer differently, commonly using ISUP grade group 2 and above and even ISUP grade group 3 and above, demonstrating the lack of consensus and evolution of its definition [121, 122]. Some papers provide more than one definition within a single study [123, 124]. Since there is insufficient data to relate modern histological grading to hard clinical endpoints, it is imperative that authors define and state in their own studies what they believe csPCa is, including exactly how the disease was diagnosed.

Table 4.3: EAU risk groups for biochemical recurrence of localised and locally-advanced prostate Cancer (based on systematic biopsy)

Definition			
Low-risk	**Intermediate-risk**	**High-risk**	
PSA < 10 ng/mL and GS < 7 (ISUP grade 1) and cT1-2a*	PSA 10–20 ng/mL or GS 7 (ISUP grade 2/3) or cT2b*	PSA > 20 ng/mL or GS > 7 (ISUP grade 4/5) or cT2c*	any PSA any GS (any ISUP grade) cT3-4 or cN+**
Localised			**Locally advanced**

GS = Gleason score; ISUP = International Society for Urological Pathology; PSA = prostate-specific antigen.
**** Based on digital rectal examination.***
***** Based on CT/bone scan.***

4.4 Prognostic relevance of stratification

Tumour, Node, Metastasis (TNM) staging is a schematic representation of anatomic tumour extent and pathological grade is reflective of intrinsic features of tumour aggressiveness. EAU risk group classification, which is essentially based on D'Amico's classification system for PCa, combines clinical information on tumour extent, PSA and pathology from systematic biopsy (Table 4.3). A more precise stratification of the clinically heterogeneous subset of intermediate-risk group patients could provide a better framework for their management [125, 126]. Specifically, the NCCN Guidelines subdivide intermediate-risk disease into favourable and unfavourable intermediate-risk, with unfavourable features including ISUP grade group 3, and/or ≥ 50% positive systematic biopsy cores and/or at least two intermediate-risk factors [119]. In 2016 Cambridge Prognostic Groups representing a 5-tier model based on ISUP grade group, PSA and cT-stage were shown to have significantly better discriminative performance than current 3-tier EAU risk groups for prostate cancer specific mortality [127]. This model separates both EAU intermediate- and high-risk groups in clinically relevant subgroups and has been validated in several cohorts [127-129].

4.5 Guidelines for classification and staging systems

Recommendations	Strength rating
Use the Tumour, Node, Metastasis (TNM) classification for staging of PCa.	Strong
Clinical stage should be based on digital rectal examination (DRE) only; additional staging information based on imaging should be reported separately.	Strong
Use the International Society of Urological Pathology (ISUP) 2019 system for grading of PCa.	Strong

5. DIAGNOSTIC EVALUATION

5.1 Screening and individual early detection

The diagnostic pathway for PCa aims for timely detection of significant PCa, while leaving insignificant PCa undetected, balancing diagnostic accuracy with the burden on an individual and healthcare provider. Patient-specific factors such as lower urinary tract symptoms (LUTS), family history, age, and comorbidity should always be considered.

Men may enter the diagnostic pathway through different indications, including clinical symptoms, opportunistic early detection (individual), or screening (population-based). The prevalence of PCa and significant PCa is different dependent on the indication, resulting in different yields of the subsequent diagnostic pathway.

5.1.1 Clinical Symptoms

Localised PCa is usually asymptomatic. Local progression may cause symptoms such as LUTS, erectile dysfunction (ED), retention, pain, or haematuria. Bone metastases may cause pain or spinal cord compression. Digital rectal examination (DRE) and PSA are usually part of the initial diagnostic work-up in these cases, after which a further diagnostic algorithm may be initiated. Definitive diagnosis normally depends on histopathological verification in prostate biopsy cores. However, men with high suspicion of malignancy (e.g. malignant feeling prostate, PSA >100 ng/mL and a positive bone scan might avoid a biopsy especially if pre-existing comorbidities would exclude second-line treatments.

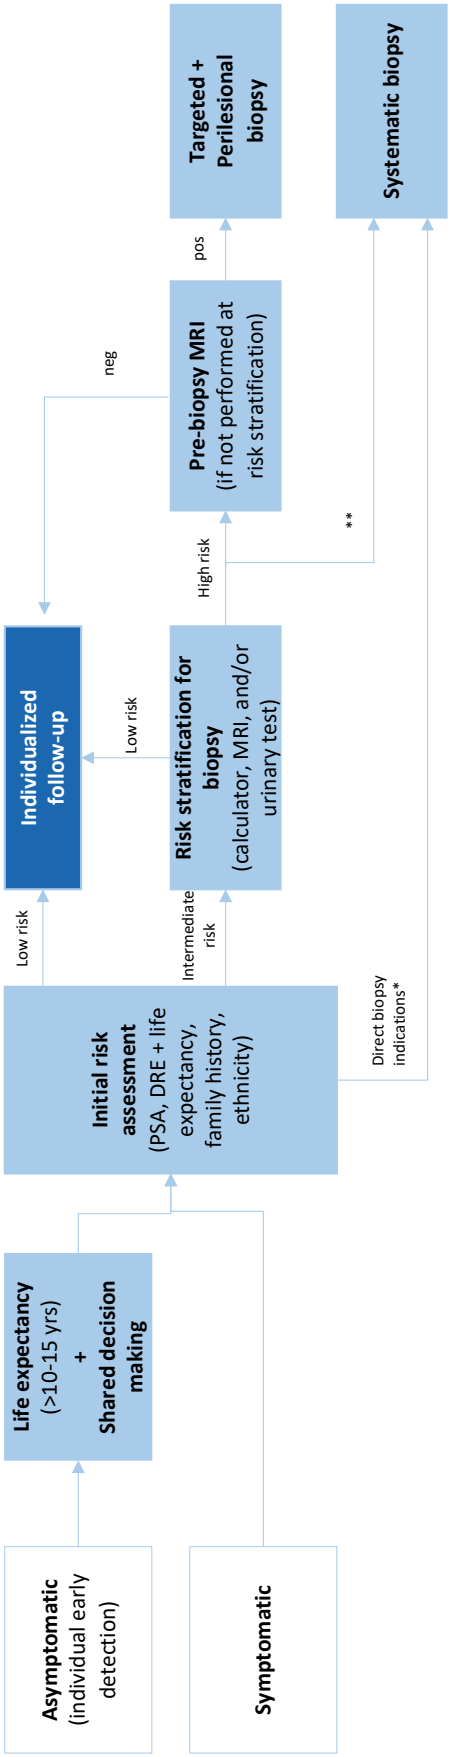
5.1.2 Individual early detection

Early detection may be initiated on an individual level. Men with risk factors include age > 50 years; men from 45 years of age with a family history of PCa; men of African descent from 45 years of age; men carrying *BRCA2* mutations from 40 years of age [130, 131]. The risk of detecting clinically insignificant cancers and possible overtreatment should be discussed along with the possibility of improved disease-specific mortality. It is difficult to accurately estimate the individual benefit or harm due to early detection for the individual man but the effect may be larger as diluting effects from intention-to-treat analyses in screening trials are not applicable (i.e. non-participation: no participation after screening invitation; contamination: screening occurring in control arm) [132]. Nevertheless, a comparison of systematic and opportunistic screening suggested over-diagnosis and mortality reduction in the systematic screening group compared to a higher over-diagnosis with only a marginal survival benefit, at best, in the opportunistic screening regimen [133].

Baseline PSA may be used to predict PCa mortality after fifteen to twenty yrs. Follow-up intervals of two years may be offered to those initially at risk (PSA > 1 ng/mL at 40 years; PSA > ng/mL at 60 years) [134, 135].

The age at which attempts an early diagnosis should be stopped remains controversial, but an individual's life expectancy must definitely be taken into account. Men who have less than a fifteen-year life expectancy are unlikely to benefit, based on data from the Prostate Cancer Intervention Versus Observation Trial (PIVOT) and the European Randomized Screening for Prostate Cancer (ERSPC) trials. Furthermore, although there is no simple tool to evaluate individual life expectancy, co-morbidity is at least as important as age. A detailed review can be found in Section 6.1 'Estimating life expectancy and health status' and in the SIOG Guidelines [136]. Informed men with one of the risk factors above, a life expectancy of > fifteen years and requesting investigation should be given a PSA test and undergo a DRE, after which a further diagnostic algorithm may be initiated [137].

Figure 5.1 Presents a flow diagram for deciding on prostate biopsy



* PSA >50, cT3-4
** If MRI not available / possible

5.1.3 Population-based screening

Population or mass screening is defined as the 'systematic examination of asymptomatic men to identify individuals at risk for a specific disease' and is usually initiated by health authorities. The co-primary objectives are:

- reduction in mortality due to PCa;
- a maintained quality of life (QoL) as expressed by QoL-adjusted gain in life years (QALYs).

Screening for PCa remains one of the most controversial topics in the urological literature [138]. A Cochrane review of randomised PCa screening trials with PCa mortality as endpoint was published in 2013 [139] and updated in 2018 [140, 141]. The main findings of the updated publication from the results of five RCTs, randomising more than 721,718 men, are:

- Screening is associated with an increased diagnosis of PCa (Incidence ratio [IR]: 1.23 95% CI: 1.03–1.48).
- Screening is associated with detection of more localised disease (RR: 1.39, [1.09–1.79]) and less advanced PCa (T3–4, N1, M1; RR: 0.85 [0.72–0.99]).
- No PCa-specific survival benefit was observed (IR: 0.96 [0.85–1.08]). This was the main endpoint in all trials.
- No overall survival (OS) benefit was observed (IR: 0.99, 95% CI: 0.98–1.01). None of the trials were designed/powered for this endpoint.

The included studies are different regarding multiple aspects including trial size, time periods, age groups, participation/compliance rates, previous screening rates (opportunistic testing in control arm, 'contamination'), one-time vs. repeat screening, and the applied diagnostic pathway. These differences account for discrepancies in results between single studies and the Cochrane review aggregated findings.

The ERSPC study started in the early 90's, included >182,000 European men, found a significant reduction in PCa mortality due to screening. ERSPC applied a mainly PSA-based screening protocol (cut-off 3.0–4.0 ng/mL followed by systematic sextant prostate biopsy, every two to four years in men aged 50–74) [142] The contamination rate was relatively low when compared to other large studies such as the Prostate Lung Colorectal and Ovarian (PLCO) screening trial [142]. A limitation is the heterogeneity in patient groups and the applied screening protocols. Since 2013, data have been updated with sixteen years of follow-up [142]. With extended follow-up, the mortality reduction (21% and 29% after non-compliance adjustment) remains unchanged. However, the number needed to screen (NNS) and to treat is decreasing and is now below the NNS observed in breast cancer trials [142, 143] (Table 5.1).

Table 5.1: Follow-up data from the ERSPC study [142]

Years of follow-up	Number needed to screen	Number needed to treat
9	1,410	48
11	979	35
13	781	27
16	570	18

In the Rotterdam section of the ERSPC, with 21 years follow-up, the risk ratio of death due to PCa was 0.73 in the screening group, with number needed to invite of 246 and number needed to diagnose (NND) of fourteen to prevent one death due to PCa [144]. To prevent one metastasized case NNS was 121 and NND seven.

In the Goteborg screening trial, with eighteen years of follow-up, the ratio of death from PCa for the screening group compared with the control group was 0.65 (95% CI: 0.49–0.87) and for men starting screening at age 55–59 it was 0.47 (95% CI: 0.29–0.78) [145]. The number needed to invite was 231; the NND ten.

The benefit of screening in reducing PCa-specific mortality (PCSM) and the even more favourable impact on metastases rates, is counter-balanced by the side effects of screening such as increased diagnosis rates, which has led to over-treatment of low-risk PCa, and subsequent treatment-related side-effects [146]. Regarding QoL, the beneficial effects of screening and the side effects seem to balance out, resulting in limited overall impact on the invited population [146, 147].

Recognition of the harms of over-diagnosis and over-treatment had led to a redesign in the pathway for early detection of PCa including identification of specific risk groups, individualised re-testing interval, improved indication for biopsy using risk calculators and/or MRI, targeted biopsies, and the application of AS for low-risk disease.

After a negative screening, PSA measurement and DRE need to be repeated [148], but the optimal intervals for PSA testing and DRE follow-up are unknown as they varied between several prospective screening trials. A risk-adapted strategy might be a consideration, based on the initial PSA level. Men with a baseline PSA < 1 ng/mL at 40 years or < 2 ng/mL at 60 years are at decreased risk of PCa metastasis or death from PCa several decades later [46, 135]. The retesting interval can therefore be every two years for those initially at increased risk or postponed up to eight years for those at low-risk [149].

An analysis of ERSPC data supports a recommendation for an eight-year screening interval in men with an initial PSA concentration < 1 ng/mL; fewer than 1% of men with an initial PSA concentration < 1 ng/mL were found to have a concentration above the biopsy threshold of 3 ng/mL at four-year follow-up; the cancer detection rate by eight years was close to 1% [150]. The long-term survival and QoL benefits of extended PSA re-testing (every eight years) remain to be proven at a population level.

5.1.4 Screening in patients with BRCA mutations

The IMPACT study evaluates targeted PCa screening using PSA in men aged 40–69 years with germline *BRCA1/2* mutations (annually, biopsy recommended if PSA > 3.0 ng/mL). After three years of screening, *BRCA2* mutation carriers were associated with a higher incidence of PCa, a younger age of diagnosis, and more clinically significant tumours compared with non-carriers [131, 151]. The influence of *BRCA1* mutations on PCa remained unclear. No differences in age or tumour characteristics were detected between *BRCA1* carriers and *BRCA1* non-carriers. The mismatch repair cohort of IMPACT in men with MSH2 and MSH6 pathogenic variants found a higher incidence of significant PCa vs. non-carriers [152].

5.1.5 Guidelines for individual early detection

Recommendations	Strength rating
Do not subject men to prostate-specific antigen (PSA) testing without counselling them on the potential risks and benefits.	Strong
Offer an individualised risk-adapted strategy for early detection to a well-informed man with a life-expectancy of at least fifteen years.	Weak
Offer early PSA testing to well-informed men at elevated risk of having PCa: • men from 50 years of age; • men from 45 years of age and a family history of PCa; • men of African descent from 45 years of age; • men carrying *breast cancer gene 2 (BRCA2)* mutations from 40 years of age.	Strong
Offer a risk-adapted strategy (based on initial PSA level), with follow-up intervals of two years for those initially at risk: • men with a PSA level of > 1 ng/mL at 40 years of age; • men with a PSA level of > 2 ng/mL at 60 years of age; Postpone follow-up up to eight years in those not at risk.	Weak
Stop early diagnosis of PCa based on life expectancy and performance status; men who have a life-expectancy of < fifteen years are unlikely to benefit.	Strong

5.1.6 Genetic testing for inherited prostate cancer

Increasing evidence supports the implementation of genetic counselling and germline testing in early detection and PCa management [153]. Several commercial screening panels are now available to assess the main PCa risk genes [154]. However, it remains unclear when germline testing should be considered and how this may impact localised and metastatic disease management. Germline *BRCA1* and *BRCA2* mutations occur in approximately 0.2% to 0.3% of the general population [155]. It is important to understand the difference between somatic testing, which is performed on the tumour, and germline testing, which is performed on blood or saliva and identifies inherited mutations. Genetic counselling is required prior to and after undergoing germline testing.

Germline mutations can drive the development of aggressive PCa. Therefore, the consensus is the following men, with a personal or family history of PCa or other cancer types arising from DNA repair gene mutations should be considered for germline testing:

- Men with metastatic PCa who are candidates for targeted treatment;
- Men with BRCA mutations on somatic testing;
- Men with multiple family members diagnosed with csPCa at age < 60 years or a family member who died from PCa;
- Men with a family history of high-risk germline mutations or a family history of multiple cancers on the same side of the family.

Further research in this field (including not so well-known germline mutations) is needed to develop screening, early detection and treatment paradigms for mutation carriers and family members.

*5.1.7 **Guidelines for germline testing****

Recommendations	Strength rating
Consider germline testing in men with multiple family members diagnosed with PCa at age < 60 years or a family member who died from PCa.	Weak
Offer germline testing in men with a family history of high-risk germline mutations or a family history of multiple cancers on the same side of the family.	Strong
Offer germline testing to patients with breast cancer gene (BRCA) mutations on somatic testing	Strong

**Genetic counselling is required prior to germline testing.*

5.2 Diagnostic tools

The different available diagnostic tools can be used separately, or in multiple-tier combinations and/or sequences to indicate prostate biopsy.

*5.2.1 **Digital rectal examination***

In ~18% of cases, PCa is detected by suspect DRE alone, irrespective of PSA level [156]. A suspect DRE in patients with a PSA level ≤ 2 ng/mL has a positive predictive value (PPV) of 5–30% [156]. In the ERSPC trial, an abnormal DRE in conjunction with an elevated PSA more than doubled the risk of a positive biopsy (48.6% vs. 22.4%) [157]. An abnormal DRE is associated with an increased risk of a higher ISUP grade, predicts clinically significant PCa in men under AS (active surveillance) [158] and is an indication for MRI and biopsy [157, 159]. Clinical T-staging is dependent on DRE, and it remains a strong predictor of advanced PCa (OR: 11.12 for cT3 and OR: 5.28 for cT4) [160].

*5.2.2 **Prostate-specific antigen***

Prostate-specific antigen (a glycoprotein enzyme secreted by prostate epithelial cells) is the primary test in the suspicion of PCa. Its use as a serum marker has revolutionised PCa diagnosis [161]. Prostate-specific antigen is organ- but not cancer specific; therefore, it may be elevated in benign prostatic hyperplasia (BPH), prostatitis and other non-malignant conditions. There are no agreed standards for defining PSA thresholds [162]. It is a continuous parameter, with higher levels indicating greater likelihood of PCa. Some men may harbour PCa despite having low serum PSA [163]. Table 5.2 demonstrates the occurrence of any PCa and ISUP ≥ grade 2 PCa in systematic biopsies at low PSA levels, precluding an optimal PSA threshold for detecting non-palpable but csPCa.

Table 5.2: Risk of PCa identified by systemic PCa biopsy in relation to low prostate-specific antigen values [163]

PSA level (ng/mL)	Risk of PCa (%)	Risk of ISUP grade ≥ 2 PCa (%)
0.0–0.5	6.6	0.8
0.6–1.0	10.1	1.0
1.1–2.0	17.0	2.0
2.1–3.0	23.9	4.6
3.1–4.0	26.9	6.7

In a screening situation, the most commonly applied threshold for PSA is ≥ 3.0 ng/ml, resulting in 16.5% of invited men returning a positive test [164]. The risk of finding PCa at a specific PSA threshold in a clinical cohort may be different than in a screening situation, due to differences in prevalence, protocol for referral, and diagnostic algorithm. PSA keeps its diagnostic value for cancer detection in symptomatic patients [165]. A review and meta-analysis on the diagnostic accuracy of PSA (≥ 4.0 ng/ml) for the detection of PCa transrectal ultrasound (TRUS) in clinical patients found an estimated combined sensitivity of 0.93 and specificity of 0.20 PSA production is androgen dependent and 5α-reductase inhibitors (e.g. finasteride, dutasteride) used for benign prostatic enlargement of the prostate such as finasteride or dutasteride will reduce PSA levels by 50% [166]. In such cases, PSA level should be corrected before a decision about further investigation is made.

In case of a moderately elevated PSA (up to 10 ng/mL), a repeated test after a few weeks should be considered to confirm the increase before going to continue the diagnostic analysis. Repeat PSA should be performed in the same laboratory using the same assay under standardised conditions (i.e. no ejaculation, manipulations, and urinary tract infections [UTIs]) [167, 168]. The type of PSA assay used may impact PSA values and rates of PSA above certain fixed thresholds [169].

A repeat PSA test before prostate biopsies in men with an initial PSA 3–10 ng/mL reduced the indication for biopsies in 16.8% of men while missing 5.4% ISUP grade > 1 in the Stockholm3 trial [170]. Similarly, in the Prostate Testing for Cancer and Treatment (ProtecT) trial men with a more than 20% lower repeat-PSA analysis within seven weeks had a lower risk of PCa (OR: 0.43, 95% CI: 0.35–0.52) as well as a lower risk of ISUP grade ≥ 2 (OR: 0.29, 95% CI: 0.19–0.44) [171]. A study with a PSA interval of four weeks showed similar findings of a reduced risk of PCa and ISUP grade > 1 [172]. These observations indicate that an early repeat-PSA prior to the decision of prostate biopsies has prognostic information.

*5.2.3 **Prostate-specific antigen density***

Prostate-specific antigen density (PSA-D) is the level of serum PSA divided by the prostate volume. The higher the PSA-D, the more likely it is that the PCa is clinically significant; in particular in smaller prostates when a PSA-D cut-off of 0.15 ng/mL/cc was applied [195]. Several studies found a PSA-D over 0.1–0.15 ng/mL/cc predictive of PCa [173, 174]. Patients with a PSA-D below 0.09 ng/mL/cc were found unlikely (4%) to be diagnosed with csPCa [175]. PSA-D is one of the strongest predictors in risk calculators.

PSA-D remains currently limited due to the lack of standardisation of prostate volume estimation that can be assessed by DRE or by imaging (TRUS or MRI using various techniques such as ellipsoid formula or planimetry). Nonetheless, one study involving seven radiologists who assessed prostate volume on 40 MRI scans using two different ellipsoid methods and a manual planimetry method suggested that intra and inter-reader reproducibility of the three methods were excellent with intraclass correlation coefficient > 0.90 [176]. In a series of 640 men, TRUS found prostate volumes on average 8% smaller than MRI; in the 109 men who underwent RP, MRI-derived prostate volume was better correlated to the volume of the surgical specimen than TRUS-derived volume [177].

Transabdominal ultrasound overestimated the prostate volume by 9.9 ml [178]. Therefore, the use of transabdominal ultrasound to evaluate prostate volume is discouraged.

*5.2.4 **Imaging***

5.2.4.1 Magnetic resonance imaging

Multi-parametric MRI combines T2-weighted, diffusion-weighted, and dynamic contrast-enhanced imaging. Although MRI is mainly initiated after suspicion of PCa based on PSA and/or DRE, it has also been analysed as an initial test [179]. Besides suggesting the presence of PCa, imaging also allows targeted prostate biopsy and provides staging information.

Prostate cancer appears as areas with low signal intensity on T2-weighted imaging, restriction of diffusion and early and intense enhancement on perfusion imaging. However, there is substantial overlap between the appearances of PCa and some prostate benign conditions. The Prostate Imaging-Reporting and Data System (PI-RADS) has been proposed to standardize interpretation and stratify men with suspected PCa on a 1- to 5- risk scale of having csPCa [180, 181].

Correlation with RP specimens shows that MRI has good sensitivity for the detection and localisation of ISUP grade group ≥ 2 cancers, especially when their diameter is larger than 10 mm [182]. MRI is less sensitive in identifying ISUP grade group 1 PCa. It identifies less than 30% of ISUP grade 1 cancers smaller than 0.5 cc identified on RP specimens by histopathology analysis [182-185].

The good sensitivity of magnetic resonance imaging for ISUP grade group ≥ 2 cancer was further confirmed in patients who underwent template biopsies. In a Cochrane meta-analysis which compared MRI to template biopsies (≥ 20 cores) in biopsy-naïve and repeat-biopsy settings, MRI had a pooled sensitivity of 0.91 (95% CI: 0.83–0.95) and a pooled specificity of 0.37 (95% CI: 0.29–0.46) for ISUP grade group > 2 cancers. For ISUP grade ≥ 3 cancers, MRI pooled sensitivity and specificity were 0.95 (95% CI: 0.87–0.99) and 0.35 (95% CI: 0.26–0.46), respectively [186].

In a meta-analysis of seventeen studies involving men with suspected or biopsy-proven PCa, the average PPVs for ISUP grade group ≥ 2 cancers of lesions with a PI-RADS version 2.1 score of 3, 4 and 5 were 16% (7–27%), 59% (39–78%), and 85% (73–94%), respectively, but with significant heterogeneity among studies [187].

In biopsy naïve men, an MRI-based indication for biopsy after referral, leads to lower rates of biopsy, lower rates of men diagnosed with PCa labelled as insignificant, and more men with PCa labelled as csPCa [121, 186, 188-190]. This is also true in men with prior negative biopsy [186, 191] (see section 5.4.2).

5.2.4.2 Transrectal ultrasound and ultrasound-based techniques

Standard TRUS is not reliable at detecting PCa [192] and the diagnostic yield of additional biopsies performed on hypoechoic lesions is negligible [190]. New sonographic modalities such as micro-Doppler, sonoelastography or contrast-enhanced US provided promising preliminary findings, either alone, or combined into the so-called 'multi-parametric US' [193, 194]. In the multi-parametric US vs. multi-parametric MRI to diagnose PCa (CADMUS) trial, 306 patients underwent both multi-parametric MRI and multi-parametric US composed of B-mode, Colour Doppler, real-time elastography, and contrast-enhanced US. Patients with at least one positive test underwent targeted biopsy. Multi-parametric US detected 4.3% fewer csPCa while submitting 11.1% more patients to biopsy than MRI [195].

High-resolution micro-US shows improved spatial resolution but struggles to assess the anterior part of large prostates. Two prospective trials assessed MRI and micro-US interpreted in a blinded manner before combined targeted and systematic biopsy. In one, MRI and micro-US detected respectively 60 (76%) and 58 (73%) of the 79 csPCas, while systematic sampling detected 45/79 cases (57%). MRI-targeted biopsy detected seven csPCas missed by micro-US; of these three were anterior lesions. Micro-US-guided biopsy detected five csPCas missed by MRI; of these, three were at the apex [196]. In the other study, MRI- and micro-US-targeted biopsy depicted csPCa in 37 (39%) and 33 (35%) of the 94 men, respectively while the MRI- plus micro-US-targeted pathway detected 38 csPCa [197]. These findings suggest that MRI and micro-US could complement each other. Micro-US could also be an interesting alternative to MRI/fusion since biopsy operators who are aware of MRI findings can localise most MRI lesions on micro-US and, thus, target them with direct US image guidance [198]. Of note, evaluation of micro-US inter-operator variability is currently lacking.

5.2.4.3 Prostate-specific antigen-Positron emission tomography/Computed tomography (or Magnetic resonance imaging)

Though mainly used for staging purposes, PSMA-PET/CT (or -PET/MRI) prostate expression may be used to indicate and target biopsies. For csPCa detection, a pooled sensitivity of 0.89 and a pooled specificity of 0.56 have been reported [199]. In a prospective trial of 291 patients, combined PSMA + MRI improved negative predicted value (NPV) compared with MRI alone (91% vs. 72%, test ratio = 1.27 [1.11–1.39], $p < 0.001$). Sensitivity also improved (97% vs. 83%, $p < 0.001$), but specificity was reduced (40% vs. 53%, $p = 0.011$) [122].

*5.2.5 **Blood and urine biomarkers***

Urine and serum biomarkers as well as tissue-based biomarkers have been proposed for improving detection and risk stratification of PCa patients, potentially avoiding unnecessary biopsies. However, further studies are necessary to validate their efficacy [200].

5.2.5.1 Blood based biomarkers: PHI/4K score/IsoPSA/Stockholm3/Proclarix

The use of biomarkers (included in a nomogram) may help in predicting indolent PCa [201, 202]. Several assays measuring a panel of kallikreins in serum or plasma are now commercially available, including the U.S. Food and Drug Administration (FDA) approved Prostate Health Index (PHI) test (combining free and total PSA and the [-2]pro-PSA isoform [p2PSA]), and the four kallikrein (4K) score test (measuring free, intact and total PSA and kallikrein-like peptidase 2 [hK2] in addition to other parameters age, DRE and prior biopsy status). Both tests are intended to reduce the number of unnecessary prostate biopsies in PSA-tested men. A few prospective multi-centre studies demonstrated that both the PHI and 4K score test out-performed f/t PSA PCa detection, with an improved prediction of csPCa in men with a PSA between 2–10 ng/mL [203, 204]. In a head-to-head comparison both tests performed equally [205].

In contrast to the 4K score and PHI, which focus on the concentration of PSA isoforms, IsoPSA utilises a technology which focuses on the structure of PSA. In a multi-centre prospective validation in 271 men the assay area under curve (AUC) was 0.784 for high-grade vs. low-grade cancer/benign histology, which was superior to the AUCs of total PSA and percent free PSA [208]. In men with a negative mpMRI, PSA-D, 4K score and family history predicted the risk of csPCa on biopsy and using a nomogram reduced the number of negative biopsies and indolent cancers by 47% and 15%, respectively, while missing 10% of csPCa [206].

The Stockholm3 test is a prediction model that is based on several clinical variables (age, first-degree family history of PCa, and previous biopsy), blood biomarkers (total PSA, free PSA, ratio of free PSA to total PSA, human kallikrein 2, macrophage inhibitory cytokine-1, and *microseminoprotein*-β *[MSMB])*, and a polygenic risk score for predicting the risk of PCa with ISUP grade group ≥ 2, and was shown to reduce the percent of clinically insignificant cancers when used in combination with MRI in a PSA screening population [207]. It also has the potential to decrease the number of mpMRI scans required in prostate cancer screening [208].

The Proclarix® test is a blood-based test that estimates the likelihood of csPCa according to measurement results for thrombospondin-1, cathepsin D, total PSA, percentage free PSA and patient age. This test has been correlated with the detection of significant PCa, notably in case of equivocal MRI (PI-RADS 3 lesions) [209].

5.2.5.2 Urine biomarkers: PCA3/SelectMDX/Mi Prostate score (MiPS)/ExoDX

Prostate cancer gene 3 (PCA3) is an overexpressed long non-coding RNA (lncRNA) biomarker that is detectable in urine sediments obtained after three strokes of prostatic massage during DRE. However, the clinical utility of the commercially available Progensa urine test for PCA3 for biopsy decision-making remains uncertain. Still, combining MRI findings with the PCA3 score may improve risk stratification [210].

The SelectMDX test is similarly based on mRNA biomarker isolation from urine. The presence of HOXC6 and DLX1 mRNA levels is assessed to provide an estimate of the risk of both presence of PCa on biopsy as well as presence of high-risk cancer [211]. A multi-centre trial evaluated SelectMDX in men with an MRI PI-RADS score < 4 or PI-RADS score < 3, and the percentage of missed csPCas was 6.5% and 3.2%, respectively, whereas 45.8% and 40% of biopsies were avoided [212]. Hendriks *et al.*, found more biopsies were avoided and more high-grade PCas detected in an MRI-based biopsy strategy compared to a SelectMDX strategy. When both tests were combined, more Gleason grade > 1 lesions were found, but the number of negative or low-grade cancer biopsies more than doubled [202]. Combining SelectMDX and MRI in men with a PSA between 3–10 ng/mL had a negative predictive value (NPV) of 93% [213]. The clinically added value of SelectMDX in the era of upfront MRI and targeted biopsies remains unclear [214].

TMPRSS2-ERG fusion, a fusion of the trans-membrane protease serine 2 (TMPRSS2) and the ERG gene can be detected in 50% of PCas [215]. When detection of TMPRSS2-ERG in urine was added to PCA3 expression and serum PSA (Mi(chigan)Prostate Score [MiPS]), cancer prediction improved [216]. Exosomes secreted by cancer cells may contain mRNA diagnostic for high-grade PCa [217, 218]. Use of the ExoDx Prostate IntelliScore urine exosome assay resulted in avoiding 27% of unnecessary biopsies when compared to standard of care (SOC). However, currently, both the MiPS-score and ExoDx assay are considered investigational.

In the screening population of the ERSPC study the use of both PCA3 and 4K panel when added to the risk calculator led to an improvement in AUC of less than 0.03 [219]. Based on the available evidence, some biomarkers could help in discriminating between aggressive and non-aggressive tumours with an additional value compared to the prognostic parameters currently used by clinicians [220]. However, upfront MRI is also likely to affect the utility of above-mentioned biomarkers (see Section 5.2.3.2).

*5.2.6 **Guidelines for screening and individual early detection***

Recommendations	**Strength rating**
In asymptomatic men with a prostate-specific antigen (PSA) level between 3 and 10 ng/mL and a normal digital rectal examination (DRE), repeat the PSA test prior to further investigations.	Weak
In asymptomatic men with a PSA level between 3 and ps. Go20 ng/mL and a normal DRE, use one of the following tools for biopsy indication: • risk-calculator, provided it is correctly calibrated to the population prevalence; • magnetic resonance imaging of the prostate.	Strong
• an additional serum, urine biomarker test	Weak

5.3 *Pathology of prostate needle biopsies*

5.3.1 Processing

Prostate core biopsies from different sites are processed separately, as delivered by the biopsy operator. Before processing, the number and length of the cores are recorded. The length of biopsy tissue significantly correlates with the PCa detection rate [221]. In case individual cores can clearly be identified in submitted jars, a maximum of three cores should be embedded per tissue cassette, and sponges or paper should be used to keep the cores stretched and flat to achieve optimal flattening and alignment [222, 223]. To optimise detection of small lesions and improve accuracy of grading, paraffin blocks should be cut at three levels and intervening unstained sections may be kept for immunohistochemistry (IHC) [224].

5.3.2 Microscopy and reporting

Diagnosis of PCa is based on histology. The diagnostic criteria include features pathognomonic of cancer, major and minor features favouring cancer and features against cancer. Ancillary staining and additional (deeper) sections should be considered if a suspect lesion is identified [224]. Diagnostic uncertainty is resolved by intradepartmental or external consultation [224]. Sections 5.3.2.1 and 5.3.2.2 list the recommended terminology and item list for reporting prostate biopsies [223]. Type and subtype of PCa should be reported such as for instance acinar adenocarcinoma, ductal adenocarcinoma and small or large cell neuroendocrine carcinoma, even if representing a small proportion of the PCa. The distinct aggressive nature of small/large cell neuroendocrine carcinoma should be commented upon in the pathology report [223]. Apart from grading acinar and ductal adenocarcinoma, the percentage of Gleason grade 4 component should be reported in Gleason score 7 (3+4 and 4+3) PCa biopsies. Percentage Gleason grade 4 has additional prognostic value and is considered in some AS protocols [225, 226]. Considerable evidence has been accumulated in recent years supporting that among the Gleason grade 4 patterns, cribriform pattern carries an increased risk of biochemical recurrence, metastatic disease and death of disease [227, 228]. Reporting of this sub-pattern based on established criteria is recommended [101, 229]. Intraductal carcinoma, defined as an extension of cancer cells into pre-existing prostatic ducts and acini, distending them, with preservation of basal cells [101], should be distinguished from high-grade prostatic intraepithelial neoplasia (PIN) [230] as it conveys unfavourable prognosis in terms of biochemical recurrence and cancer-specific survival (CSS) [231, 232]. Its presence should be reported whether occurring in isolation or associated with adenocarcinoma [101]. Some intra-epithelial lesions have architectural complexity and/or cytological atypia exceeding those of high-grade PIN but fall short for a definitive diagnosis of IDC. These lesions have been referred to as Atypical Intraductal Proliferation (AIP) and amongst others encompass lesions that were previously classified as cribriform high-grade PIN. Small retrospective series suggest that AIP at biopsy is associated with unsampled IDC [233, 234]. Therefore, presence of AIP should be reported and commented on in non-malignant biopsies and biopsies with ISUP grade group 1 and 2 cancers in the absence of overt invasive cribriform and IDC.

5.3.2.1 Recommended terminology for reporting prostate biopsies [235]

Heading
Benign/negative for malignancy; if appropriate, include a description
Active inflammation
Granulomatous inflammation
High-grade prostatic intraepithelial neoplasia (PIN)
High-grade PIN with atypical glands, suspicious for adenocarcinoma
Focus of atypical glands/lesion suspicious for adenocarcinoma/atypical small acinar proliferation, suspicious for cancer
Adenocarcinoma, provide type and subtype, and presence or absence of cribriform pattern
Atypical intraductal proliferation (AIP)
Intraductal carcinoma

Each biopsy site should be reported individually, including its location (in accordance with the sampling site) and histopathological findings, which include the histological type and the ISUP 2019 grade group [101, 236, 237]. For MRI targeted biopsies consisting of multiple cores per target the aggregated (or composite) ISUP grade group should be reported per targeted lesion [101]. If the targeted biopsies are negative, presence of specific benign pathology should be mentioned, such as dense inflammation, fibromuscular hyperplasia or granulomatous inflammation [101, 238]. A global ISUP grade group comprising all systematic (non-targeted) and targeted biopsies is also reported (see Section 4.2). The global ISUP grade group takes into account all biopsies positive

for carcinoma, by estimating the total extent of each Gleason grade present. For instance, if three biopsy sites are entirely composed of Gleason grade 3 and one biopsy site of Gleason grade 4 only, the global ISUP grade group would be 2 (i.e. GS 7[3+4]) or 3 (i.e. GS 7[4+3]), dependent on whether the extent of Gleason grade 3 exceeds that of Gleason grade 4, whereas the worst grade would be ISUP grade group 4 (i.e. GS 8[4+4]). Neither global nor worst ISUP grade group is clearly superior over the other [239]. The majority of clinical studies have not specified whether global or worst biopsy grade was taken into account. In addition to GS /ISUP grade group, the presence/absence of intraductal/invasive cribriform pattern should be reported [101, 236, 237]. Furthermore, in biopsy GS 7 (ISUP grade group 2 and 3) percentage Gleason grade 4 should be monitored at the case and/or biopsy level [101, 237]. Lymphovascular invasion (LVI), EPE and ejaculatory duct/seminal vesicle involvement must each be reported, if identified, since they carry unfavourable prognostic information [240, 241].

Recently, a series of studies have demonstrated that computer-assisted PCa grading artificial intelligence algorithms can perform grading at the level of experienced genito-urinary pathologists. These algorithms have potential in supporting grading of less experienced pathologists, by reducing inter-observer variability, and in quantitative analyses. However, more extensive and prospective validation of these algorithms is needed for implementation in daily clinical practise [101, 236, 237, 242]. The proportion of systematic (non-targeted) carcinoma-positive cores as well as the extent of tumour involvement per biopsy core correlate with the ISUP grade group, tumour volume, surgical margins and pathological stage in RP specimens and predict BCR, post-prostatectomy progression and RT failure. These parameters are included in nomograms created to predict pathological stage and SV invasion after RP and RT failure [243, 244]. A pathology report should therefore provide both the number of carcinoma positive cores and the extent of cancer involvement for each core. The length in mm and percentage of carcinoma in the biopsy have equal prognostic impact [245]. An extent of >50% of adenocarcinoma in a single core is used as a cut-off in some AS protocols [246] triggering immediate treatment vs. AS in patients with ISUP grade group 1 (see Section 6.1.1.1).

5.3.2.2 Recommended item list for reporting prostate cancer biopsies [101, 236, 237]

Type of carcinoma
Primary and secondary Gleason grade, per biopsy site and global International Society of Urological Pathology (ISUP) grade group
Percentage of global Gleason grade 4 in Gleason Score (GS) 7 biopsies
Presence/absence of intraductal/invasive cribriform carcinoma
Presence of Atypical Intraductal Proliferation (AIP) in intraductal/invasive cribriform-negative cases
Number of cancer-positive biopsy cores
Extent of cancer (in mm or percentage)
For Magnetic resonance imaging (MRI)-targeted biopsies with multiple cores aggregate (or composite) ISUP grade group per lesion For carcinoma-negative MRI-targeted biopsy, specific benign pathology, e.g. fibromuscular hyperplasia or granulomatous inflammation
If present, lymphovascular invasion (LVI), extraprostatic extension and ejaculatory duct/seminal vesicle involvement

*5.3.3 **Tissue-based prognostic biomarker testing***

After a comprehensive literature review and several panel discussions an American Society of Clinical Oncology (ASCO)-EAU-American Urological Association (AUA) multi-disciplinary expert panel made recommendations regarding the use of tissue-based PCa biomarkers. The recommendations were limited to five commercially available tests (Oncotype Dx, Prolaris, Decipher, Decipher PORTOS and ProMark) with extensive validation in large retrospective studies and evidence that their test results might actually impact clinical decision-taking. The selected commercially available tests significantly improved the prognostic accuracy of clinical multi-variable models for identifying men who would benefit of AS and those with csPCa requiring curative treatment, as well as for guidance of patient management after RP. Few studies showed that tissue biomarker tests and MRI findings independently improved the detection of csPCa in an AS setting, but it remains unclear which men would benefit of both tests. Decipher® test outcome has been associated with presence of intraductal/invasive cribriform carcinoma but retains independent value in multi-variable analysis. Since the long-term impact of the use of these commercially available tests on oncological outcome remains unproven and prospective trials are largely lacking, the Panel concluded that these tests should not be offered routinely but only in subsets of patients where the test result provides clinically actionable information, such as for instance in men with favourable intermediate-risk PCa who might opt for AS or men with unfavourable intermediate-risk PCa

scheduled for RT to decide on treatment intensification with hormone therapy (HT) [247].

5.3.4 Tissue samples for homologous recombination repair (HRR)-testing

Homologous recombination repair-testing in the PROfound trial was conducted on archival or recent biopsy tissue from primary or metastatic disease with successful sequencing in 69% [248]. Alterations in HRR genes are relatively unchanged comparing matched treatment-naïve diagnostic and mCRPC biopsies [249, 250]. Whereas there is no preference for use of archival or new metastatic biopsies for HRR-testing, bone biopsies might be associated with lower success rates related to decalcification of tissue [251]. Testing of circulating tumour DNA might be a good alternative if tumour tissue is not available [250, 252]. With tissue as reference, ctDNA showed 81% positive and 92% negative percentage agreement [253].

5.3.5 Histopathology of radical prostatectomy specimens

5.3.5.1 Processing of radical prostatectomy specimens

Histopathological examination of RP specimens describes the pathological stage, histopathological type, grade and surgical margins of PCa. It is recommended that RP specimens are totally embedded to enable assessment of cancer location, multi-focality and heterogeneity. For cost-effectiveness, partial embedding may also be considered, particularly for prostates >60 g. The most widely accepted method includes complete embedding of the posterior prostate and a single mid-anterior left and right section. Compared with total embedding, partial embedding with this method missed 5% of positive margins and 7% of EPE [254].

The entire RP specimen should be inked upon receipt in the laboratory to demonstrate the surgical margins. Specimens are fixed by immersion in buffered formalin for at least 24 hours, preferably before slicing. After fixation, the apex and the base (bladder neck) are removed and cut into (para)sagittal or radial sections; the shave method is not recommended [99]. The remainder of the specimen is cut in transverse, 3–4 mm sections, perpendicular to the long axis of the urethra. The resultant tissue slices can be embedded and processed as whole-mounts or after quadrant sectioning. Whole-mounts provide better topographic visualisation, faster histopathological examination and better correlation with pre-operative imaging, although they are more time-consuming and require specialist handling. For routine sectioning, the advantages of whole mounts do not outweigh their disadvantages.

5.3.5.2 Radical prostatectomy specimen report

The pathology report provides essential information on the prognostic characteristics relevant for clinical decision-making (Table 5.6). As a result of the complex information to be provided for each RP specimen, the use of synoptic(-like) or checklist reporting is recommended. Synoptic reporting results in more transparent and complete pathology reporting [255].

Table 5.3: Mandatory elements provided by the pathology report

Histopathological (sub)type
Type of carcinoma, e.g., conventional acinar adenocarcinoma, (small cell) neuroendocrine cell carcinoma or ductal carcinoma
Subtype and unusual variants, e.g. pleomorphic giant cell or mucinous
Histological grade
Primary (predominant) Gleason grade Secondary Gleason grade Tertiary Gleason grade (if applicable) Global ISUP grade group Approximate percentage of Gleason grade 4 or 5
Tumour quantitation (optional)
Percentage of prostate involved Size/volume of dominant tumour nodule
Pathological staging (pTNM)

If extraprostatic extension is present: • indicate whether it is focal or extensive (see Section 5.2.9.4.4); • specify sites; • indicate whether there is seminal vesicle invasion. *If applicable, regional lymph nodes:* • location; • number of nodes retrieved; • number of nodes involved.
Surgical margins
If carcinoma is present at the margin: • specify sites; • extent: focal or extensive (see Section 5.2.9.4.6) • (highest) grade at margin.
Other
Presence of lymphovascular/angio-invasion Location of dominant tumour Presence of intraductal carcinoma/cribriform architecture

5.3.5.3 ISUP grade group in prostatectomy specimens

Grading of conventional prostatic adenocarcinoma using the Gleason system is the strongest prognostic factor for clinical behaviour and treatment response [100]. The GS is incorporated in nomograms that predict disease-specific survival (DSS) after prostatectomy [256, 257]. The ISUP grade group in prostatectomy specimens is determined mostly in a similar way as in biopsies, with a minor exception, i.e. the exclusion of minor (< 5%) high-grade components from the ISUP grade group. For instance, in a carcinoma almost entirely composed of Gleason grade 3 the presence of a minor (< 5%) Gleason grade 4 or 5 component is not included in the GS (ISUP grade group 1), but its presence is commented upon [101]. In case of multi-focality the ISUP grade group of the index lesion i.e. the tumour having the highest grade, stage or volume, is given.

5.3.5.4 Definition of extra-prostatic extension

Extra-prostatic extension is defined as carcinoma mixed with peri-prostatic adipose tissue, or tissue that extends beyond the prostate gland boundaries (e.g., neurovascular bundle, anterior prostate). Microscopic bladder neck invasion is considered EPE. It is useful to report the location and extent of EPE because the latter is related to recurrence risk [258]. There are no internationally accepted definitions of focal or microscopic, vs. non-focal or extensive EPE. Some describe focal as a few glands [259] or <1 high-power field in one or at most two sections whereas others measure the depth of extent in millimetres [259]. At the apex of the prostate, tumour mixed with skeletal muscle does not constitute EPE. In the bladder neck, microscopic invasion of smooth muscle fibres is not equated to bladder wall invasion, i.e. not as pT4, because it does not carry independent prognostic significance for PCa recurrence and should be recorded as EPE (pT3a) [260, 261]. Stage pT4 is assigned when the tumour invades the bladder muscle wall as determined macroscopically [94].

5.3.5.5 PCa volume

Although PCa volume at RP correlates with tumour grade, stage and surgical margin status, the independent prognostic value of PCa volume has not been established [259, 262, 263]. Improvement in prostatic radio-imaging allows more accurate pre-operative measurement of cancer volume. Since the independent value of pathological tumour volume at RP has not been established, reporting of the diameter/volume of the dominant tumour nodule, or a rough estimate of the percentage of cancer tissue, is optional [264].

5.3.5.6 Surgical margin status

Surgical margin status is an independent risk factor for BCR. Margin status is positive if tumour cells are in contact with the ink on the specimen surface. Margin status is negative if tumour cells are close to the inked surface [265] or at the surface of the tissue lacking ink. In tissues that have severe crush artefacts, it may not be possible to determine margin status [266]. Surgical margin is separate from pathological stage, and a positive margin is not evidence of EPE [267]. There is evidence for a relationship between margin extent and recurrence risk [268, 269]. Some indication must be given of the multi-focality and extent of margin positivity, such as the linear extent in mm of involvement: focal, ≤ 1 mm vs. extensive, > 1 mm [270], or number of blocks with positive margin involvement. Gleason score at the positive margin was found to correlate independently with outcome and should be reported [255, 268, 271].

5.3.5.7 *Intra-operative assessment of surgical margin status*

Intra-operative surgical margin assessment can be performed during RP to reduce positive margins and increase neurovascular bundle preservation. A SR reported a 1-15% decrease of positive surgical margins in eight out of ten studies [272]. Intra-operative evaluation of the posterolateral prostatic margin according to the neurovascular structure-adjacent frozen section examination (NeuroSAFE) technique is a systematic way of intra-operative surgical margin evaluation [273]. Non-randomised studies showed that men subjected to NeuroSAFE had lower positive surgical margin rates and more frequently underwent uni- or bilateral nerve-sparing surgery [273-276]. Pending the results on long-term oncological and functional outcome as well as the outcome of the randomised NeuroSAFE PROOF trial, intra-operative frozen section analysis should not be considered standard of care [277].

5.4 Biopsy indication

5.4.1 ***Risk assessment before MRI and biopsy***

An elevated risk of significant PCa is established based on one or more of the primary diagnostic tools applied, such as PSA level, DRE, or primary imaging. While in the classic diagnostic algorithm the indication for biopsy was generally solely based on a PSA-threshold or abnormal DRE, different two- or three-tier sequential / conditional pathways are now available to indicate prostate biopsy, such as imaging and/or biomarkers. These can be combined and/or sequenced into two or multiple-tier conditional diagnostic pathways (e.g. PSA -> MRI, PSA -> risk calculator, PSA -> risk calculator -> MRI, etc). Age, co-morbidity, life expectancy, and therapeutic consequences should also be considered and discussed beforehand [278].

The chosen diagnostic algorithm may be elected based on availability, expertise, and resources. The different approaches impact cancer detection rates, number of (un)necessary biopsies, number of patient visits, and option of targeted biopsies. The elected strategy may also be decided based on prevalence of disease in men entering the pathway (e.g. screening versus clinical symptoms).

Different sequences and combinations of these tools, lead to different rates of biopsy indications, detection rates of insignificant PCa, and significant PCa, but also on the burden and costs of the diagnostic algorithm [279].

5.4.1.1 *Risk calculators assessing the risk of csPCa*

At different steps during the diagnostic process, available parameters may be combined into risk calculators to optimise risk-assessment of csPCa. Validation and adaption to the target population are important issues before use. Risk calculators, combining clinical data (age, DRE findings, PSA level, prostate volume, etc.) may be useful in helping to determine (on an individual basis) what the potential risk of cancer may be, thereby improving the balance of the cancer detection rates and number of biopsies [280].

Several tools developed from cohort studies are available including (among others) the calculator derived from the ERSPC cohort (http://www.prostatecancer-riskcalculator.com/seven-prostate-cancer-risk-calculators) that has been updated by incorporating the 2014 ISUP Pathology Gleason Grading and Cribriform growth [150], and the one derived from the Prostate Cancer Prevention Trial (PCPT) cohort (PCPTRC 2.0 https://riskcalc.org/PCPTRC/). However, calculators are limited by their dependency on disease prevalence. All calculators show miscalibration when tested in populations with a different prevalence than that of the training population of the model. Recalibrations taking into account the local prevalence are possible, but this approach is difficult in routine as the local prevalence is difficult to estimate and may change over time.

5.4.1.2 *Using risk-stratification to avoid Magnetic resonance imaging scans and biopsy procedures*

A retrospective analysis including 200 men from a prospective database of patients who underwent MRI and combined systematic and targeted biopsy showed that upfront use of the Rotterdam Prostate Cancer Risk Calculator would have avoided MRI and biopsy in 73 men (37%). Of these 73 men, ten had ISUP grade group 1 cancer and 4 had ISUP grade group ≥ 2 cancer [281]. A prospective multi-centre study evaluated several diagnostic pathways in 545 biopsy-naive men who underwent MRI and systematic and targeted biopsy. Using a PHI threshold of > 30 to perform MRI and biopsy would have avoided MRI and biopsy in 25% of men at the cost of missing 8% of the ISUP grade group ≥ 2 cancers [282]. Another prospective multi-centre trial including 532 men (with or without history of prostate biopsy) showed that using a threshold of ≥ 10% for the Stockholm3 test to perform MRI and biopsy would have avoided MRI and biopsy in 38% of men at the cost of missing 8% of ISUP grade group ≥ 2 cancers [207]. Finally, a risk calculator developed on 1,486 men who underwent MRI and biopsy was externally validated on a cohort of 946 men from two institutions; using a risk threshold that provided 95% sensitivity in the development cohort could have avoided 22% of the MRI scans in the validation cohort while missing 5% of csPCa [283].

5.4.2 *MRI based indication for biopsy*

5.4.2.1 *MRI as a triage test for biopsy ('MRI pathway')*

Owing to its high sensitivity, MRI showed an excellent NPV for ruling out the presence of csPCa not only at subsequent biopsy [284], but also after four years of follow-up [285].

The diagnostic yield and number of biopsy procedures potentially avoided by the 'MR pathway' (in which only patients with positive MRI undergo biopsy) depends on the Likert/PI-RADS threshold used to define a positive MRI. In pooled studies on biopsy-naive patients and patients with prior negative biopsies, a Likert/PI-RADS threshold of ≥ 3 would have avoided 30% (95% CI: 23–38) of all biopsy procedures while missing 11% (95% CI: 6–18) of all detected ISUP grade group ≥ 2 cancers (relative percentage) [186]. Increasing the threshold to ≥ 4 would have avoided 59% (95% CI: 43–78) of all biopsy procedures while missing 28% (95% CI: 14–48) of all detected ISUP grade group ≥ 2 cancers [186]. Of note, the percentages of negative MRI (Likert/PI-RADS score ≤ 2) may show substantial variability among series. In the PRECISION, MRI-FIRST and 4M trials were 21.1%, 28.9% and 49%, with related ISUP grade group ≥ 2 cancer prevalence of 27.7% (23.7–32.6), 37.5% (31.4–43.8), and 30% (ND) respectively [121, 189, 190].

In the MR PROPER trial, a prospective, multi-centre, non-randomised opportunistic early detection setting (PSA > 3 ng/mL), comparable rates of ISUP grade group ≥ 2 cancer detection (24% vs. 25%) were obtained by the MRI pathway and by a strategy indicating systematic biopsy based on a risk calculator. However, the MRI pathway avoided biopsy in more men as compared to the diagnostic pathway using a risk calculator (559/1015, 55% vs. 403/950, 42%; difference -13%, 95% 27 CI: -17% to -8.3%; p < 0.01); it also detected less ISUP grade group 1 cancers (84/1015, 8.3% vs. 121/950, 13%; difference 4.5%, 95% CI: 1.8–7.2%; p < 0.01) [286].

5.4.2.2 *Combining MRI and PSA Density*

Prostate-specific antigen density (PSA-D) may help refine the risk of csPCa in patients undergoing MRI as PSA-D and the PI-RADS score are significant independent predictors of csPCa at biopsy [287, 288]. Combinations of PSA-D and MRI have been explored [289, 290], showing guidance in biopsy-decisions whilst safely avoiding redundant biopsy testing and detection of insignificant PCa. In a meta-analysis of eight studies, pooled MRI NPV for ISUP grade group ≥ 2 cancer was 84% (95% CI: 81–87) in the whole cohort, 83% (95% CI: 80–84) in biopsy-naive men and 88% (95% CI: 85–91) in men with prior negative biopsies. In the subgroup of patients with PSA-D < 0.15 ng/mL/cc, NPV increased to respectively 90% (95% CI: 87–93), 89% (95% CI: 83–93) and 94% (95% CI: 91–97) [291]. In contrast, the risk of ISUP grade group ≥ 2 cancer is as high as 27–40% in patients with negative MRI and PSA-D > 0.15–0.20 ng/mL/cc [189, 288, 292-294].

Based on a meta-analysis of > 3,000 biopsy-naive men, a risk-adapted data table of csPCa was developed, linking PI-RADS score (1-2, 3, and 4-5) to PSA-D categories (< 0.10, 0.10–0.15, 0.15–0.20 and > 0.20 ng/mL) (Table 5.4) [289]. This risk-adapted matrix table may guide the decision to perform a biopsy.

In a multi-centre retrospective cohort of 1476 men with PIRADS 3 lesions and a prevalence of 18.5% of ISUP grade group ≥ 2 cancer, age, prior negative biopsy and PSA-D were significant independent predictors of the presence of ISUP grade group ≥ 2 cancer at subsequent systematic and targeted biopsy. Applying a PSA-D cut-off of 0.15 ng/mL/cc, 817 biopsy procedures (58.4%) would have been avoided at the cost of missing ISUP grade group ≥ 2 cancer in 91 men (6.5%); ISUP grade group 1 cancer would not have been detected in 115 men (8.2%) [295]. Two studies provided follow-up data for patients with PI-RADS scores of 1-3 and PSA-D <0.15 ng/ml/cc for whom biopsy was omitted. The cumulative incidence of ISUP grade group ≥ 2 cancer detection was 1.3% at two years [296] and 3.2% at 36 months [297].

Table 5.4: Risk data table of clinically significant prostate cancer, related to PI-RADS score and PSA-D categories in biopsy-naive men, clinically suspected of having significant disease [289]*

Detection of clinically significant prostate cancer (ISUP grade 2 and higher)					
		PSA-density risk groups			
PI-RADS risk categories	Prevalence ISUP ≥ 2 PCa	Low < 0.10	Intermediate-low 0.10–015	Intermediate-high 0.15–0.20	High ≥ 0.20
		31% (678/2199)	28% (612/2199)	16% (360/2199)	25% (553/2199)
Compiled totals of csPCa risk					
PI-RADS 1–2	6% (48/839)	3% (11/411)	7% (17/256)	8% (8/104)	18% (12/68)

PI-RADS 3	16% (41/254)	4% (3/74)	13% (11/88)	29% (12/41)	29% (15/51)
PI-RADS 4–5	62% (687/1106)	31% (59/189)	54% (144/286)	69% (148/215)	77% (336/434)
All PI-RADS	35% (776/2199)	11% (73/674)	28% (172/612)	47% (168/360)	66% (363/553)
Risk-adapted matrix table for biopsy decision management					
PI-RADS 1–2		No biopsy	No biopsy	No biopsy	Consider biopsy
PI-RADS 3		No biopsy	Consider biopsy	Highly consider biopsy	Perform biopsy
PI-RADS 4–5		Perform biopsy	Perform biopsy	Perform biopsy	Perform biopsy

very low	0–5% csPCa (below population risk) #
low	5–10% csPCa (acceptable risk) ##
Intermediate-low	10–20% csPCa
Intermediate-high	20–30% csPCa
High	30–40% csPCa
Very high	> 40% csPCa

Thompson IM *et al.* N Engl J Med. 2004 May 27;350(22):2239-46. Prevalence of prostate cancer among men with a prostate-specific antigen level < or = 4.0 ng/mL. [163].

Table adapted from: Schoots, IG and Padhani AR. BJU Int 2021 127(2):175. Risk-adapted biopsy decision based on prostate magnetic resonance imaging and prostate-specific antigen density for enhanced biopsy avoidance in first prostate cancer diagnostic evaluation, with permission from Wiley.

5.4.2.3 Risk calculators incorporating MRI finding

Several groups have developed comprehensive risk calculators which combine MRI findings with simple clinical data as a tool to predict subsequent biopsy results [298]. Some calculators underwent external validation with good results both in terms of discrimination and clinical utility and tended to outperform risk calculators not incorporating MRI findings [299-302]. However, their use is hindered by their miscalibration due to prevalence dependency (see section 5.4.1.1).

5.4.2.4 MRI in screening protocols

The inclusion of MRI may improve the diagnostic algorithm after a screening PSA, as it reduces the number of men that undergo biopsies while detecting more high-grade and less low-grade PCa [179, 303, 304]. The Stockholm-3 (STHLM3) screening trial randomised men with a PSA > 3 ng/mL between standard biopsies (10–12 cores) or MRI and standard plus targeted biopsies in the presence of a suspicious MRI. The percentage of men that underwent prostate biopsies in the standard group was double that of the MRI group. In this non-inferiority trial, the intention-to-treat (ITT) analysis found 18% and 21% ISUP grade group ≥2 cancer and 12% and 4% ISUP grade group 1 cancer in the standard and the MRI group, respectively [304].

In the GÖTEBORG-2 screening trial, 37,887 men between 50 and 60 years of age were invited to undergo regular PSA screening [305]. Participants with a PSA level above 3 ng/mL were randomly allocated to MRI and combined systematic- and targeted biopsy (reference group) or to MRI and targeted biopsy only in case of PI-RADS ≥ 3 lesions (experimental group). In the experimental group, the detection rate of ISUP grade group 1 cancers was reduced by half (detection ratio: 0.46, 95% CI: 0.33–0.64, p < 0.001); that of ISUP grade group ≥ 2 cancers was lower but not significantly different (detection ratio: 0.81, 95% CI: 0.60 to 1.1). In the reference group, ten of the 68 men with ISUP grade group ≥ 2 cancer were diagnosed by systematic biopsy only. All these ten patients were of intermediate risk. Thus, in a screening setting, the 'MRI pathway' may reduce the risk of over-diagnosis by half, at the cost of delaying detection of intermediate-risk tumours in a small percentage of patients. However, these good results were obtained at a single academic centre with double reading of the MRI, which may limit their generalisability in less experienced centres (see Sections 5.5.4).

The IP1-PROSTAGRAM study (PSA > 3 ng/mL; MRI PIRADS [Prostate Imaging – Reporting and Data System] > 2), tested MRI as the initial screening test, showed highest detection of csPCa for MRI compared to a PSA threshold followed by transrectal ultrasound-guided prostate (TRUS) biopsy in a population screening setting, with similar rates of biopsy and insignificant cancer [179]. This study proposed a pathway that combines PSA >=1 ng/ml and MRI score >=4, maintaining the detection of grade group ≥2 cancers while recommending fewer men for biopsies, as the preferred strategy to evaluate in future studies at the first screening round [306].

5.5 Biopsy strategy

Prostate biopsy can be performed using different strategies (systematic, targeted etc) and approaches (i.e. transperineal vs. transrectal).

*5.5.1 **Systematic biopsy strategy***

For systematic biopsies, where no prior imaging is used for targeting, the sample sites should be bilateral from apex to base, as far posterior and lateral as possible in the peripheral gland regardless of the approach used. A 2006 SR showed that twelve is the minimum number of cores for systematic biopsies, with > twelve cores not increasing cancer detection rate significantly [307].

*5.5.2 **Targeted biopsy strategy***

Where MRI has shown a suspicious lesion, MR-targeted biopsy can be obtained through cognitive guidance, US/MR fusion software or direct in-bore guidance. Current literature, including SRs and meta-analyses, does not show a clear superiority of one image-guided technique over another [308-310]. The Target Biopsy Techniques Based on Magnetic Resonance Imaging in the Diagnosis of Prostate Cancer in Patients with Prior Negative Biopsies (FUTURE) randomised trial compared three techniques (cognitive fusion, software fusion, in-bore MRI) of MRI-targeted biopsy in the repeat-biopsy setting and found no differences in cancer detection [309].

*5.5.3 **Targeted biopsy versus systematic biopsy***

5.5.3.1 Increased detection of cancers labelled as clinically significant

The PRECISION (Prostate Evaluation for Clinically Important Disease: Sampling Using Image Guidance or Not?) [121] and PRECISE (Prostate Evaluation for Clinically Important Disease: MRI vs. Standard Evaluation Procedures) [188] prospective trials randomized biopsy naïve patients to either ten to twelve core systematic biopsy or to MRI with subsequent MRI-targeted biopsy (up to four cores) in case of positive MRI. They found that MRI-targeted biopsy significantly out-performed [121] or was not inferior to [188] systematic biopsy for the detection of ISUP grade group ≥ 2 cancers. In pooled data of 25 reports on agreement analysis (head-to-head comparisons) between systematic biopsy (median number of cores: 8–15) and MRI-targeted biopsies (median number of cores: 2–7), the detection ratio (i.e. the ratio of the detection rates obtained by MRI-targeted biopsy alone and by systematic biopsy alone) was 1.12 (95% CI: 1.02–1.23) for ISUP grade group ≥ 2 cancers and 1.20 (95% CI: 1.06–1.36) for ISUP grade group ≥ 3 cancers, and therefore in favour of MRI-targeted biopsy [168]. Another meta-analysis of studies limited to biopsy-naive patients with a positive MRI also found that MRI-targeted biopsy detected significantly more ISUP grade group ≥ 2 cancers than systematic biopsy (risk difference, -0.11 [95% CI: -0.2 to 0.0]; p = 0.05) [311]. This data was confirmed in prospective multi-centre trials evaluated MRI-targeted biopsy in biopsy-naive patients [121, 189].

In a subgroup of 152 patients from the FUTURE trial who underwent both MRI-targeted biopsy and systematic biopsy in a repeat biopsy setting, MRI-targeted biopsy detected significantly more ISUP grade group ≥ 2 cancers than systematic biopsy (34% vs. 16%; p < 0.001, detection ratio of 2.1) [191]. These findings support that MRI-targeted biopsy significantly out-performs systematic biopsy for the detection of ISUP grade ≥ 2 also in the repeat-biopsy setting.

5.5.3.2 Reduced detection of cancers labelled as ISUP grade group 1

In pooled data of 25 head-to-head comparisons between systematic biopsy and MRI-targeted biopsy, the detection ratio for ISUP grade group 1 cancers was 0.62 (95% CI: 0.44–0.88) in patients with prior negative biopsy and 0.63 (95% CI: 0.54–0.74) in biopsy-naive patients [186]. In the PRECISION and 4M trials, the detection rate of ISUP grade group 1 patients was significantly lower in the MRI-targeted biopsy group as compared to systematic biopsy (9% vs. 22%, p < 0.001, detection ratio of 0.41 for PRECISION; 14% vs. 25%, p < 0.001, detection ratio of 0.56 for 4M) [121, 189]. In the MRI-FIRST trial, MRI-targeted biopsy detected significantly fewer patients with clinically insignificant PCa (defined as ISUP grade group 1 and maximum cancer core length < 6 mm) than systematic biopsy (5.6% vs. 19.5%, p < 0.0001, detection ratio of 0.29) [190]. Consequently, MRI-targeted biopsy without systematic biopsy significantly reduces over-diagnosis of low-risk disease, as compared to systematic biopsy. This seems true even when systematic biopsies are indicated after risk stratification with the Rotterdam Prostate Cancer Risk Calculator) [286].

5.5.3.3 Added value of systematic biopsy and targeted biopsy

From head-to-head comparisons between the two biopsy techniques, it is possible to compute their added value, i.e. the percentage of additional patients with csPCa they contribute to diagnose. Table 5.3 shows the added value of systematic and MRI-targeted biopsy for ISUP grade group ≥ 2 and ≥ 3 cancer detection. The absolute added values in the table refer to the percentage of patients in the entire cohort; if the cancer prevalence is considered, the 'relative' percentage of additional detected csPCa can be computed. Adding MRI-targeted biopsy to systematic biopsy in biopsy-naive patients increases the number of detected ISUP grade ≥ 2 and grade ≥ 3 PCa by approximately 20% and 30%, respectively. In the repeat-biopsy setting, adding MRI-targeted biopsy increases detection of ISUP grade group ≥ 2 and grade group ≥ 3 PCa by approximately 40% and 50%, respectively. Omitting systematic biopsy in biopsy-naive patients would miss approximately 16% of all detected ISUP grade group ≥ 2 PCa and 18% of all ISUP grade ≥ 3 PCa. In the repeat-biopsy setting, it would miss approximately 10% of ISUP grade group ≥ 2 PCa and 9% of ISUP grade group ≥ 3 Pca. The low added value of systematic biopsy in the repeat biopsy setting has been further confirmed by other studies that reported absolute added values of 1.2-3.9% for the detection of ISUP grade group ≥2 cancers and of 1.2-1.6% for ISUP grade group ≥ 3 cancers [191, 312, 313].

Table 5.5: Absolute added values of targeted and systematic biopsies for ISUP grade ≥ 2 and ≥ 3 Cancer Detection

		ISUP ≥ 2			ISUP ≥ 3		
ISUP grade		**Cochrane meta-analysis*** [186]	**MRI-FIRST trial*** [190]	**4M trial** [189]	**Cochrane meta-analysis*** [186]	**MRI-FIRST trial*** [190]	**4M trial** [189]
Biopsy-naïve	Added value of MRI-TBx	6.3% (4.8–8.2)	7.6% (4.6–11.6)	7.0% (ND)	4.7% (3.5–6.3)	6.0% (3.4–9.7)	3.2% (ND)
	Added value of systematic biopsy	4.3% (2.6–6.9)	5.2% (2.8–8.7)	5.0% (ND)	2.8% (1.7–4.8)	1.2% (0.2–3.5)	4.1% (ND)
	Overall prevalence	27.7% (23.7–32.6)	37.5% (31.4–43.8)	30% (ND)	15.5% (12.6–19.5)	21.1% (16.2–26.7)	15% (ND)
Prior negative biopsy	Added value of MRI-TBx	9.6% (7.7–11.8)	-	-	6.3% (5.2–7.7)	-	-
	Added value of systematic biopsy	2.3% (1.2–4.5)	-	-	1.1% (0.5–2.6)	-	-
	Overall prevalence	22.8% (20.0–26.2)	-	-	12.6% (10.5–15.6)	-	-

**Intervals in parenthesis are 95% CI.*

The absolute added value of a given biopsy technique is defined by the percentage of patients of the entire cohort diagnosed only by this biopsy technique.

ISUP = International Society of Urological Pathology (grade); MRI-TBx = magnetic resonance imaging-targeted biopsies; ND = not defined.

Table 5.6: Detection rates of ISUP grade group 1 cancers by targeted and systematic biopsies

Study	Targeted biopsy	Systematic biopsy	p-value
PRECISION [121]	9%	22%	<0.001
PRECISE [188]	10.1	21.7	<0.001
MRI-FIRST [190]*	5.6%	19.5%	<0.0001
4M [189]	14%	24.7%	<0.0001
Cochrane meta-analysis [186]	13.5%	22.4%	<0.01

** In the MRI-FIRST trial, the percentages refer to the detection rates of ISUP 1 cancers with a maximum cancer core length < 6 mm*

5.5.4 ***Perilesional biopsy***

A minimum of three to five cores is required for proper sampling of an MRI detected lesion [313, 314]. Including additional peri-lesional/regional systematic biopsies, rather than standard sextant-based systematic biopsies may decrease the total number of cores taken (by avoiding systematic biopsies in MRI-negative lobes) and improve the detection of csPCa (by compensating for guiding imprecision). In addition, the MRI-targeted and regional biopsy approach could avoid detecting 12-17% of the insignificant cancers detected by the classical combined approach [315-317].

A meta-analysis of eight studies showed a non-significant difference in detection of ISUP grade group ≥2 cancer in the MRI-directed targeted and regional biopsy approach, compared to the recommended practice of MRI-directed targeted- and systematic biopsy approach (RR: 0.95, 95% CI: 0.90–1.01; p = 0.09). However, the MRI-directed targeted- and regional biopsy approach detected significantly more ISUP grade group ≥2 cancers than MRI-targeted biopsy alone (RR: 1.18, 95% CI: 1.10–1.25; p < 0.001) [255]. Other prospective [318] and retrospective [317, 319] studies not included in the meta-analysis provided similar evidence (Table 5.7).

Two studies retrospectively used the location of biopsy cores registered by MRI/US fusion systems to assess the added value of systematic cores based on their distance from the nearest MRI lesion. The diagnostic yield of these systematic cores decreased with increasing distance. Combining the targeted and systematic cores located within a 10 mm and a 15 mm radius from the MR lesions detected 90-92% and 94-97% of the csPCa respectively [315, 316]. The width of the distance from the MRI lesion which enclosed 90% of csPCa may also depend on the PI-RADS score of the lesion; in one series it was found to be 5.5 mm, 12 mm and 16 mm for lesions with PI-RADS scores of 5, 4 and 3 respectively [315]. As a consequence, in men with a PI-RADS 5 index lesion, the absolute added value of additional biopsy has been repeatedly found to be less than 4% for ISUP grade group ≥ 2 cancers and less than 2% for ISUP grade group ≥ 3 cancers [313, 320-322].

5.5.5 ***Prostate MRI and MRI-targeted biopsy reproducibility***

Despite the use of the PI-RADS scoring systems, MRI inter-reader reproducibility remains moderate at best. MRI performance is better with experienced radiologists and at high-volume centres. This currently limits its broad use by non-dedicated radiologists [314, 323].

The accuracy of MRI-targeted biopsy is also substantially impacted by the experience of the biopsy operator [314]. The PRECISE trial, that reproduced the design of the PRECISION trial obtained quite different results. In both trials, the detection rate for ISUP grade group ≥2 PCa was higher for the MRI pathway than for the classical systematic biopsy pathway. Yet, the difference was much lower in the PRECISE trial (+5.2% vs. +12.1% for ISUP grade group ≥2 cancers; +2.1% vs. +5.5% for ISUP grade group ≥3 cancers). In addition, there was major intersite variability in the PRECISE trial: the centre with the highest csPCa detection rate on MRI-targeted biopsy had the lowest on systematic biopsy and vice versa.

These factors of variability give rise to concerns about the reproducibility of the good results of the MRI-directed diagnostic pathways. Efforts towards standardization of the whole diagnostic pathway (MRI acquisition and interpretation, biopsy planning and acquisition) through quality assurance and quality control are currently undertaken [314, 324]. However, significant improvement in the accuracy of MRI and MRI-targeted biopsy can be observed over time through simple measures such as training and participation to MDT meeting with pathological correlation and feedback [314, 325]. Whether artificial intelligence-based assistance will improve MRI interpretation accuracy remains questionable, as preliminary studies reported conflicting results on the topic [326].

5.5.6 ***Cancer grade shift***

MRI findings are significant predictors of adverse pathology features on prostatectomy specimens, and of survival-free BCR after RP or RT [96, 327, 328]. In addition, tumours visible on MRI are enriched in molecular hallmarks of aggressivity, as compared to invisible lesions [329]. Thus, MRI does identify aggressive tumours.

Nonetheless, as MRI-targeted biopsy is more sensitive than systematic biopsy in detecting areas of high-grade cancer, ISUP grade group ≥ 2 cancers detected by MRI-targeted biopsy are, on average, of better prognosis than those detected by the classical diagnostic pathway (Will Rogers phenomenon [98]. This is illustrated in a retrospective series of 1,345 patients treated by RP which showed that, in all risk groups, patients diagnosed by MRI-targeted biopsy had better BCR-free survival than those diagnosed by systematic biopsy only [96]. To mitigate this grade shift, in case of targeted biopsies, the 2019 ISUP consensus conference recommended using an aggregated ISUP grade group summarizing the results of all biopsy cores from the same MR lesion, rather than using the result from the core with the highest ISUP grade group [101] (see pathology section 4.2). When long term follow-up of patients who underwent MRI-targeted biopsy is available, a revision of the risk-groups definition will become necessary. In the meantime, results of MRI-targeted biopsy must be interpreted in the context of this potential grade shift [330].

Table 5.7: Detection rates for ISUP grade group ≥2 prostate cancer achieved by targeted biopsy, combined systematic and targeted biopsy and targeted biopsy with perilesional sampling

	Type of study	Nb of pts	Targeted biopsy with perilesional sampling vs. Combined systematic and targeted biopsy		Targeted biopsy with perilesional sampling vs. Targeted biopsy	
			Ratio of detection rates	Median number of cores	Ratio of detection rates	Median number of cores
Hagens MJ [331]	Meta-analysis	2603	0.95 (0.90 – 1.01), p=0.09	9.5 [7.5-12.3] vs. 16.5 [15.3 – 12.3]	1.18 (1.1 – 1.25), p<0.001	9.5 [7.5 – 12.3] vs. 3.5 [3 – 4]
Hagens MJ [317]	Retrospective, single centre	235	0.968 (0.91 – 0.993)	7 [6 – 9] vs. 12 [10 – 15]	-	-
Hsieh PF, J 18:127 [332]	Prospective, single centre	100	1	15 [12.8 – 18] vs. 26 [23 – 28]	1.20, p=0.008	15 [12.8 – 18] vs. 6 [4 – 7]

5.5.7 Guidelines for MRI imaging in biopsy indication and strategy

Recommendations	Strength rating
Do not use magnetic resonance imaging (MRI) as an initial screening tool.	Strong
Adhere to PI-RADS guidelines for MRI acquisition and interpretation and evaluate MRI results in multidisciplinary meetings with pathological feedback.	Strong
Where MRI has shown a suspicious lesion, MR-targeted biopsy can be obtained through cognitive guidance, US/MR fusion software or direct in-bore guidance.	Weak
Perform MRI before prostate biopsy in men with suspected organ confined disease.	Strong
In men with suspicion of locally advanced disease on digital rectal examination (DRE) and/or prostate-specific antigen (PSA)>50 ng/mL, or those not for curative treatments, consider limited biopsy without MRI.	Weak
When MRI is positive (i.e. PI-RADS ≥ 4), combine targeted biopsy with perilesional sampling.	Weak
When MRI is negative (i.e., PI-RADS ≤ 2), and clinical suspicion of PCa is low (PSA density < 0.20 ng/mL/cc, negative DRE findings, no family history), omit biopsy and offer PSA monitoring; otherwise consider systematic biopsy.	Weak
When MRI is indeterminate (PI-RADS = 3), and clinical suspicion of PCa is very low (PSA density < 0.10 ng/mL/cc, negative DRE findings, no family history), omit biopsy and offer PSA monitoring; otherwise consider targeted biopsy with perilesional sampling.	Weak
If MRI is not available, use a risk calculator and systematic biopsies if indicated.	Strong
When performing systematic biopsy only, at least twelve cores are recommended.	Strong

5.6 Biopsy approach

Ultrasound (US)-guided prostate biopsy is now the standard of care although MRI in-bore biopsy is now possible in a few centres. Ultrasound-guided prostate biopsy can be performed by either the transperineal approach or the transrectal one. Both can be performed under local anaesthesia [333]. However, the only SR and meta-analysis comparing MRI-targeted transrectal biopsy to MRI-targeted transperineal biopsy, analysing 8 studies, showed a higher sensitivity for detection of csPCa when the transperineal approach was used (86% vs. 73%) [334]. This benefit was especially pronounced for anterior tumours. Evidence also suggests reduced infection risk with the transperineal route (see Section 5.2.8.1.1) [335, 336].

5.6.1 Local anaesthesia prior to biopsy

Ultrasound-guided peri-prostatic block is recommended [337]. Ten mL of 2% lidocaine is infiltrated bilaterally along the apex to base. Intra-rectal instillation of local anaesthesia is inferior to peri-prostatic infiltration [338]. Local anaesthesia can also be used effectively for MRI-targeted and systematic transperineal biopsy [339].

Patients are placed in the lithotomy position. Twenty mL of 0.5% bupivacaine with adrenaline (1 in 200,000) is injected into the perineal skin and subcutaneous tissues anterior to the anus, followed two minutes later by a peri-prostatic block. A SR evaluating pain in 3 studies comparing transperineal vs. transrectal biopsies found that the transperineal approach significantly increased patient pain (RR: 1.83 [1.27–2.65]) [340]. In a randomised comparison a combination of peri-prostatic and pudendal block anaesthesia reduced pain during transperineal biopsies compared to peri-prostatic anaesthesia only [341]. Targeted biopsies can then be taken via a brachytherapy grid or a freehand needle-guiding device under local infiltration anaesthesia [339, 342]. Perineal nerve-block was superior for the relief of pain during the biopsy procedure versus periprostatic block (2.80 vs. 3.98; on 1-10 scale) [343].

*5.6.2 **Transperineal prostate biopsy***

A total of eight randomised studies including 1,596 patients compared the impact of biopsy route on infectious complications. Infectious complications were significantly higher following transrectal biopsy (48 events among 789 men) compared to transperineal biopsy (22 events among 807 men) (RR: 95% CI: 2.48 [1.47–4.2]) [344, 345]. In addition, a SR including 165 studies with 162,577 patients described sepsis rates of 0.1% and 0.9% for transperineal and transrectal biopsies, respectively [346]. Finally, a population-based study from the UK (n = 73,630) showed lower re-admission rates for sepsis in patients who had transperineal vs. transrectal biopsies (1.0% vs. 1.4%, respectively) [347]. The available evidence demonstrates that the transrectal approach should be abandoned in favour of the transperineal approach despite any possible logistical challenges. A SR and meta-analysis of eight non-RCTs reported no significant differences between patients receiving or not receiving antibiotic prophylaxis in terms of post-biopsy infection (0,11% vs. 0.31%) and sepsis (0.13% vs. 0,09%), for the transperineal approach [348]. This is in line with another SR and meta-analysis of 112 individual patient cohorts which also showed no significant difference in the number of patients experiencing post-transperineal-biopsy infection 1.35% of 29,880 patients receiving antibiotic prophylaxis and 1.22% of 4,772 men not receiving antibiotic prophylaxis (p = 0.8) [349]. In addition, two published RCTs have reported comparably low post-biopsy infection rates for transperineal biopsy regardless of whether antibiotic prophylaxis was administered or not [350, 351]. A SR and meta-analysis comparing transperineal with and without antibiotic prophylaxis showed very low percentages of septic complications (0.05% vs. 0.08%; p=0.2) and overall infections (1.35% vs. 1.22%; p=0.8)

Thus, there is a growing body of evidence to suggest that antibiotic prophylaxis may not be required for transperineal biopsy; however, the Panel has chosen to wait until a number of ongoing RCTs report their study findings before making a recommendation on this.

*5.6.3 **Transrectal prostate biopsy***

An updated meta-analysis of eleven RCTs including 2,237 men showed that use of a rectal povidone-iodine preparation before biopsy, in addition to antimicrobial prophylaxis, resulted in a significantly lower rate of infectious complications (RR: 95% CI: 0.47 [0.36–0.61]) [345, 352, 353]. Single RCTs showed no evidence of benefit for perineal skin disinfection [354], but reported an advantage for rectal povidone-iodine preparation before biopsy compared to after biopsy [355].

A meta-analysis of four RCTs including 671 men evaluated the use of rectal preparation by enema before transrectal biopsy. No significant advantage was found regarding infectious complications (RR: 95% CI: 0.96 [0.64–1.54]) [345].

An updated meta-analysis of 28 RCTs with 4,027 patients found no evidence that use of periprostatic injection of local anaesthesia resulted in more infectious complications than no injection (RR: 95% CI: 1.08 [0.79–1.48]) [344, 345, 353]. A meta-analysis of nine RCTs including 2,230 patients found that extended biopsy templates showed comparable infectious complications to standard templates (RR: 95% CI: 0.80 [0.53–1.22]) [345]. Additional meta-analyses found no difference in infectious complications regarding needle guide type (disposable vs. reusable), needle type (coaxial vs. non-coaxial), needle size (large vs. small), and number of injections for peri-prostatic nerve block (standard vs. extended) [345].

A meta-analysis of eleven studies with 1,753 patients showed significantly reduced infections after transrectal prostate biopsy when using antimicrobial prophylaxis as compared to placebo/control (RR: 95% CI: 0.56 [0.40–0.77]) [356].

Fluoroquinolones have been traditionally used for antibiotic prophylaxis in this setting; however, in recent years there has been an increase in fluoroquinolone resistance. In addition, the European Commission has implemented stringent regulatory conditions regarding the use of fluoroquinolones resulting in the suspension of the indication for peri-operative antibiotic prophylaxis including prostate biopsy [357].

A SR and meta-analysis on antibiotic prophylaxis for the prevention of infectious complications following prostate biopsy concluded that in countries where fluoroquinolones are allowed as antibiotic prophylaxis, a minimum of a full one-day administration, as well as targeted therapy in case of fluoroquinolone resistance, or augmented prophylaxis (combination of two or more different classes of antibiotics) is recommended [356]. In countries where use of fluoroquinolones are suspended, cephalosporins or

aminoglycosides can be used as individual agents with comparable infectious complications based on meta-analysis of two RCTs [356]. A meta-analysis of three RCTs reported that fosfomycin trometamol was superior to fluoroquinolones (RR: 95% CI: 0.49 [0.27–0.87]) [356], but routine general use should be critically assessed due to the relevant infectious complications reported in non-randomised studies [358]. Of note the indication of fosfomycin trometamol for prostate biopsy has been withdrawn in Germany as the manufacturers did not submit the necessary pharmacokinetic data in support of this indication. Urologists are advised to check their local guidance in relation to the use of fosfomycin trometamol for prostate biopsy. Another possibility is the use of augmented prophylaxis without fluoroquinolones, although no standard combination has been established to date. Finally, targeted prophylaxis based on rectal swap/stool culture is plausible, but no RCTs are available on non-fluoroquinolones. See figure 5.1 for prostate biopsy workflow to reduce infections complications.

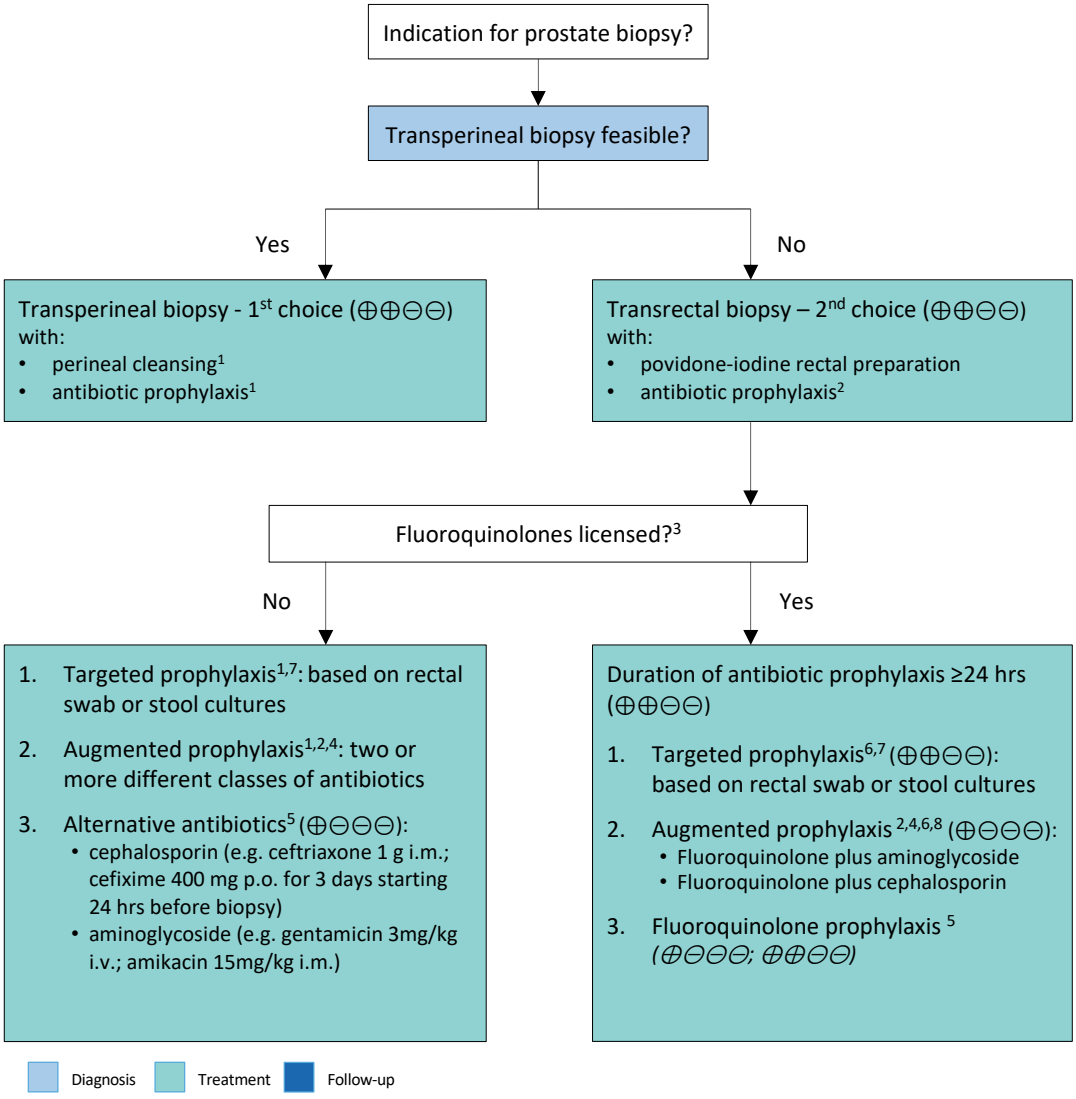
5.6.4 *Summary of evidence and recommendations for performing prostate biopsy (in line with the EAU Urological Infections Guidelines Panel)*

Summary of evidence	LE
A meta-analysis of eight studies including 1,596 patients showed significantly reduced infectious complications in patients undergoing transperineal biopsy as compared to transrectal biopsy.	1a
A meta-analysis of eight non-RCTS reported comparable rates of post-biopsy infections in patients undergoing transperineal biopsy irrespective if antibiotic prophylaxis was given or not.	1a
A meta-analysis of eleven RCTs including 2,036 men showed that use of a rectal povidone-iodine preparation before transrectal biopsy, in addition to antimicrobial prophylaxis, resulted in a significantly lower rate of infectious complications.	1a
A meta-analysis on eleven studies with 1,753 patients showed significantly reduced infections after transrectal biopsy when using antimicrobial prophylaxis as compared to placebo/control.	1a

Recommendations	Strength rating*
Perform prostate biopsy using the transperineal approach due to the lower risk of infectious complications.	Strong
Use routine surgical disinfection of the perineal skin for transperineal biopsy.	Strong
Use rectal cleansing with povidone-iodine prior to transrectal prostate biopsy.	Strong
Use either target prophylaxis based on rectal swab or stool culture; or augmented prophylaxis (two or more different classes of antibiotics); for transrectal biopsy.	Weak
Ensure that prostate core biopsies from different sites are submitted separately for processing and pathology reporting.	Strong

** Note on strength ratings:*
The above strength ratings are explained here due to the major clinical implications of these recommendations. Although data showing the lower risk of infection via the transperineal approach is low in certainty, its statistical and clinical significance warrants its strong rating. Strong ratings are also given for routine surgical disinfection of skin in transperineal biopsy and povidone-iodine rectal cleansing in transrectal biopsy as, although quality of data is low, the clinical benefit is high and practical application simple. A 'Strong' rating is given for avoiding fluoroquinolones in prostate biopsy due to its legal implications in Europe.
*** The indication of fosfomycin trometamol for prostate biopsy has been withdrawn in Germany as the manufacturers did not submit the necessary pharmacokinetic data in support of this indication. Urologists are advised to check their local guidance in relation to the use of fosfomycin trometamol for prostate biopsy.*

Figure 5.2: Prostate biopsy workflow to reduce infectious complications*



Suggested workflow on how to reduce post biopsy infections.
1. Two systematic reviews including non-RCTs and two RCTs describe comparable rates of post-transperineal biopsy infection in patients with and without antibiotic prophylaxis.
2. Be informed about local antimicrobial resistance.
3. Banned by European Commission due to side effects.
4. Contradicts principles of Antimicrobial Stewardship.
5. Only one RCT comparing targeted and augmented prophylaxis.
6. Originally introduced to use alternative antibiotics in case of fluoroquinolone resistance.
7. Various schemes: fluoroquinolone plus aminoglycoside (3 RCTs); and fluoroquinolone plus cephalosporin (1 RCT).

GRADE Working Group grades of evidence. High certainty: (⊕⊕⊕⊕) very confident that the true effect lies close to that of the estimate of the effect. Moderate certainty: (⊕⊕⊕⊖) moderately confident in the effect estimate: the true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different. Low certainty: (⊕⊕⊖⊖) confidence in the effect estimate is limited: the true effect may be substantially different from the estimate of the effect. Very low certainty: (⊕⊖⊖⊖) very little confidence in the effect estimate: the true effect is likely to be substantially different from the estimate of effect. Figure adapted from Pilatz et al., [356] with permission from Elsevier.

** Of note: local guidance in relation to the use of fosfomycin trometamol for prostate biopsy needs to be checked.*

5.6.5 *Complications*

Complications of TRUS biopsy are listed in Table 5.5 [359]. Mortality after prostate biopsy is extremely rare and most are consequences of sepsis [360]. Low-dose aspirin is not an absolute contra-indication [361]. A SR found favourable infection rates for transperineal compared to TRUS biopsies with similar rates of haematuria, haematospermia and urinary retention [362]. A meta-analysis of 4,280 men randomised between transperineal vs. TRUS biopsies in thirteen studies found no significant differences in complication rates, however, data on sepsis compared only 497 men undergoing TRUS biopsy to 474 having transperineal biopsy. The transperineal approach required more (local) anaesthesia [363].

5.7 What diagnostic pathway in clinical practice?

The 'combined pathway', in which patients with a positive MRI undergo combined systematic and targeted biopsy, and patients with a negative MRI undergo systematic biopsy, maximises the detection of ISUP grade group ≥2 cancers. However, it has the disadvantage of leading to a greater detection of ISUP grade group 1 cancers and of referring all patients with a clinical suspicion of cancer to biopsy. Given the growing concerns about over-detection of insignificant PCa, the development of AS protocols in patients with ISUP grade group 2 cancers (see section 6.2.1.2.1) and the grade shift induced by MRI-targeted biopsy (see section 5.5.5) the clinical relevance of a diagnostic strategy aimed only at maximising the detection of ISUP grade group ≥ 2 cancers is questionable [364, 365].

The 'MRI pathway' in which patients with a positive MRI undergo only MRI-targeted biopsy and patients with a negative MRI are not biopsied at all could avoid biopsy in 21-49% of the patients if a PI-RADS threshold of ≥3 is used to trigger biopsy [121, 186, 189, 190], at the cost of missing some significant cancers, especially in biopsy-naïve patients or in highly selected populations with high prevalence of csPCa (in which the MRI NPV decreases) [284, 366].

Several alternative MRI-directed diagnostic pathways can be envisaged to correct these limitations, for example by selecting patients for biopsy based on a combination of MRI findings and clinical data or by adding perilesional sampling to MRI-targeted biopsy.

The best pathway remains unclear as prospective evaluations are lacking. Interestingly, in a study different MRI-directed pathways were compared to the classical combined pathway in a retrospective cohort of 499 men. The highest clinical utility above a risk threshold of 6.25% was obtained by a risk-based pathway in which patients with a PI-RADS score of 1-3 and a low-risk profile (PSA-D<0.15 ng/ml/cc, negative DRE, no family history, no ASAP or ISUP1 cancer at prior biopsy) could forgo biopsy while the others underwent combined systematic and

MRI-targeted biopsy. In this pathway, biopsy could have been avoided in 99 men (19%) while missing ISUP grade group ≥ 2 cancers in only 6 men (1.2%) [367].

*5.7.1 **Repeat biopsy after negative biopsy***

During follow-up after negative systematic biopsy, the incidence of PCa is higher, but the risk of PCa death is lower than the population average [368]. Men with prior negative systematic biopsy and persistent suspicion of PCa should have an MRI if not already performed.

Significant PCa may still be present in men with abnormal MRI and negative targeted biopsy [369]. Follow-up or direct repeat biopsy should be considered dependent on risk factors (e.g. PSA density, PIRADS).

In a contemporary series of biopsies the likelihood of finding a csPCa after follow-up biopsy after a diagnosis of atypical small acinar proliferation and high-grade prostatic intraepithelial neoplasia (PIN) was only 6-8%, not significantly different from follow-up biopsies after a negative biopsy [370, 371].

The added value of other biomarkers remains unclear (see Sections 5.2.5.1 and 5.2.5.2).

*5.7.2 **Saturation biopsy***

The incidence of PCa detected by saturation repeat biopsy (> 20 cores) is 30–43% and depends on the number of cores sampled during earlier biopsies [372]. Saturation biopsy may be performed with the transperineal technique, which detects an additional 38% of PCa. The rate of urinary retention varies substantially from 1.2% to 10% [235, 373].

However, given the very low risk of subsequent csPCa after a negative biopsy and/or in case of negative MRI, the clinical utility of saturation biopsy in the repeat biopsy setting remains uncertain in the current MRI-driven diagnostic pathway and such schemes should not be routinely used [374].

*5.7.3 **Seminal vesicle biopsy***

Indications for SV (staging) biopsies are poorly defined. At a PSA of > 15 ng/mL, the odds of tumour involvement are 20–25% [375]. A SV staging biopsy is only useful if it has a decisive impact on treatment, such as ruling out radical tumour resection or for potential subsequent RT. Its added value compared with MRI is questionable.

*5.7.4 **Transition zone biopsy***

Transition zone sampling during baseline biopsies has a low detection rate and should be limited to MRI detected lesions or repeat template biopsies [376].

5.8 Diagnosis - Clinical Staging

*5.8.1 **T-staging***

The cT category listed in Table 4.1 (TNM Classification) only relies on DRE findings. Imaging parameters and biopsy results for local staging are, so far, not part of the T staging (within TNM) and the EAU risk category stratification [377].

5.8.1.1 Ultrasound-based techniques and Computed Tomography

Transrectal US has limited accuracy for PCa local staging [378]. More advanced US-based techniques have not yet been tested in large-scale studies. In case of locally-advanced cancers, abdominopelvic US or CT may show rectal or bladder invasion and dilatation of the upper collecting systems [378].

5.8.1.2 Magnetic Resonance Imaging

T2-weighted imaging remains the most useful method for local staging on MRI. Pooled data from a meta-analysis showed a sensitivity and specificity of 0.57 (95% CI: 0.49–0.64) and 0.91 (95% CI: 0.88–0.93), 0.58 (95% CI: 0.47–0.68) and 0.96 (95% CI: 0.95–0.97), and 0.61 (95% CI: 0.54–0.67) and 0.88 (95% CI: 0.85–0.91), for EPE, SVI, and overall stage T3 assessment, respectively [379]. Detection of EPE and SVI seems more accurate at high field strength (3 Tesla) [379], while the added value of functional imaging remains debated [379, 380].

In 552 men treated by RP at seven different Dutch centres, MRI showed significantly higher sensitivity (51% vs. 12%; $p < 0.001$), and lower specificity (82% vs. 97%; $p < 0.001$) than DRE for non-organ confined disease. All risk groups redefined using MRI findings rather than DRE findings showed better BCR-free survival due to improved discrimination and the Will Roger's phenomenon [381].

Traditionally, EPE/SVI is assessed visually using qualitative signs (e.g., capsular disruption, visible tumour within peri-prostatic fat). Inter-reader agreement with such subjective reading is moderate, with kappa (k) values ranging from 0.41 to 0.68 [382]. The length of tumour capsule contact (LCC) is also a significant predictor of EPE; it has the advantage of being quantitative, although the ideal cut-off value remains debated [383, 384].

Several grading systems combining subjective qualitative signs and/or LCC into a score have shown good sensitivity (0.64–0.82) and specificity (0.64-0.93) for EPE, with substantial inter-reader agreement (κ = 0.56–0.74). None of these scores has shown definitive superiority over the others [385, 386].

Magnetic resonance imaging findings can improve the prediction of the pathological stage when combined with clinical and biopsy data. As a result, several groups developed multivariate risk calculators for predicting EPE/SVI or positive surgical margins [387]. In external validation cohorts, these risk calculators showed significantly better discrimination than nomograms without MRI-based features [388-390]. However, their results must be interpreted with care given potential miscalibration due to varying prevalence of EPE/SVI.

Given its low sensitivity for focal (microscopic) EPE, MRI is not recommended for local staging in low-risk patients. However, MRI can still be useful for treatment planning.

*5.8.2 **N-staging***

5.8.2.1 Computed tomography and MRI

Abdominal CT and T1-T2-weighted MRI indirectly assess nodal invasion by using LN diameter and morphology. However, the size of non-metastatic LNs varies widely and may overlap the size of LN metastases. Usually, LNs with a short axis > 8 mm in the pelvis and > 10 mm outside the pelvis are considered malignant. Decreasing these thresholds improves sensitivity but decreases specificity. As a result, the ideal size threshold remains unclear [391, 392]. Computed tomography and MRI sensitivity is less than 40% [393, 394]. Detection of microscopic LN invasion by CT is < 1% in patients with ISUP grade group < 4 cancer, PSA < 20 ng/mL, or localised disease [391, 395].

Diffusion-weighted MRI (DW-MRI) may detect metastases in normal-sized nodes, but a negative DW-MRI cannot rule out the presence of LN metastases, and DW-MRI provides only modest improvement for LN staging over conventional imaging [396].

5.8.2.2 Risk calculators incorporating MRI findings and clinical data

Because CT and MRI lack sensitivity for direct detection of positive LNs, nomograms combining clinical and biopsy findings have been used to estimate the risk of patients harbouring positive LNs [397-399]. Although these nomograms are associated with good performance, they have been developed using systematic biopsy findings and may therefore not be appropriate for patients diagnosed with combined MRI-targeted biopsy and systematic biopsy.

Two models incorporating MRI-targeted biopsy findings and MRI-derived findings recently underwent external validation [256, 400]. One model was tested on an external cohort of 187 patients with a prevalence of LN invasion of 13.9% (vs. 16.9% in the development cohort). The C-index was 0.73 (vs. 0.81 in the development cohort); at calibration analysis, the model tended to overpredict the actual risk [400]. The Briganti 2019 model was validated in an external multi-centre cohort of 487 patients with a prevalence of 8% of LN invasion (vs. 12.5% in the development cohort). The AUC was 0.79 (vs. 0.81 in the development cohort). Using a risk cut-off of 7% would have avoided LN dissection in 273 (56% of the cohort), while missing LN invasion in seven patients (2.6% of the patients below the 7% threshold; 18% of the 38 patients with LN invasion) [401]. Another cohort of 150 high-risk patients with a LN invasion prevalence of 26% was retrospectively used to externally assess four different nomograms. All showed high sensitivity (>0.95) and low specificity (<0.19) at the tested thresholds. Using the 7% threshold, the Briganti 2019 nomogram had a sensitivity of 0.96 and a specificity of 0.18 [402]. The calibration of the nomogram will be affected by the prevalence of LN involvement in your population.

5.8.2.3 Choline PET/CT

In a meta-analysis of 609 patients, pooled sensitivity and specificity of choline PET/CT for pelvic LN metastases were 62% (95% CI: 51–66%) and 92% (95% CI: 89–94%), respectively [403]. In a prospective trial of 75 patients at intermediate risk of nodal involvement (10–35%), the sensitivity was only 8.2% at region-based analysis and 18.9% at patient-based analysis, which is too low to be of clinical value [404]. The sensitivity of choline PET/CT increases to 50% in patients at high risk and to 71% in patients at very high risk [405].

5.8.2.4 Prostate-specific membrane antigen-based PET/CT

Prostate-specific membrane antigen PET/CT uses several different radiopharmaceuticals; most published studies used 68Ga-labelling for PSMA PET imaging, but some used 18F-labelling (e.g., 18F-DCFPyL,

18F-PSMA-1007, 18F-PSMA-JK-7). PSMA is also an attractive target because of its specificity for prostate tissue, even if the expression in other non-prostatic malignancies or benign conditions may cause incidental false-positive findings [406, 407].

A multi-centre prospective phase III imaging trial, investigating men with intermediate- and high-risk PCa who underwent RP and PLND, showed a sensitivity and specificity of 68Ga-PSMA-11 PET of 0.40 (95% CI: 0.34-0.46), and 0.95 (95% CI: 0.92-0.97), respectively [408]. This is line with previous results from prospective, multi-centre studies addressing the accuracy of 68Ga-PSMA and 18F-DCFPyL PET/CT for LN staging in patients with newly diagnosed PCa [409, 410]. Comparable results were also demonstrated in a phase II/III prospective, multi-centre study (OSPREY) with a median specificity of 97.9% (95% CI: 94.5–99.4%) and median sensitivity of 40.3% (28.1–52.5%) for pelvic nodal involvement [411]. Prostate-specific antigen may be a predictor of a positive PSMA PET/CT. In the primary staging cohort from a meta-analysis, however, no robust estimates of positivity were found [412].

Comparison between PSMA PET/CT and MRI was performed in a SR and meta-analysis including 13 studies (n = 1,597) [413]. 68Ga-PSMA was found to have a higher sensitivity and a comparable specificity for staging pre-operative LN metastases in intermediate- and high-risk PCa [414].

Prostate specific membrane antigen PET/CT has a good sensitivity and specificity for LN involvement, possibly impacting clinical decision-making. In a review and meta-analysis including 37 articles, a subgroup analysis was performed in patients undergoing PSMA PET/CT for primary staging. On a per-patient-based analysis, the sensitivity and specificity of 68Ga-PSMA PET were 77% and 97%, respectively, after eLND at the time of RP. On a per-lesion based analysis, sensitivity and specificity were 75% and 99%, respectively [412].
In summary, PSMA PET/CT is more sensitive in N-staging as compared to MRI, abdominal contrast-enhanced CT or choline PET/CT. However, small LN metastases, under the spatial resolution of PET, may still be missed.

5.8.2.5 Risk calculators incorporating MRI and PSMA findings

An international, multi-centre study incorporated PSMA PET into existing nomograms in order to predict pelvic LN metastatic disease in PCa patients. Performance of three nomograms was assessed in 757 patients undergoing RARP and ePLND. Addition of PSMA PET to the nomograms substantially improved the discriminative ability of the models yielding cross-validated AUCs of 0.76 (95% CI: 0.70–0.82), 0.77 (95% CI: 0.72–0.83), and 0.82 (95% CI: 0.76–0.87), respectively [415].

*5.8.3 **M-staging***

5.8.3.1 Bone scan

^{99m}Tc-Bone scan is a highly sensitive conventional imaging technique, evaluating the distribution of active bone formation in the skeleton related to malignant and benign disease. A meta-analysis showed combined sensitivity and specificity of 79% (95% CI: 73–83%) and 82% (95% CI: 78–85%) at patient level [416]. Bone scan diagnostic yield is significantly influenced by the PSA level, the clinical stage and the tumour ISUP grade group [391, 417]. A retrospective study investigated the association between age, PSA and GS in 703 newly diagnosed PCa patients who were referred for bone scintigraphy. The incidence of bone metastases increased substantially with rising PSA and upgrading GS [418]. In two studies, a dominant Gleason pattern of 4 was found to be a significant predictor of positive bone scan [419, 420]. Bone scanning should be performed in symptomatic patients, independent of PSA level, ISUP grade group or clinical stage [391].

5.8.3.2 Fluoride PET/CT, choline PET/CT and MRI

^{18}F-sodium fluoride (^{18}F-NaF) PET or PET/CT, similarly to bone scintigraphy, only assesses the presence of bone metastases. The tracer was reported to have similar specificity and superior sensitivity to bone scintigraphy for detecting bone metastases in patients with newly diagnosed high-risk PCa [421, 422]. Interobserver agreement for the detection of bone metastases was excellent, demonstrating that 18F-NaF PET/CT is a robust tool for the detection of osteoblastic lesions in patients with PCa [423].

It remains unclear whether choline PET/CT is more sensitive than bone scan but it has higher specificity with fewer indeterminate bone lesions [424-426]. Choline PET/CT has also the advantage of detecting visceral and nodal metastases.

Diffusion-weighted whole-body and axial skeleton MRI are more sensitive than bone scan and targeted conventional radiography in detecting bone metastases in high-risk PCa. Whole-body MRI can also detect visceral and nodal metastases; it was shown to be more sensitive and specific than combined bone scan, targeted radiography and abdominopelvic CT [427]. A meta-analysis found that whole-body MRI is more sensitive than choline PET/CT and bone scan for detecting bone metastases on a per-patient basis, although choline PET/CT had the highest specificity [416].

5.8.3.3 *PSMA PET/CT*

A SR including twelve studies (n = 322) reported high variation in ^{68}Ga-PSMA PET/CT sensitivity for initial staging (range 33–99%; median sensitivity on per-lesion analysis 33–92%, and on per-patient analysis 66–91%), with good specificity (per-lesion 82–100%, and per-patient 67–99%), with most studies demonstrating increased detection rates with respect to conventional imaging modalities (bone scan and CT) [428].

In a prospective multi-centre study in patients with high-risk PCa before curative surgery or RT (proPSMA), 302 patients were randomly assigned to conventional imaging or ^{68}Ga-PSMA-11 PET/CT [429]. The primary outcome focused on the accuracy of first-line imaging for the identification of pelvic LN or distant metastases. Accuracy of ^{68}Ga-PSMA PET/CT was 27% (95% CI: 23–31) higher than that of CT and bone scintigraphy (92% [95% CI: 88–95] vs. 65% [95% CI: 60–69]; p < 0.0001). Conventional imaging had a lower sensitivity (38% [95% CI: 24–52] vs. 85% [95% CI: 74–96]) and specificity (91% [95% CI: 85–97] vs. 98% [95% CI: 95–100]) than PSMA PET/CT. Furthermore, ^{68}Ga-PSMA PET/CT scan prompted management change more frequently as compared to conventional imaging (41 [28%] men [95% CI: 21–36] vs. 23 [15%] men [95% CI: 10–22], p = 0.08), with less equivocal findings (7% [95% CI: 4–13] vs. 23% [95% CI: 17–31]) and lower radiation exposure (8.4 mSv vs. 19.2 mSv; p < 0.001) [429].The comparison of whole body MRI and PSMA PET/CT in detecting bone metastases has led to inconclusive opposite results in two small cohorts [414, 430].

5.8.4 ***Summary of evidence and practical considerations on initial N/M staging***

The field of non-invasive N- and M-staging of PCa patients is evolving very rapidly. Evidence shows that choline PET/CT, PSMA PET/CT and whole-body MRI provide a more sensitive detection of LN- and bone metastases than the classical work-up with bone scan and abdominopelvic CT. In view of the evidence offered by the randomised, multi-centre proPSMA trial [429], replacing bone scan and abdominopelvic CT by more sensitive imaging modalities may be a consideration in patients with high-risk PCa undergoing initial staging. However, in absence of prospective studies demonstrating survival benefit, caution must be used when taking therapeutic decisions [431]. The prognosis and ideal management of patients diagnosed as metastatic by these more sensitive tests is unknown. In particular, it is unclear whether patients with metastases detectable only with PET/CT or whole-body MRI should be managed using systemic therapies only, or whether they should be subjected to aggressive local and metastases-directed therapies [432].

Results from RCTs evaluating the management and outcome of patients with (and without) metastases detected by choline PET/CT, PSMA PET/CT and MRI are awaited before a recommendation can be made to treat patients based on the results of these tests.

5.8.5 ***Summary of evidence and guidelines for staging of prostate cancer***

Recommendations	Strength rating
Any risk group staging	
Use pre-biopsy magnetic resonance imaging (MRI) for local staging information.	Weak
Low-risk localised disease	
Do not use additional imaging for staging purposes.	Strong
Intermediate-risk disease	
For patients with International Society of Urological Pathology (ISUP) grade group 3 disease, include at least cross-sectional abdominopelvic imaging and a bone-scan for metastatic screening.	Weak
Perform prostate-specific antigen-positron emission tomography/computed tomography (PSMA-PET/CT) if available to increase accuracy.	Weak
High-risk localised disease/locally advanced disease	
Perform metastatic screening using PSMA-PET/CT if available and at least cross-sectional abdominopelvic imaging and a bone-scan.	Strong

6. TREATMENT

This chapter reviews the available treatment modalities, followed by separate sections addressing treatment for the various disease stages.

6.1 Estimating life expectancy and health status

6.1.1 ***Introduction***

Evaluation of life expectancy and health status is important in clinical decision-making for early detection, diagnosis, and treatment of PCa. Prostate cancer is common in older men (median age 68) and diagnoses in men > 65 will result in a 70% increase in annual diagnosis by 2030 in Europe and the USA [433, 434].

Active treatment mostly benefits patients with intermediate- or high-risk PCa and longest expected survival. In localised disease, over ten years life expectancy is considered mandatory for any benefit from local treatment and an improvement in CSS may take longer to become apparent. Older age and worse baseline health status have been associated with a smaller benefit in PCSM and life expectancy of surgery vs. AS [435]. Although in a RCT the benefit of surgery with respect to death from PCa was largest in men < 65 years of age (RR: 0.45), RP was associated with a reduced risk of metastases and use of androgen deprivation therapy (ADT) also among older men (RR: 0.68 and 0.60, respectively) [436]. External beam RT shows similar cancer control regardless of age, assuming a dose of > 72 Gy when using intensity-modulated or image-guided RT [437].

Older men have a higher incidence of PCa and may be under-treated despite the high overall mortality rates [438, 439]. Of all PCa-related deaths 71% occur in men aged > 75 years [440], probably due to the higher incidence of advanced disease and death from PCa despite higher death rates from competing causes [441-443]. In the USA, only 41% of patients aged > 75 years with intermediate- and high-risk disease received curative treatment compared to 88% aged 65–74 [444].

6.1.2 ***Life expectancy***

Life expectancy tables for European men are available online: https://ec.europa.eu/eurostat/. Survival may be variable and therefore estimates of survival must be individualised. Gait speed is a good single predictive method of life expectancy (from a standing start, at usual pace, generally over 6 meters). For men at age 75, ten-year survival ranged from 19% < 0.4 m/s to 87%, for ≥ 1.4 m/s [445].

Figure 6.1: Predicted Median Life Expectancy by Age and Gait Speed for males* [445]

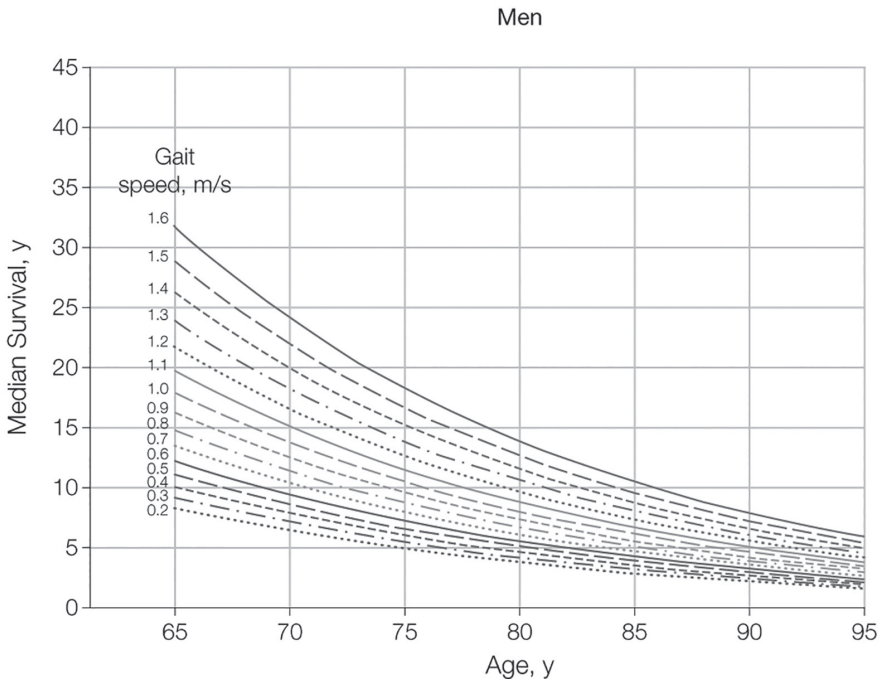

**Figure reproduced with permission of the publisher, from Studenski S, et al. JAMA 2011 305(1)50.*

*6.1.3 **Health status screening***

Heterogeneity in performance increases with advancing age, so it is important to use measures other than just age or performance status (PS) when considering treatment options. The International SIOG PCa Working Group recommends that treatment for adults over 70 years of age should be based on a systematic evaluation of health status using the G8 (Geriatric 8) screening tool (see Table 5.7) [136]. This tool helps to discriminate between those who are fit and those with frailty, a syndrome of reduced ability to respond to stressors. Patients with frailty have a higher risk of mortality and negative side effects of cancer treatment [446]. Healthy patients with a G8 score > 14 or vulnerable patients with reversible impairment after resolution of their geriatric problems should receive the same treatment as younger patients. Frail patients with irreversible impairment should receive adapted treatment. Patients who are too ill should receive only palliative treatment (see Figure 5.3) [136]. Patients with a G8 score ≤ 14 should undergo a comprehensive geriatric assessment (CGA) as this score is associated with three-year mortality. A CGA is a multi-domain assessment that includes co-morbidity, nutritional status, cognitive and physical function, and social supports to determine if impairments are reversible [447]. A SR of the effect of geriatric evaluation for older cancer patients showed improved treatment tolerance and completion [448].

The Clinical Frailty Scale (CFS) is another screening tool for frailty (see Figure 5.4) [449]. Although not frequently used in the cancer setting, it is considered to be a common language for expressing degree of frailty. The scale runs from one to nine, with higher scores indicating increasing frailty. Patients with a higher CFS score have a higher 30-day mortality after surgery and are less likely to be discharged home [450].

It is important to use a validated tool to identify frailty, such as the G8 or CFS, as clinical judgement has been shown to be poorly predictive of frailty in older patients with cancer [451].

6.1.3.1 Co-morbidity

Co-morbidity is a major predictor of non-cancer-specific death in localised PCa treated with RP and is more important than age [452, 453]. Ten years after watchful waiting for PCa, most men with a high co-morbidity score had died from competing causes, irrespective of age or tumour aggressiveness [452]. Measures for co-morbidity include: Cumulative Illness Score Rating-Geriatrics (CISR-G) [454, 455] (Table 5.8) and Charlson Co-morbidity Index (CCI) [456].

6.1.3.2 Nutritional status

Malnutrition can be estimated from body weight during the previous three months (good nutritional status < 5% weight loss; risk of malnutrition: 5–10% weight loss; severe malnutrition: > 10% weight loss) [457].

6.1.3.3 Cognitive function

Cognitive impairment can be screened for using the mini-COG (https://mini-cog.com/) which consists of three-word recall and a clock-drawing test and can be completed within five minutes. A score of ≤ 3/5 indicates the need to refer the patient for full cognitive assessment. Patients with any form of cognitive impairment (e.g., Alzheimer's or vascular dementia) may need a capacity assessment of their ability to make an informed decision, which is an increasingly important factor in health status assessment [458-460]. Cognitive impairment also predicts risk of delirium, which is important for patients undergoing surgery [461].

6.1.3.4 Physical function

Measures for overall physical functioning include: Karnofsky score and ECOG scores [462]. Measures for dependence in daily activities include Activities of Daily Living (ADL; basic activities) and Instrumental Activities of Daily Living (IADL; activities requiring higher cognition and judgement) [463-465].

6.1.3.5 Shared decision-making

The patient's own values and preferences should be considered as well as the above factors. A shared decision-making process also involves anticipated changes to QoL, functional ability, and a patient's hopes, worries and expectations about the future [466]. Particularly in older and frail patients, these aspects should be given equal importance to disease characteristics during the decision-making process [467]. Older patients may also wish to involve family members, and this is particularly important where cognitive impairment exists.

*6.1.4 **Conclusion***

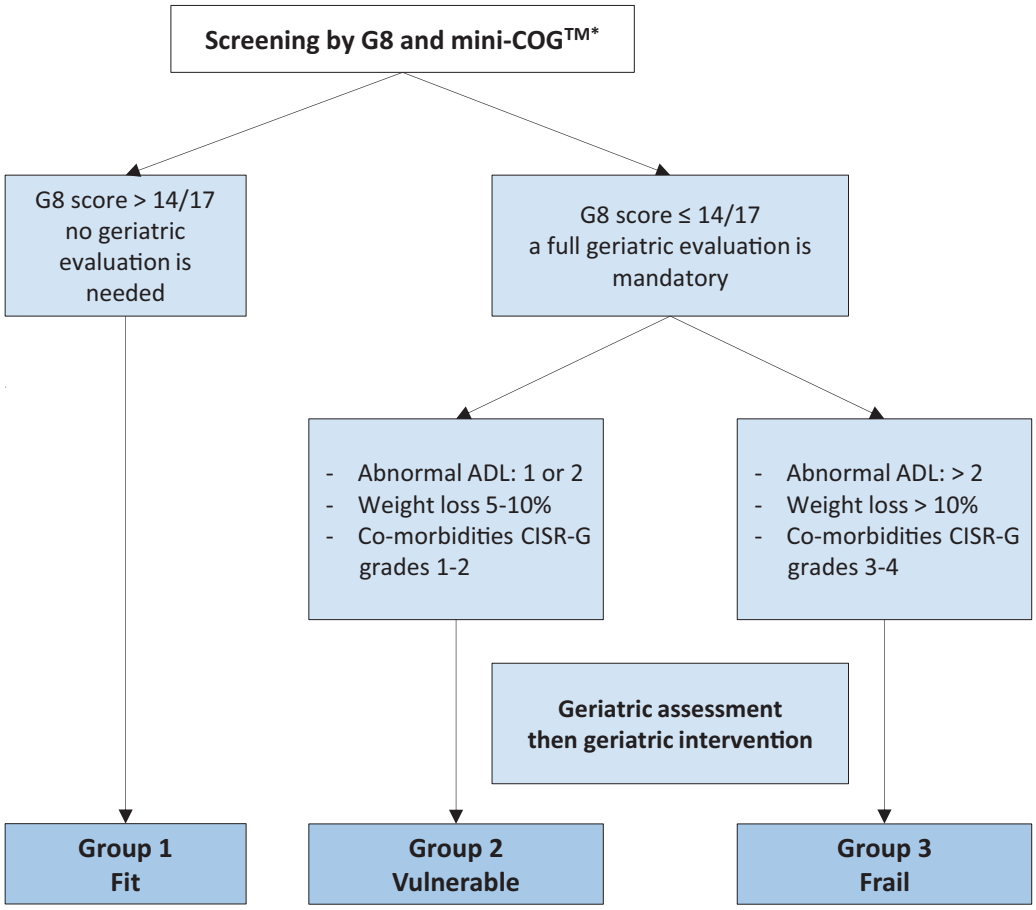
Individual life expectancy, health status, frailty, and co-morbidity, not only age, should be central in clinical decisions on screening, diagnostics, and treatment for PCa. A life expectancy of ten years is most commonly used as a threshold for benefit of local treatment. Older men may be under-treated. Patients aged 70 years of age or older who have frailty should receive a comprehensive geriatric assessment. Resolution of impairments in vulnerable men allows a similar urological approach as in fit patients.

Table 6.1: G8 screening tool (adapted from [468]**)**

	Items	**Possible responses (score)**
A	Has food intake declined over the past three months due to loss of appetite, digestive problems, chewing, or swallowing difficulties?	0 = severe decrease in food intake
		1 = moderate decrease in food intake
		2 = no decrease in food intake
B	Weight loss during the last three months?	0 = weight loss > 3 kg
		1 = does not know
		2 = weight loss between 1 and 3 kg
		3 = no weight loss
C	Mobility?	0 = bed or chair bound
		1 = able to get out of bed/chair but does not go out
		2 = goes out
D	Neuropsychological problems?	0 = severe dementia or depression
		1 = mild dementia
		2 = no psychological problems
E	BMI? (weight in kg)/(height in m^2)	0 = BMI < 19
		1 = BMI 19 to < 21
		2 = BMI 21 to < 23
		3 = BMI ≥ 23
F	Takes more than three prescription drugs per day?	0 = yes
		1 = no

G	In comparison with other people of the same age, how does the patient consider his/her health status?	0.0 = not as good
		0.5 = does not know
		1.0 = as good
		2.0 = better
H	Age	0 = ≥ 85
		1 = 80-85
		2 = < 80
	Total score	**0-7**

Figure 6.2: Decision tree for health status screening (men > 70 years)** [136]



Mini-COGTM = Mini-COGTM cognitive test; ADLs = activities of daily living; CIRS-G = Cumulative Illness Rating Score - Geriatrics; CGA = comprehensive geriatric assessment.
** For Mini-COGTM, a cut-off points of ≤ 3/5 indicates a need to refer the patient for full evaluation of potential dementia.*

Table 6.2: Cumulative Illness Score Rating-Geriatrics (CISR-G)

1	Cardiac (heart only)
2	Hypertension (rating is based on severity; affected systems are rated separately)
3	Vascular (blood, blood vessels and cells, marrow, spleen, lymphatics)
4	Respiratory (lungs, bronchi, trachea below the larynx)
5	ENT (eye, ear, nose, throat, larynx)
6	Upper GI (esophagus, stomach, duodenum. Biliar and parcreatic trees; do not include diabetes)
7	Lower GI (intestines, hernias)
8	Hepatic (liver only)
9	Renal (kidneys only)
10	Other GU (ureters, bladder, urethra, prostate, genitals)
11	Musculo-Skeletal-Integumentary (muscles, bone, skin)
12	Neurological (brain, spinal cord, nerves; do not include dementia)
13	Endocrine-Metabolic (includes diabetes, diffuse infections, infections, toxicity)
14	Psychiatric/Behavioural (includes dementia, depression, anxiety, agitation, psychosis)
	All body systems are scores on a 0 - 4 scale. - 0: No problem affecting that system. - 1: Current mild problem or past significant problem. - 2: Moderate disability or morbidity and/or requires first line therapy. - 3: Severe problem and/or constant and significant disability and/or hard to control chronic problems. - 4: Extremely severe problem and/or immediate treatment required and/or organ failure and/or severe functional impairment.
Total score 0-56	

6.1.5 *Guidelines for evaluating health status and life expectancy*

Recommendations	Strength rating
Use individual life expectancy, health status, and co-morbidity in PCa management.	Strong
Use the Geriatric-8, mini-COG and Clinical Frailty Scale tools for health status screening.	Strong
Perform a full specialist geriatric evaluation in patients with a G8 score ≤ 14.	Strong
Consider standard treatment in vulnerable patients with reversible impairments (after resolution of geriatric problems) similar to fit patients, if life expectancy is > ten years.	Weak
Offer adapted treatment or watchful waiting to patients with irreversible impairment.	Weak
Offer palliative symptom-directed therapy alone to frail patients.	Strong

6.2 Treatment modalities

6.2.1 *Deferred treatment (watchful waiting/active surveillance)*

As the prevalence of cancer cells in the prostate is so much higher than the risk of dying from PCa, together with the increased rate of early detection of small tumours after the introduction of PSA, there is a distinct risk of over-diagnosis and subsequent over-treatment of the disease (Chapter 3.1 Epidemiology) [8, 12, 469]. All available radical PCa treatment options may cause significant side effects so conservative treatment options are needed for patients with a low risk of PCa death or symptomatic progression from their PCa. Data from studies conducted on patients who did not undergo local treatment with up to 25 years of follow-up, with endpoints of OS and CSS, are available. Several series have shown a consistent CSS rate of 82–87% at ten years [470, 471], and 80–95% for T1/T2 and ISUP grade group ≤ 2 PCas [472]. In three studies with data beyond 15 years, the CSS was 80%, 79% and 58% respectively [470, 471, 473], and two reported 20-year CSS rates of 57% and 32% [470, 473]. The observed heterogeneity in outcomes is due to different inclusion criteria, with some older studies from the pre-PSA era showing worse outcomes [473]. In addition, many patients classified as ISUP grade group 1 would now be classified as ISUP grade group 2–3 based on the 2005 Gleason classification, suggesting that the above-mentioned results should be considered as minimal and current outcomes would be more favourable. Patients with well-, moderately- and poorly-differentiated tumours had 10-year CSS rates of 91%, 90% and 74%, respectively, correlating with data from a pooled analysis [472]. In screen-detected localised PCa there is also a lead-time bias, resulting in a higher rate of early detected PCa, but also an even higher risk of detecting clinically insignificant PCa that never would have caused any problems [469]. Cancer-specifc survival from untreated screen-detected PCa in patients with ISUP grade groups 1–2 is therefore likely to be even more favourable than for PCa detected of other reasons. Consequently, a high proportion of men with PSA-detected PCa are suitable for conservative management such as active surveillance (AS) or watchful waiting (WW). As the decision to choose WW is more independent from the tumour stage, and mainly dependent on patient factors/life expectancy, this approach may include patients of all ISUP grade groups (see Chapter 6.2.1.1).

The high CSS rates of localised PCa requires that a life expectancy of at least ten years should be considered mandatory for any benefit from active treatment. Co-morbidity is as important as age in predicting life expectancy in men with PCa. Increasing co-morbidity greatly increases the risk of dying from non-PCa-related causes. In an analysis of 19,639 patients aged > 65 years who were not given curative treatment, most men with a CCI score ≥ 2 had died from competing causes at ten years follow-up regardless of their age at time of diagnosis. Tumour aggressiveness had little impact on OS suggesting that patients could have been spared biopsy and diagnosis of cancer. Men with a CCI score ≤ 1 had a low risk of death at ten years, especially for well- or moderately-differentiated lesions [452]. Additionally, in the ProtecT trial (see 6.2.1.2), prostate cancer-related death was 3% at 15 years compared to death from any cause in 21.7% of patients, numbers that have been further validated in two large population-based studies from Canada and Sweden [474-476]. Estimation of competing benefits of active versus conservative treatment and death from any cause at ten and 15 years can be estimated using the PREDICT Prostate tool (available from https://prostate.predict.nhs.uk/), which was developed using registry data from the UK with external validation and is endorsed by the National Institute for Health and Care Excellence in the UK [477]. This highlights the importance of assessing co-morbidity even before considering a biopsy, but also before advising a patient with a PCa diagnosis on the optimal treatment for him.

There are two distinct strategies for conservative management that aim to reduce over-treatment: AS and WW (Table 6.2.1).

Table 6.2.1: Definitions of active surveillance and watchful waiting [478]

	Active surveillance	Watchful waiting
Treatment intent	Curative	Palliative
Follow-up	Pre-defined schedule	Patient-specific
Assessment/markers* used	DRE, PSA, MRI at recruitment, re-biopsy	Annual (biannual) PSA and DRE if significant PSA-rise
Life expectancy	> ten years	< ten years
Aim	Minimise treatment-related toxicity without compromising survival, as the PCa is so indolent that it is unlikely to cause symptoms even with long life expectancy	Minimise treatment-related toxicity without compromising survival, as the lifespan is so limited that PCa is unlikely to cause symptoms
Eligible patients	Low- and selected intermediate-risk patients	Can apply to patients with all stages

DRE = digital rectal examination; PSA = prostate-specific antigen; MRI = magnetic resonance imaging.

**Molecular markers and/or PSMA-PET/CT (-MRI) may be used.*

6.2.1.1 Watchful Waiting

Watchful waiting refers to conservative management for patients deemed unsuitable for curative treatment from the outset. The aim of WW is to balance the potential harms and benefits of early hormonal treatment, and patients are clinically 'watched' for the development of local or systemic progression with (imminent) disease-related complaints, at which stage they are then treated palliatively according to their symptoms in order to maintain QoL. Traditionally WW has meant waiting for symptoms of the tumour to develop and has, in some practices, not included regular follow-up in any active way. However, today we have evidence that early hormonal treatment could prolong short term survival (within a few years) for locally advanced disease, for patients with a PSAdt < twelve months, and for PSA-values over 30-50 ng/ml [479, 480]. A more active follow-up of men on WW could therefore be beneficial, so that a local progression (often associated with a higher ISUP grade group), or start of metastatic spread, can be detected before they present with significant symptoms. Hormonal treatment could then be considered before symptoms emerge. The WW strategy should therefore be individualised and planned together with the patient. Biannual PSA, or annual after a period of stable disease, followed by DRE if PSA rises significantly, could then be of value, especially for men with a life expectancy > five years but unsuitable for curative treatment. There are two RCTs and one Cochrane review comparing the outcomes of WW to RP. The SPCG-4 study was a RCT from the pre-PSA era, randomising patients to either WW or RP [481]. The study found RP to provide superior CSS, OS and progression-free survival (PFS) compared to WW at a median follow-up of 23.6 years (range 3 weeks–28 years). However, the benefit in favour of RP over WW was only apparent after ten years. The PIVOT trial, a RCT conducted in the early PSA era, made a similar comparison between RP vs. WW in 731 men (50% with nonpalpable disease) but in contrast to the SPCG-4, it found little, to no, benefit of RP (cumulative incidence of all-cause death, RP vs. observation: 68% vs. 73%; RR: 0.92, 95% CI: 0.84–1.01) within a median follow-up period of 18.6 years (interquartile range, 16.6 to 20 years) [482]. Exploratory subgroup analysis showed that the borderline benefit from RP was most marked for intermediate-risk disease (RR: 0.84, 95% CI: 0.73–0.98) but there was no benefit in patients with low- or high-risk disease. Overall, no adverse effects on health related QoL (HRQoL) and psychological well-being was apparent in the first five years [483]. However, one of the criticisms of the PIVOT trial is the relatively high overall mortality rate in the WW group compared with more contemporary series. A Cochrane review performed a pooled analysis of RCTs comparing RP vs. WW [484]. Three studies were included; the previously mentioned SPCG-4 [481] and PIVOT [482] and the Veteran's Administration Cooperative Urological Research Group (VACURG) study which was conducted in the pre-PSA era [485]. The authors found that RP compared with WW reduced time to death by any cause (HR: 0.79, 95% CI: 0.70–0.90), time to death by PCa (HR: 0.57, 95% CI: 0.44–0.73) and time to metastatic progression (HR: 0.56, 95% CI: 0.46–0.70) at 29 years' follow-up. However, RP was associated with higher rates of urinary incontinence (RR: 3.97, 95% CI: 2.34–6.74) and ED (RR: 2.67, 95% CI: 1.63–4.38).

The overall evidence indicates that for men with asymptomatic, clinically localised PCa, and with a life expectancy of < ten years based on comorbidities and/or age, the oncological advantages of active treatment over WW are unlikely to be relevant to them. Consequently, WW should be adopted for such patients. For assistance in estimating life expectancy and health status see Section 5.4.

6.2.1.2 Active surveillance

Active surveillance aims to delay or completely avoid unnecessary treatment, and consequently unnecessary side effects, in men with clinically localised PCa, and a life expectancy of ten years or more, who do not require immediate treatment, but at the same time achieve the correct timing for curative treatment in those who eventually do [486]. Patients remain under close surveillance through structured surveillance programmes with regular follow-up consisting of PSA testing, clinical examination, MRI imaging and repeat prostate biopsies, with curative treatment being prompted by pre-defined thresholds indicative of development to potentially significant disease, which is still curable, while considering individual life expectancy.

No formal RCT is available comparing AS to curative treatment. Several cohorts have investigated AS in organ-confined disease, the findings of which were summarised in a SR [487]. A largest prospective series of men with low-risk PCa managed by AS was published [488]. Table 6.1.2 summarises the results of selective AS cohorts. It is clear that the long-term OS and CSS of patients on AS are extremely good. However, more than one-third of patients are 'reclassified' during follow-up, most of whom undergo curative treatment due to disease upgrading, increase in disease extent, disease stage, progression, or patient preference. There is considerable variation and heterogeneity between studies regarding patient selection and eligibility, follow-up policies (including frequency and type of imaging such as MRI imaging, type and frequency of repeat prostate biopsies, such as MRI-targeted biopsies or transperineal template biopsies, use of PSA kinetics and density, and frequency of clinical follow-up), when active treatment should be instigated (i.e., reclassification criteria) and which outcome measures should be prioritised [486]. For specific guidelines on inclusion criteria and follow-up strategies for AS, see Sections 6.2.1.2.

In the ProtecT RCT, 1,643 patients were randomised into one of three arms: active treatment with either RP or EBRT or AM with outcomes reported at ten years and 15 years [474, 489]. Even though the ProtecT trial is a RCT it is not, strictly speaking, a study comparing AS to active treatment as it does not include a formal AS strategy as described above and in Sections 6.2.1.2. Active monitoring (AM), as used in the study, was a significantly less stringent surveillance strategy in terms of clinical follow-up, using PSA only, with relaxed criteria to define progression. No imaging and repeat biopsies were performed as in AS. At enrolment fifty-six percent of the patients had low-risk disease, with 90% having a PSA < 10 ng/mL, 77% ISUP grade group 1 (20% ISUP grade group 2–3), and 76% had T1c disease. The remaining patients had mainly intermediate-risk disease. The key finding was that AM was as effective as active treatment at 15 years (CSS = 96.9% in the AM-group vs. 97.8% in the RP-group and 97.1% in the EBRT-group, p=0.53), but at a cost of increased metastatic progression risk (9.4% vs. 4.7% and 5.0% respectively), as well as clinical progression at 15 years (25.9% for AM vs. 10.7% for RP/RT). Death from any cause occurred in 21.7% of the cohort, with similar numbers across treatment groups. Metastases, although rare, were more frequent than seen with comparable AS protocols [487]. A comprehensive characterisation of the ProtecT study cohort was performed after ten years, stratifying patients at baseline according to risk of progression using clinical stage, grade at diagnosis and PSA level [490]. Additionally, detailed clinico-pathological information on participants who received RP were analysed. The 15-year paper reported updated contemporary risk-stratification according to D'Amico (24.1% Intermediate risk, 9.6% high risk), CAPRA (26.4% Score 3-5, 2.5% Score 6-10) and Cambridge Prognostic Group (20.5% Group 2, 8.8% Groups 3-5). Among patients who underwent prostatectomy, 50.5% were ISUP grade group ≥2, while 28.5% had an increase in pathological stage and 32% had an increase in tumour grade. Additionally, 51% of patients who developed metastases displayed ISUP grade group 1 and 47.6% were low CAPRA risk. Over time, 61.1% of patients in the AM group received radical treatment (from 54.8% at ten years). From the ten year report the authors aimed identify prognostic markers. The results showed that treatment received, age (65–69 vs. 50–64 years), PSA, ISUP grade group at diagnosis, cT stage, risk group, number of PCa-involved biopsy cores, maximum length of tumour (median 5.0 vs. 3.0 mm), aggregate length of tumour (median 8.0 vs. 4.0 mm), and presence of perineural invasion were each associated with increased risk of disease progression (p < 0.001 for each). However, these factors could not reliably predict progression in individuals. Notably, 53% (n = 105) of patients who progressed had biopsy ISUP grade group 1 disease, although, conversely, none of the participants who received RP and subsequently progressed had pathological ISUP grade group 1 tumours. This discrepancy in progression and metastases rate between the AM arm of the ProtecT study and comparable AS protocols can, most likely, be explained by inadequate sampling by PSA testing and 10-core TRUS-guided biopsies and differences in intensity of surveillance.

It is important to note that the AM arm in ProtecT represented an intermediate approach between contemporary AS protocols and WW in terms of a monitoring strategy based almost entirely on PSA measurements alone; there was no use of MRI scan, either at recruitment or during the monitoring period, nor were there any protocol-mandated repeat prostate biopsies at regular intervals. In addition, approximately 40% of randomised patients had intermediate-risk disease (both ISUP grade group 2 and 3). Nevertheless, the ProtecT study has reinforced

the role of deferred active treatment (i.e., either AS or some form of initial AM) as a feasible alternative to active curative interventions in all patients with low-grade and low-stage disease, as well as for many patients with favourable intermediate risk disease. Beyond 15 years, no RCT-data are available, as yet, although AS is likely to give more reassurance especially in younger men, based on more accurate risk stratification at recruitment and more stringent criteria regarding follow-up, imaging, repeat biopsy and reclassification. Individual life expectancy must continuously be evaluated before considering any active treatment in low-risk patients and in those with up to ten to 15 years' individual life expectancy [490].

6.2.1.2.1 Active surveillance - inclusion criteria

Guidance regarding selection criteria for AS is limited by the lack of data from prospective RCTs. As a consequence, the Panel undertook an international collaborative study involving healthcare practitioners and patients to develop consensus statements for deferred treatment with curative intent for localised PCa, covering all domains of AS (DETECTIVE Study) [330], as well as a formal SR on the various AS protocols [491]. The criteria most often published include: ISUP grade group 1, clinical stage cT1c or cT2a, PSA < 10 ng/mL and PSA-D < 0.15 ng/mL/cc, as based on systematic biopsy schemes [487, 492]. The latter threshold remains controversial [492, 493]. These criteria were supported by the DETECTIVE study consensus. There was no agreement on the maximum number of systematic cores that can be involved with cancer or the maximum percentage core involvement (CI), although there was recognition that extensive disease on MRI should exclude men from AS, even though there is no firm definition on this, especially when targeted biopsies confirm ISUP grade group 1 [330]. The Movember consensus group, consisting of 27 healthcare professional and 12 lived experience participants from across the world, agreed that ISUP grade group and MRI were the most important criteria for determining eligibility to AS [494]. A SR and meta-analysis found three clinico-pathological variables which were significantly associated with reclassification, high PSA-D, > 2 positive cores (on systematic biopsies) and African-American descent [495]. A review on the risk of progression for African-American men on AS also indicated a potential increased risk of progression, but the association was not strong enough to discourage African-American men from undergoing AS, but thorough confirmatory testing is important [496]. In addition, a previous pathology consensus group suggested excluding men from AS when any of the following features were present: predominant ductal carcinoma (including pure IDC), cribriform histology, sarcomatoid carcinoma, small cell carcinoma, EPE or LVI in needle biopsy [497] and perineural invasion [498].

A multi-disciplinary consensus conference on germline testing has suggested a genetic implementation framework for the management of PCa [154]. Based on consensus, *BRCA2*-gene testing was recommended for AS discussions and could be performed in men with family history of prostate, breast or ovarian cancers. However, the nature of such discussions and how a positive result influences management were beyond the scope of the project. Currently, *BRCA2* mutation does not exclude a patient from AS if tumour factors are otherwise favourable. Furthermore, if included in AS programmes, patients with a known *BRCA2* mutation should be cautiously monitored until such time that more robust data are available.

6.2.1.2.2 Tissue-based prognostic biomarker testing for selection for AS

Biomarkers, including Oncotype Dx®, Prolaris®, Decipher®, PORTOS and ProMark® are promising (see Section 5.2.8.3). However, further data will be needed before such markers can be used in standard clinical practice [220].

6.2.1.2.3 Magnetic resonance imaging for selection for active surveillance

In men eligible for AS based upon systematic biopsy findings alone who did not have a pre-biopsy MRI, a re-biopsy within six to twelve months months (usually referred to as 'confirmatory biopsy') seems mandatory to exclude sampling error. A large body of literature including two RCTs and a SR, showed that adding MRI-targeted biopsy to systematic sampling at confirmatory biopsy improved detection of ISUP grade group ≥ 2 cancers and thus, patient selection for AS [121, 499-504]. Adding MRI-targeted biopsy to systematic sampling at confirmatory biopsy improved upgrade detection by increments of 0-7.9 per 100 men depending on the series [499]. In a meta-analysis of 6 studies, the rate of upgrading to ISUP grade group ≥ 2 cancer increased from 20% (95% CI: 16–25%) to 27% (95% CI: 22–34%) when MRI-targeted biopsy was added to systematic biopsy [504]. The Active Surveillance MRI Study (ASIST) randomised men on AS scheduled for confirmatory biopsy to either 12-core systematic biopsy or to MRI with targeted biopsy (when indicated), combined with systematic biopsy (up to 12 cores in total). After two years of follow-up, use of MRI before confirmatory biopsy resulted in fewer failures of surveillance (19% vs. 35%, p = 0.017) and in fewer patients progressing to ISUP grade group ≥ 2 cancer (9.9% vs. 23%, p = 0.048) [502]. However, systematic biopsy retains its additional value, which argues for a combined biopsy approach [499, 504]. The DETECTIVE study agreed that men eligible for AS after combined systematic- and MRI-targeted biopsy do not require a confirmatory biopsy, a recommendation further supported by the results of the MRIAS trial [330, 505].

If the PCa diagnosis is made on MRI-targeted biopsy alone in order to lower the risk of over-detection of insignificant (see 5.4.1 and 5.4.2.), a confirmative systematic biopsy should be performed before definite decision of AS to rule out more widespread cancer growth in the prostate [186, 189, 190].

A few studies indicate that PSMA-PET-CT or PSMA-PET-MRI may have additional value to above mentioned clinico-pathological variables for risk stratification before AS [122, 506]. However, so far, the studies are too small and the follow-up too short to draw any hard conclusions and for this modality to be recommended outside clinical trials.

6.2.1.2.4 Active surveillance management

Based on the DETECTIVE consensus study, the surveillance strategy should be based on serial DRE (at least once yearly), PSA (at least once, every six months) and repeated biopsy. It was also agreed that PSA progression or change in PSA kinetics alone should lead to reclassification only if accompanied by changes in histology on repeat biopsy [330]. The Movember consensus group stated that patients suitable for AS who suffer, or are at risk of, significant psychological distress should be offered more support, rather than active treatment. Furthermore, they made a number of recommendations that in some ways differ from the DETECTIVE consensus study, e.g. that routine DRE was not supported if MRI or other imaging was carried out routinely during AS, that if MRI and other parameters (PSA kinetics and density) are stable routine biopsy may be omitted and that change in clinical parameters should prompt MRI with possible biopsy rather than immediate biopsy [494]. The somewhat contradicting recommendations, made by these two different international consensus groups so close in time, clearly illustrate the lack of high-level evidence on how the strategy of AS should be planned and the urgent need of prospective randomised trials.

In 2016, the Prostate Cancer Radiological Estimation of Change in Sequential Evaluation (PRECISE) criteria were established to standardise the assessment of tumour progression on serial MRI [507]. Progression on MRI, or not, as defined by PRECISE criteria, is a strong predictor of histological upgrading [508, 509]. Two independent meta-analyses assessed the value of MRI progression criteria for predicting histological progression (mostly defined as progression to ISUP grade group ≥ 2). The pooled histological progression rate was 27% in both reviews. If biopsies were triggered only by MRI progression findings, approximately two thirds of the biopsies would be avoided, at the cost of missing 40% of men with histological progression. In addition, at least half of biopsied men would have had negative findings for histological progression and thus would have undergone unnecessary biopsies. If histological progression was restricted to progression to ISUP grade group > 3, approximately 30% of histological progression would be missed and approximately 80% of the biopsies performed would be unnecessary. The use of the PRECISE criteria did not seem to change these results [510, 511]. This supports maintaining protocol-mandated repeat biopsies during the course of AS.

Thus, the basis for AS protocols includes standard repeat biopsy. However, several factors have been found to be associated with low re-classification rates and long PFS: negative baseline or repeat MRI during AS [505, 512-518], low PSA-D [505, 513, 515, 518], low PSA velocity (PSAV) [519, 520] or negative biopsy (i.e., no cancer at all) at confirmatory or repeat biopsy during AS [521]. Patients with stable (PRECISE 3) on repeat MRI during AS and a low PSA-D (<0.15) have a very low rate of progression and repeat biopsy may therefore be omitted [522].

A Panel SR incorporating 263 surveillance protocols showed that 78.7% of protocols mandated per-protocol confirmatory biopsies within the first two years and that 57.7% of the protocols performed repeat biopsy at least every three years for ten years after the start of AS [491]. In another review it was concluded that a negative repeat biopsy during AS was associated with a 50% decrease in the risk of future reclassification and upgrading [523]. In a single-centre AS cohort of 514 patients who underwent at least three protocol-mandated biopsies after diagnosis (the confirmatory biopsy and at least two additional surveillance biopsies), men with one negative biopsy (i.e., no cancer at all) at confirmatory or second biopsy, or men with two consecutive negative biopsies had a lower likelihood of a positive third biopsy and significantly better 10-year treatment free survival [521]. This suggests that men with repetitive negative biopsies may pursue AS with at least less frequent untriggered biopsies.

6.2.1.2.5 Active Surveillance - change in treatment

Men may remain on AS whilst they continue to consent, have a life expectancy of > ten years and the disease remains indolent. Patient anxiety about continued surveillance occurs in around 10% of patients on AS [524] and was recognised as a valid reason for active treatment [329]. An alternative for patients suitable for continuing AS would be to offer psychological support to reduce the level of anxiety [494]. A review on patient reported factor influencing the decision making, including thirteen qualitative papers and 426 men, identified a number of factors influencing the decision making when considering AS. Among the identified factors were personal

risk assessment, influence of family and friends, beliefs about treatment as well as doctor and system factors, underscoring the importance of individualised, relevant, and clear information to support decision making [525]. A recent population-based cohort study from Sweden on regional differences in AS uptake and subsequent transition to radical treatment concluded that a regional tradition of a high uptake of AS was associated with a lower probability of transition to radical treatment, but not with AS failure [526]. These studies further emphasise the importance of thorough information and discussion with the patients on pros/cons of AS vs. active treatment already at the time of diagnosis for the patients to feel secure in their treatment choice and to avoid over-treatment.

A PSA change alone, including PSA-doubling time (PSA-DT, < 3 years) should not change management based on its weak link with grade progression [527, 528] but rather trigger further investigation. There was clear agreement in the DETECTIVE consensus meeting as well as in the Movember consensus group that a change in PSA should lead to repeat-MRI and repeat-biopsy. It was also agreed that changes on repeat MRI during AS needed a confirmatory biopsy before considering active treatment [330, 494].

The histopathology criteria required to trigger a change in management in the targeted biopsy era remain debated. MRI-targeted biopsy induces a grade shift and ISUP grade group 2–3 cancers detected by MRI-targeted biopsy have, on average, a better prognosis than those detected by systematic sampling (see Section 5.2.4.2.6.4). As an increasing number of men with favourable intermediate-risk disease are managed with AS (see section 6.2.2.1), it seems illogical to use progression to ISUP grade group 2 based on targeted biopsies as the sole criterion for reclassification. In addition, as acknowledged in the DETECTIVE consensus meeting, the number of positive cores is not an indicator of tumour volume anymore if targeted biopsies are performed [330, 529]. No agreement could be reached on the pathological criteria required to trigger a change in management during the DETECTIVE consensus meeting [330]. However, based on the findings of a SR incorporating 271 reclassification protocols, patients with low-volume ISUP grade group 2 disease at recruitment, and with increased systematic core positivity (> 3 cores involvement [> 50% per core]) on repeat systematic biopsies not using MRI, should be reclassified [491]. Furthermore, in a study from the MUSIC registry over half of men with favourable intermediate-risk prostate cancer on AS remained free of treatment five years after diagnosis [530]. Their results are in concordance with the DETECTIVE and the Movember consensus statements and indicate that most men on AS will not lose their window of cure and have similar short-term oncologic outcomes as men undergoing up-front treatment and that AS is an oncologically safe option for appropriately selected men with favourable intermediate-risk prostate cancer.

The development of other comorbidities, resulting in a life expectancy of less than ten years should merit a new discussion with the patient and may result in a decision to transfer to a WW strategy.

Table 6.2.2: Active surveillance in screening-detected prostate cancer (large cohorts with longer-term follow-up)

Studies	N	Median FU (mo)	pT3 in RP patients*	10-year OS (%)	10-year CSS (%)
Adamy, *et al.* 2011 [489]	533-1,000	48	4/24 (17%)	90	99
Godtman, *et al.* 2013 [492]	439	72	-	81	99.5

** Patients receiving active therapy following initial active surveillance.*
CSS = cancer-specific survival; FU = follow-up; mo = months; n = number of patients; n.r. = not reported; OS = overall survival; RP = radical prostatectomy.

*6.2.2 **Radical prostatectomy***

6.2.2.1 Introduction

The goal of RP by any approach is the eradication of cancer while, whenever possible, preserving pelvic organ function [531]. The procedure involves removing the entire prostate with its capsule intact and SVs, followed by vesico-urethral anastomosis. Surgical approaches have expanded from perineal and retropubic open approaches to laparoscopic and robotic-assisted techniques; anastomoses have evolved from Vest approximation sutures to continuous suture watertight anastomoses under direct vision and mapping of the anatomy of the dorsal venous complex (DVC) and cavernous nerves has led to excellent visualisation and

potential for preservation of erectile function [532]. The main results from multi-centre RCTs involving RP are summarised in Table 6.1.3.

Table 6.2.3: Oncological results of radical prostatectomy in organ-confined disease in RCTs

Study	Acronym	Population	Treatment period	Median FU (mo)	Risk category	CSS (%)
Bill-Axelson, *et al.* 2018 [481]	SPCG-4	Pre-PSA era	1989-1999	283	Low risk and intermediate risk	80.4 (at 23 yr.)
Wilt, *et al.* 2017 [482]	PIVOT	Early years of PSA testing	1994-2002	152	Low risk and intermediate risk	95.9 91.5 (at 19.5 yr.)
Hamdy, *et al.* 2023 [474]	ProtecT	Screened population	1999-2009	180	Mainly low- and intermediate risk	97 (at 15 yr.)

CSS = cancer-specific survival; FU = follow-up; mo = months; PSA = prostate-specific antigen; yr. = year.

6.2.2.2 Pre-operative preparation

6.2.2.2.1 Pre-operative patient education

As before any surgery appropriate education and patient consent is mandatory prior to RP. Peri-operative education has been shown to improve long-term patient satisfaction following RP [533]. Augmentation of standard verbal and written educational materials such as use of interactive multimedia tools [534, 535] and pre-operative patient-specific 3D printed prostate models has been shown to improve patient understanding and satisfaction and should be considered to optimise patient-centred care [536].

6.2.2.3 Surgical techniques

6.2.2.3.1 Pelvic lymph node dissection

A SR has demonstrated that performing PLND during RP failed to improve oncological outcomes, including survival [536]. Moreover, two RCTs have failed to show a benefit of an extended approach vs. a limited PLND on early oncologic outcomes [537, 538].

Extended PLND includes removal of the nodes overlying the external iliac artery and vein, the nodes within the obturator fossa located cranially and caudally to the obturator nerve, and the nodes medial and lateral to the internal iliac artery. With this template, the majority of patients are correctly staged [539] and as such, ePLND provides accurate information for staging and prognosis [540].

6.2.2.3.2 Lymph-node-positive patients during radical prostatectomy

Although no RCTs are available, data from prospective cohort studies comparing survival of pN+ patients (as defined following pathological examination after RP) support that RP may have a survival benefit over abandonment of RP in node-positive cases [541]. As a consequence, there is no role for performing frozen section of suspicious LNs.

6.2.2.3.3 Sentinel node biopsy analysis

The rationale for a sentinel node biopsy (SNB) is based on the concept that a sentinel node is the first to be involved by migrating tumour cells. Therefore, when this node is negative it is possible to avoid an ePLND [542]. Intraprostatic injections of indocyanine green (ICG) have been used to visualise prostate-related LNs for SNB. In a randomised comparison, Harke *et al.*, found more cancer-containing LNs in men who underwent a PLND guided by ICG but no difference in BCR at 22.9-month follow-up [543]. A SR of 21 studies showed a sensitivity of 95.2% and NPV of 98.0% for SNB in detecting men with metastases at ePLND [544]. However, this review was hampered by widespread heterogeneity of both definitions and how SNB is performed. This prompted the development of an expert consensus report to guide further research [542].

The prospective SENTINELLE study investigated the diagnostic accuracy of sentinel lymph node biopsy-guided lymph node dissection compared to extended pelvic LN dissection in patients with intermediate- or high-risk prostate cancer. Sensitivity, specificity, NPV, and positive predictive value of SNB method in detecting patients with at least one LN metastasis were 95.4% (95% CI, 75.1-99.7), 100% (95% CI, 96.6-100), 99.2% (95% CI, 95.5-99.9), and 100% (95% CI, 80.7-100), respectively [545].

6.2.2.3.4 Prostatic anterior fat pad dissection and histologic analysis

Several multi-centre and large single-centre series have shown the presence of lymphoid tissue within the fat pad anterior to the endopelvic fascia; the prostatic anterior fat pad (PAFP) [546-552]. This lymphoid tissue is present in 5.5–10.6% of cases and contains metastatic PCa in up to 1.3% of intermediate- and high-risk patients.

When positive, the PAFP is often the only site of LN metastasis. The PAFP is therefore a rare but recognised route of spread of disease. The PAFP is always removed at RP for exposure of the endopelvic fascia and should be sent for histologic analysis as per all removed tissue.

6.2.2.3.5 Management of the dorsal venous complex

Since the description of the anatomical open RP by Walsh and Donker in the 1980s, various methods of controlling bleeding from the DVC have been proposed to optimise visualisation [553]. In the open setting, blood loss and transfusion rates have been found to be significantly reduced when ligating the DVC prior to transection [554]. However, concerns have been raised regarding the effect of prior DVC ligation on apical margin positivity and continence recovery due to the proximity of the DVC to both the prostatic apex and the urethral sphincter muscle fibres. In the robotic-assisted laparoscopic technique, due to the increased pressure of pneumoperitoneum, whether prior DVC ligation was used or not, blood loss was not found to be significantly different in one study [555]. In another study, mean blood loss was significantly less with prior DVC ligation (184 vs. 176 mL, $p = 0.033$), however it is debatable whether this was clinically significant [556]. The positive apical margin rate was not different, however, the latter study showed earlier return to full continence at five months post-operatively in the no prior DVC ligation group (61% vs. 40%, $p < 0.01$).

Ligation of the DVC can be performed with standard suture or using a vascular stapler. One study found significantly reduced blood loss (494 mL vs. 288 mL) and improved apical margin status (13% vs. 2%) when using the stapler [557].

Given the relatively small differences in outcomes, the surgeon's choice to ligate prior to transection or not, or whether to use sutures or a stapler, will depend on their familiarity with the technique and the equipment available.

6.2.2.3.6 Nerve-sparing surgery

During prostatectomy, preservation of the neurovascular bundles (NVB) with parasympathetic nerve branches of the pelvic plexus can spare erectile function [558, 559].

Extra-, inter-, and intra-fascial dissection planes can be planned, with those closer to the prostate and performed bilaterally associated with superior (early) functional outcomes [560-563]. Furthermore, many different techniques are propagated such as retrograde approach after anterior release (vs. antegrade), and athermal and traction-free handling of bundles [564-566]. Nerve-sparing (NS) surgery may be performed using clips or low bipolar energy without clear benefit favouring one technique over another regarding functional outcomes [567].

A 2021 large retrospective study of high-risk patients also found that NS did not affect BCR, risk of metastasis or of death [568]. Notably, clinical and pathological stage T3 and ISUP grade group 5 did not impact these oncological outcomes. However, as a retrospective study, it was subject to selection bias, whereby patients with unfavourable characteristics were more likely to have undergone non-nerve-sparing surgery.

A 2021 SR of 19 studies analysing the parameters used for selection of NS found that individual clinical and radiological factors were poor at predicting EPE, and consequently, the appropriateness of NS. However, nomograms that incorporated mpMRI performed better. As with all nomograms, the question remains as to where to set the cut-off point [569].

A 2022 SR of 18 comparative studies (no RCTs) of NS vs. non-nerve-sparing RP showed a RR of side-specific positive margins of 1.5, but none of them included patients with high-risk PCa [570]. There was no effect seen of NS on BCR. However, follow-up was short, and studies were subject to selection bias with mainly low-risk patients. For those patients with high-risk PCa, side-specific NS was avoided if disease was palpable or EPE was present on MRI. Indeed, a 2019 SR showed that MRI affected the decision to perform NS or not in 35% of cases without any negative impact on surgical margin rate [571] (See Section 5.3.2).

Although age and pre-operative function may remain the most important predictors for post-operative erectile function, NS has also been associated with improved continence outcomes and may therefore still be relevant for men with poor erectile function [572, 573]. The association with continence may be mainly due to the dissection technique used during NS surgery, and not due to the preservation of the NVB themselves [572].

In summary, the quality of data is not adequate to permit a strong recommendation in favour of NS or non-nerve-sparing, but pre-operative risk factors for side-specific EPE such as PSA, PSA density, clinical stage, ISUP grade group, and PIRADS score, EPE and capsule contact length on MRI, should be taken into account.

6.2.2.3.7 Removal of seminal vesicles

The more aggressive forms of PCa may spread directly into the SVs. For oncological clearance, the SVs have traditionally been removed intact with the prostate specimen [574]. However, in some patients the tips of the SVs can be challenging to dissect free. Furthermore, the cavernous nerves run past the SV tips such that indiscriminate dissection of the SV tips could potentially lead to ED [575]. However, a RCT comparing nerve-sparing RP with and without a SV-sparing approach found no difference in margin status, PSA recurrence, continence or erectile function outcomes. Whilst complete SV removal should be the default, preservation of the SV tips may be considered in cases of low risk of involvement.

6.2.2.3.8 Techniques of vesico-urethral anastomosis

Following prostate removal, the bladder neck is anastomosed to the membranous urethra. The objective is to create a precisely aligned, watertight, tension-free, and stricture-free anastomosis that preserves the integrity of the intrinsic sphincter mechanism. Several methods have been described, based on the direct or indirect approach, the type of suture (i.e. barbed vs. non-barbed/monofilament), and variation in suturing technique (e.g., continuous vs. interrupted, or single-needle vs. double-needle running suture). The direct vesico-urethral anastomosis, which involves the construction of a primary end-to-end inter-mucosal anastomosis of the bladder neck to the membranous urethra by using 6 interrupted sutures placed circumferentially, has become the standard method of reconstruction for open RP [576].

The development of laparoscopic- and robotic-assisted techniques to perform RP have facilitated the introduction of new suturing techniques for the anastomosis. A SR and meta-analysis compared unidirectional barbed suture vs. conventional non-barbed suture for vesico-urethral anastomosis during robotic-assisted laparoscopic prostatectomy (RALP) [577]. The review included 3 RCTs and found significantly reduced anastomosis time, operative time and posterior reconstruction time in favour of the unidirectional barbed suture technique, but there were no differences in post-operative leak rate, length of catheterisation and continence rate. However, no definitive conclusions could be drawn due to the relatively low quality of the data. In regard to suturing technique, a SR and meta-analysis compared continuous vs. interrupted suturing for vesico-urethral anastomosis during RP [578]. The study included only one RCT with 60 patients [579]. Although the review found slight advantages for continuous suturing over interrupted suturing in terms of catheterisation time, anastomosis time and rate of extravasation, the overall quality of evidence was low and no clear recommendations were possible. A RCT [580] compared the technique of suturing using a single absorbable running suture vs. a double-needle single-knot running suture (i.e. Van Velthoven technique) in laparoscopic RP [581]. The study found slightly reduced anastomosis time with the single running suture technique, but anastomotic leak, stricture, and continence rates were similar.

Overall, although there are a variety of approaches, methods, and techniques for performing the vesico-urethral anastomosis, no clear recommendations are possible due to the lack of high-certainty evidence. In practice, the chosen method should be based on surgeon experience and individual preference [576-581].

6.2.2.3.9 Bladder neck management

Bladder neck mucosal eversion

Some surgeons perform mucosal eversion of the bladder neck as its own step in open RP with the aim of securing a mucosa-to-mucosa vesico-urethral anastomosis and avoiding anastomotic stricture. Whilst bringing bladder and urethral mucosa together by the everted bladder mucosa covering the bladder muscle layer, this step may actually delay healing of the muscle layers. An alternative is to simply ensure bladder mucosa is included in the full thickness anastomotic sutures. A non-randomised study of 211 patients with and without bladder neck mucosal eversion showed no significant difference in anastomotic stricture rate [582]. The strongest predictor of anastomotic stricture in RP is current cigarette smoking [583], but it is also 2.2 higher in open RP than RARP [584].

Bladder neck preservation

Whilst the majority of urinary continence is maintained by the external urethral sphincter at the membranous urethra (see below), a minor component is contributed by the internal lissosphincter at the bladder neck [585]. Preservation of the bladder neck has therefore been proposed to improve continence recovery post-RP. A RCT assessing continence recovery at twelve months and four years showed improved objective and subjective urinary continence in both the short- and long term without any adverse effect on oncological outcome [586].

These findings were confirmed by a SR [587]. However, concern remains regarding margin status for cancers located at the prostate base.

A SR addressing site-specific margin status found a mean base-specific positive margin rate of 4.9% with bladder neck preservation vs. only 1.9% without [585]. This study was inconclusive, but it would be sensible to exercise caution when considering bladder neck preservation if significant cancer is known to be at the prostate base. Bladder neck preservation should be performed routinely when the cancer is distant from the base. However, bladder neck preservation cannot be performed in the presence of a large median lobe or a previous transurethral resection of the prostate (TURP) [588].

6.2.2.3.10 Urethral length preservation

The membranous urethra sits immediately distal to the prostatic apex and is chiefly responsible, along with its surrounding pelvic floor support structures, for urinary continence. It consists of the external rhabdosphincter which surrounds an inner layer of smooth muscle. Using pre-operative MRI, the length of membranous urethra has been shown to vary widely.

Systematic reviews and meta-analyses found that every extra millimetre of membranous urethral length seen on MRI pre-operatively improves early return to continence post-RP [589-591]. A greater membranous urethral length as measured on preoperative MRI was an independent prognostic factor for return to urinary continence within one month after RP and remained prognostic at twelve months [591]. Therefore, it is likely that preservation of as much urethral length as possible during RP will maximise the chance of early return to continence. It may also be useful to measure urethral length pre-operatively on MRI to facilitate counselling of patients on their relative likelihood of early post-operative continence [592].

6.2.2.3.11 Cystography prior to catheter removal

Cystography may be used prior to catheter removal to check for a substantial anastomotic leak. If such a leak is found, catheter removal may then be deferred to allow further healing and sealing of the anastomosis. However, small comparative studies suggest that a cystogram to assess anastomotic leakage is not indicated as SOC before catheter removal eight to ten days after surgery [593]. If a cystogram is used, men with LUTS, large prostates, previous TURP or bladder neck reconstruction, may benefit as these factors have been associated with leakage [594, 595]. Contrast-enhanced transrectal US is an alternative [596].

6.2.2.3.12 Urinary catheter

A urinary catheter is routinely placed during RP to enable bladder rest and drainage of urine while the vesicourethral anastomosis heals. Compared to a traditional catheter duration of around one week, some centres remove the transurethral catheter early (post-operative day 2–3), usually after thorough anastomosis with posterior reconstruction or in patients selected peri-operatively on the basis of anastomosis quality [597-600]. No higher complication rates were found. Although shorter catheterisation has been associated with more favourable short-term functional outcomes, no differences in long-term function were found [601]. One RCT has shown no difference in rate of UTI following indwelling catheter (IDC) removal whether prophylactic ciprofloxacin was given prior to IDC removal or not, suggesting antibiotics should not be given at catheter removal [602].

As an alternative to transurethral catheterisation, suprapubic catheter insertion during RP has been suggested. Some reports suggest less bother regarding post-operative hygiene and pain [603-607], while others did not find any differences [608, 609]. No impact on long-term functional outcomes were seen.

6.2.2.3.13 Use of a pelvic drain

A pelvic drain has traditionally been used in RP for potential drainage of urine leaking from the vesico-urethral anastomosis, blood, or lymphatic fluid when a PLND has been performed. Two RCTs in the robotic-assisted laparoscopic setting have been performed [610, 611]. Patients with urine leak at intra-operative anastomosis watertight testing were excluded. Both trials showed non-inferiority in complication rates when no drain was used. When the anastomosis is found to be watertight intra-operatively, it is reasonable to avoid inserting a pelvic drain. There is no evidence to guide usage of a pelvic drain in PLND.

6.2.2.4 Acute and chronic complications of radical prostatectomy

Post-operative incontinence and ED are common problems following surgery for PCa. A key consideration is whether these problems are reduced by using newer techniques such as RALP. Systematic reviews have documented complication rates after RALP [612-616], and can be compared with contemporaneous reports after radical retropubic prostatectomy (RRP) [617]. A prospective controlled non-RCT of patients undergoing RP in 14 centres using RALP or RRP showed that twelve months after RALP, 21.3% of patients were incontinent, as were 20.2% after RRP (adjusted OR: 1.08, 95% CI: 0.87–1.34) [618]. Erectile dysfunction was observed in 70.4% after RALP and 74.7% after RRP. The adjusted OR was 0.81 (95% CI: 0.66–0.98) [618].

A SR and meta-analysis of unplanned hospital visits and re-admissions post-RP analysed 60 studies with over 400,000 patients over a 20-year period up to 2020. It found an emergency room visit rate of 12% and a hospital re-admission rate of 4% at 30 days post-operatively [619].

A RCT comparing RALP and RRP reported outcomes at 12 weeks in 326 patients and functional outcomes at two years [620]. Urinary function scores did not differ significantly between RRP vs. RALP at 6 and 12 weeks post-surgery (74–50 vs. 71–10, p = 0.09; 83–80 vs. 82–50, p = 0.48), with comparable outcomes for sexual function scores (30–70 vs. 32–70, p = 0.45; 35–00 vs. 38–90, p = 0.18). In the RRP group 14 (9%) patients had post-operative complications vs. 6 (4%) in the RALP group. The intra- and peri-operative complications of RRP and RALP are listed in Table 6.1.4. Table 6.1.5 lists the Clavien-Dindo definition of surgical complications. The early use of phosphodiesterase-5 (PDE5) inhibitors in penile rehabilitation remains controversial resulting in a lack of clear recommendations (see Section 8.3.2.1).

Table 6.2.4: Intra-and peri-operative complications of retropubic RP, laparoscopic RP and RALP (adapted from [612])

Predicted probability of event	**RALP (%)**	**Laparoscopic RP (%)**	**RRP (%)**
Bladder neck contracture	1.0	2.1	4.9
Anastomotic leak	1.0	4.4	3.3
Infection	0.8	1.1	4.8
Organ injury	0.4	2.9	0.8
Ileus	1.1	2.4	0.3
Deep-vein thrombosis	0.6	0.2	1.4
Predicted rates of event	**RALP (%)**	**Laparoscopic RP (%)**	**RRP (%)**
Clavien-Dindo I	2.1	4.1	4.2
Clavien-Dindo II	3.9	7.2	17.5
Clavien-Dindo IIIa	0.5	2.3	1.8
Clavien-Dindo IIIb	0.9	3.6	2.5
Clavien-Dindo IVa	0.6	0.8	2.1
Clavien-Dindo V	< 0.1	0.2	0.2

RALP = robot-assisted laparoscopic prostatectomy; RP = radical prostatectomy; RRP = radical retropubic prostatectomy.

Table 6.2.5: Clavien-Dindo grading of surgical complications [621]

Grade	**Definition**
I	Any deviation from the normal post-operative course not requiring surgical, endoscopic or radiological intervention. This includes the need for certain drugs (e.g. antiemetics, antipyretics, analgesics, diuretics and electrolytes), treatment with physiotherapy and wound infections that are opened at the bedside
II	Complications requiring drug treatments other than those allowed for Grade I complications; this includes blood transfusion and total parenteral nutrition (TPN)
IIIa	Complications requiring surgical, endoscopic or radiological intervention - intervention not under general anaesthetic
IIIb	Complications requiring surgical, endoscopic or radiological intervention - intervention under general anaesthetic
IVa	Life-threatening complications; this includes central nervous system (CNS) complications (e.g. brain haemorrhage, ischaemic stroke, subarachnoid haemorrhage) which require intensive care, but excludes transient ischaemic attacks (TIAs) - single-organ dysfunction (including dialysis)
IVb	Life-threatening complications; this includes CNS complications (e.g. brain haemorrhage, ischaemic stroke, subarachnoid haemorrhage) which require intensive care, but excludes transient ischaemic attacks (TIAs) - multi-organ dysfunction
V	Death of the patient

6.2.2.4.1 Effect of anterior and posterior reconstruction on continence

Preservation of integrity of the external urethral sphincter is critical for continence post-RP. Less clear is the effect of reconstruction of surrounding support structures to return to continence. Several small RCTs have been conducted, however, pooling analyses is hampered by variation in the definitions of incontinence and surgical approach, such as open vs. robotic and intra-peritoneal vs. extra-peritoneal. In addition, techniques used to perform both anterior suspension or reconstruction and posterior reconstruction are varied. For example, anterior suspension is performed either through periosteum of the pubis or the combination of ligated DVC and puboprostatic ligaments (PPL). Posterior reconstruction from rhabdosphincter is described to either Denonvilliers fascia posterior to bladder or to posterior bladder wall itself.

Two trials assessing posterior reconstruction in RALRP found no significant improvement in return to continence [622, 623]. A third trial using posterior bladder wall for reconstruction showed only an earlier return to 1 pad per day (median 18 vs. 30 days, p = 0.024) [624]. When combining both anterior and posterior reconstruction, where for anterior reconstruction the PPL were sutured to the anterior bladder neck, another RCT found no improvement compared to a standard anastomosis with no reconstruction [625].

Four RCTs including anterior suspension have also shown conflicting results. Anterior suspension alone through the pubic periosteum, in the setting of extra-peritoneal RALRP, showed no advantage [626]. However, when combined with posterior reconstruction in RRP, one RCT showed significant improvement in return to continence at one month (7.1% vs. 26.5%, p = 0.047) and three months (15.4% vs. 45.2%, p = 0.016), but not at six months (57.9% vs. 65.4%, p = 0.609) [627]. Another anterior plus posterior reconstruction RCT using the Advanced Reconstruction of VesicoUrethral Support (ARVUS) technique and the strict definition of continence of 'no pads', showed statistically significant improvement in continence at 2 weeks (43.8% vs. 11.8%), 4 weeks (62.5% vs. 14.7%), 8 weeks (68.8% vs. 20.6%), six months (75% vs. 44.1%) and twelve months (86.7% vs. 61.3%), when compared to standard posterior Rocco reconstruction [628]. Anterior suspension alone through the DVC and PPL combined without posterior construction in the setting of RRP has shown improvement in continence at one month (20% vs. 53%, p = 0.029), three months (47% vs. 73%, p = 0.034) and six months (83% vs. 100%, p = 0.02), but not at twelve months (97% vs. 100%, p = 0.313) [629]. Together, these results suggest a possible earlier return to continence, but no long-term difference.

As there is conflicting evidence on the effect of anterior and/or posterior reconstruction on return to continence post-RP, no recommendations can be made. However, no studies showed an increase in adverse oncologic outcome or complications with reconstruction.

6.2.2.4.2 Deep venous thrombosis prophylaxis

For EAU Guidelines recommendations on post-RP deep venous thrombosis prophylaxis, please see the Thromboprophylaxis Guidelines Section 3.1.6 [630]. However, these recommendations should be adapted based on national recommendations, when available.

6.2.2.4.3 Complications of extended pelvic lymph node dissection

Extended PLND increases morbidity in the treatment of PCa [540]. Overall complication rates of 19.8% vs. 8.2% were noted for ePLND vs. limited PLND, respectively, with lymphoceles (10.3% vs. 4.6%) being the most common adverse event (AE). Other authors have reported lower complication rates [631]. Briganti *et al.*, [632] also showed more complications after extended compared to limited PLND. Twenty percent of men suffer a complication of some sort after ePLND. Thromboembolic events occur in less than 1% of cases overall, but the RR of DVT and PE associated with PLND has been found to be 7.8 and 6.3, respectively [633].

*6.2.3 **Radiotherapy***

Intensity-modulated RT (IMRT) or volumetric modulated arc therapy (VMAT) with image-guided RT (IGRT) is currently widely recognised as the standard treatment approach for EBRT.

6.2.3.1 External beam radiation therapy

6.2.3.1.1 Technical aspects

Intensity-modulated RT and VMAT employ dynamic multi-leaf collimators, which automatically and continuously adapt to the contours of the target volume seen by each beam. Viani *et al.*, show significantly reduced acute and late grade ≥ 2 genito-urinary (GU) and gastro-intestinal (GI) toxicity in favour of IMRT, while BCR-free rates did not differ significantly when comparing IMRT with three-dimensional conformal RT (3D-CRT) in a RCT comprising 215 patients [634]. A meta-analysis by Yu *et al.*, (23 studies, 9,556 patients) concluded that IMRT significantly decreases the occurrence of grade 2–4 acute GI toxicity, late GI toxicity and late rectal bleeding, and achieves better PSA relapse-free survival in comparison with 3D-CRT. Intensity-modulated EBRT and 3D-CRT show comparable acute rectal toxicity, late GU toxicity and OS, while IMRT slightly increases the morbidity of

acute GU toxicity [635]. Zapatero *et al.*, found, based on 733 consecutive patients (295 IMRT vs. 438 3D-CRT), that compared with 3D-CRT, high-dose IMRT/IGRT is associated with a lower rate of late urinary complications despite a higher radiation dose [636]. In conclusion, IMRT plus IGRT remain the SOC for the treatment of PCa.

The advantage of VMAT over IMRT is shorter treatment times, generally two to three minutes in total. Both techniques allow for a more complex distribution of the dose to be delivered and provide concave isodose curves, which are particularly useful as a means of sparing the rectum. Radiotherapy treatment planning for IMRT and VMAT differs from that used in conventional EBRT, requiring a computer system capable of 'inverse planning' and the appropriate physics expertise. Treatment plans must conform to pre-specified dose constraints to critical organs at risk of normal tissue damage and a formal quality assurance process should be routine.

With dose escalation using IMRT/VMAT, organ movement becomes a critical issue in terms of both tumour control and treatment toxicity. Techniques will therefore combine IMRT/VMAT with some form of IGRT (usually gold marker or cone-beam CT), in which organ movement can be visualised and corrected for in real time, although the optimum means (number of applications per week) of achieving this is still unclear [637, 638]. Tomotherapy is another technique for the delivery of IMRT, using a linear accelerator mounted on a ring gantry that rotates as the patient is delivered through the centre of the ring, analogous to spiral CT scanning.

The use of MR-guided adapted RT is still investigational [639]. Planning studies confirm that MR-based adaptive RT significantly reduces doses to organs at risk (OAR) and this may translate into clinical benefit [640]. Although the rates of acute GI- and GU toxicity appear low, mostly on the basis of patients treated with stereotactic RT [641], follow-up is too short for definitive conclusions [639]. The daily fraction time of up to 45 minutes [639, 641], the heavy MR-workflow and the limited field size (rendering most pelvic fields too large) make its implementation not yet a routine [639]. A prospective single center RCT, the MIRAGE trial (CT-guided Stereotactic Body Radiation Therapy and MRI-guided Stereotactic Body Radiation Therapy for Prostate Cancer) demonstrates reduced acute GU and GI toxicity with MRI-guided SBRT and margin reduction from 4mm to 2mm [642]. The impact on long term toxicity, biochemical control and cost effectiveness remains undefined.

6.2.3.1.2 Dose escalation

Local control is a critical issue for the outcome of RT of PCa. It has been shown that local failure due to insufficient total dose is prognostic for death from PCa as a second wave of metastases is seen five to ten years later on [643]. Several RCTs have shown that dose escalation (range 74–80 Gy) has a significant impact on 10-year biochemical relapse as well as metastases and disease-specific mortality [644-651]. These trials have generally included patients from several risk groups, and the use of neoadjuvant/adjuvant HT has varied (see Table 6.1.6). The best evidence of an OS benefit in patients with intermediate- or high-risk PCa, but not with low-risk PCa, derives from a non-randomised but well conducted propensity-matched retrospective analysis of the U.S. National Cancer Database by Kalbasi *et al.*, including a total of 42,481 patients [652]. If IMRT/VMAT and IGRT are used for dose escalation, rates of severe late side effects (> grade 3) for the rectum are 2–4% and for the GU tract 2–6% [646, 653].

The concept of a focal boost to the dominant intraprostatic lesion (DIL) visible on MRI rather than global prostate dose escalation has been successfully validated in a RCT of 571 intermediate- and high-risk patients [653]. Patients were randomised between 77 Gy in 35 fractions of 2.2 Gy and the same dose plus a focal boost up to 18 Gy. Additional ADT was given to 65% of patients in both arms. However, the duration of the ADT was not reported. With a median follow-up of 72 months there was a moderate improvement of biochemical PFS (BPFS) (primary endpoint). In addition, focal boosting decreased local failure (HR: 0.33) and increased the rate of regional + distant MFS (HR: 0.58) [654]. No significant difference for late GU- or GI toxicity grade ≥ 2 (23% and 12% vs. 28% and 13%) was documented. For grade ≥ 3 GU-toxicity these numbers were 3.5% and 5.6% ($p > 0.05$). However, longer follow-up is needed to assess late GU-toxicity [654]. Of note, there was a clear decrease in biochemical failure with increasing boost dose, individually given up to 18 Gy. Systematic review of MRI-defined DIL focal boost studies using standard fractionation shows good tolerability and improved BPFS [655]. Its role when using hypofractionation and ultra-hypofractionation is under investigation.

Table 6.2.6: Randomised trials of dose escalation in localised PCa

Trial	n	PCa condition	Radiotherapy Dose	Follow-up (median)	Outcome	Results
MD Anderson study 2011 [651]	301	T1-T3, N0, M0, PSA ≤ 10 ng/mL PSA 10-20 ng/mL PSA > 20 ng/mL	70 vs.78 Gy	15 yr.	DM, DSM, FFF	All patients: 18.9% FFF at 70 Gy 12% FFF at 78 Gy (p = 0.042) 3.4% DM at 70 Gy 1.1% DM at 78 Gy (p = 0.018) 6.2% DSM at 70 Gy 3.2% DSM at 78 Gy (p = 0.043) No difference in OS (p > 0.05)
PROG 95-09 2010 [645]	393	T1b-T2b PSA ≤ 15 ng/mL 75% low-risk pts. Low-risk: T1-2a, PSA < 10 mg/mL, GS ≤ 6 Interm-risk: PSA 10-15 ng/mL or GS 7 or T2b High-risk: GS 8-10	70.2 vs.79.2 Gy including proton boost 19.8 vs. 28.8 Gy	8.9 yr.	10-yr. ASTRO BCF	All patients: 32% BF at 70.2 Gy 17% BF at 79.2 Gy (p < 0.0001) Low-risk patients: 28% BF at 70.2 Gy 7% BF at 79.2 Gy (p < 0.0001

6.2.3.1.3 Hypofractionation

Fractionated RT utilises differences in the DNA repair capacity of normal and tumour tissue and slowly proliferating cells are very sensitive to an increased dose per fraction [656]. A meta-analysis of 25 studies including > 14,000 patients concluded that since PCa has a slow proliferation rate, hypofractionated RT could be more effective than conventional fractions of 1.8–2 Gy [657]. Hypofractionation (HFX) has the added advantage of being more convenient for the patient at lower cost.

Moderate HFX is defined as RT with 2.5–3.4 Gy/fx. Several studies report on moderate HFX applied in various techniques also including HT in part [658-665]. A SR concluded that studies on moderate HFX (2.5–3.4 Gy/fx) delivered with conventional 3D-CRT/IMRT have sufficient follow-up to support the safety of this therapy but long-term efficacy data are still lacking [664]. These results were confirmed by a Cochrane review on moderate HFX for clinically localised PCa [666]. Eleven studies were included (n = 8,278) with a median follow-up of 72 months showing little or no difference in PCa-specific survival (HR: 1.00). Based on 4 studies (n = 3,848), HFX probably makes little or no difference to late radiation GU toxicity (RR: 1.05) or GI toxicity (RR: 1.1), but this conclusion is based on relatively short follow-up, and ten to 15-year data will be required to confirm these findings.

Moderate HFX should only be done by experienced teams using high-quality EBRT using IGRT and IMRT/VMAT and published phase III protocols should be adhered to (Table 6.1.7).

ADT = androgen deprivation therapy; BCDF = biochemical or clinical disease failure; BED = biologically equivalent dose, calculated to be equivalent in 2 Gy fractions using an α/ß of 1.5 Gy; DFS = diseasefree survival; EBRT = external beam radiotherapy; FU = follow-up; fx = fractions; HR = hazard ratio; ISUP = International Society of Urological Pathology; mo. = month; n = number of patients; NCCN = National Comprehensive Cancer Network; n.s. = not significant; TF = treatment failure; yr. = year.

Ultra-HFX has been defined as RT with > 3.4 Gy per fraction [665]. It requires IGRT and (ideally) stereotactic body RT (SBRT). Table 6.1.8 provides an overview of selected studies investigating its role in treating predominantly intermediate risk localised disease. Short-term biochemical control (5-years) is comparable to conventional fractionation. However, there are concerns about high-grade GU and rectal toxicity and full long-term side effects may not yet be known [664, 668]. In the HYPO-RT-PC randomised trial by Widmark et al., (n = 1,200), no difference in failure-free survival was seen for conventional or ultra-HFX but acute grade ≥ 2 GU toxicity was 23% vs. 28% (p = 0.057), favouring conventional fractionation. There were no significant differences in long-term toxicity [668]. A SR by Jackson et al., included 38 studies with 6,116 patients who received RT with < 10 fractions and ≥ 5 Gy per fraction. Five and seven-year biochemical recurrence-free survival (BRFS) rates were 95.3% and 93.7%, respectively, and estimated late grade ≥ 3 GU and GI toxicity rates were 2.0% and 1.1%, respectively [669]. The authors conclude that there is sufficient evidence to support SBRT as a standard treatment option for localised PCa, even though the median follow-up in this review was only 39 months and it included at least one trial (HYPO-RT-PC) which used 3D-CRT in 80% and IMRT/VMAT in the remainder for ultra-HFX. In their review on SBRT, Cushman et al., evaluated 14 trials, including 2,038 patients and concluded that despite a lack of long-term follow-up and the heterogeneity of the available evidence, prostate SBRT affords appropriate biochemical control with few high-grade toxicities [670]. In the Intensity-modulated fractionated RT vs. stereotactic body RT for PCa (PACE-B) trial, acute grade ≥ 2 GU or GI toxicities did not differ significantly between conventional fractionation and ultra- HFX [671]. At two years, treatment was well tolerated in both arms with no differences in RTOG ≥ Grade 2 GU or GI toxicities, but clinician scoring of urinary toxicity using CTCAE and patient reported Expanded Prostate Cancer Index Composite (EPIC)-26 urinary bother scores were both higher in the SBRT arm suggesting SBRT may increase moderate but not severe urinary symptoms post-teatment [672]. Adopting planning dose constraints to the penile bulb might minimise ED, especially in younger patients (Table 6.1.8) [673].

First results of a small (n = 30) randomised phase-II trial in intermediate-risk PCa of 'ultra-high single dose RT' (SDRT) with 24 Gy compared with an ultra HFX stereotactic body RT regime with 5x9 Gy, have been published [674].

Table 6.2.8: Selected trials on ultra-hypofractionation for intact localised PCa

6.2.3.1.4 Neoadjuvant or adjuvant hormone therapy plus radiotherapy

The combination of RT with luteinising hormone releasing hormone (LHRH) ADT has superiority compared with RT alone followed by deferred ADT on relapse, as shown by phase III RCTs [675-685] (Table 6.1.9). The main message is that for intermediate-risk disease a short duration of four to six months is optimal while a longer one, 2-3 years, is needed for high-risk patients. The largest RCT in intermediate risk disease comparing dose escalated RT with or without six months of ADT failed to demonstrate an OS advantage with a median follow-up time of 6.3 years. Six months of ADT use was associated with reduced PSA failure, fewer distant metastases and improved prostate cancer specific mortality [685].

Table 6.2.9: Selected studies of use and duration of ADT in combination with RT for PCa

Study	TNM stage	n	Trial	ADT	RT	Effect on OS
RTOG 85-31 2005 [676]	T3 or N1 M0	977	EBRT ± ADT	Orchiectomy or LHRH agonist 15% RP	65–70 Gy	**Significant benefit for combined treatment (p = 0.002) seems to be mostly caused by patients with ISUP grade group 2-5**

RTOG 0815 2023 [685]	Intermediate risk	1,492	Dose escalated RT ± ADT	LHRH agonist/ antagonist + bicalutamide or flutamide 6 mo. 2 mo.prior to RT	79.2Gy (89%) 45Gy + BT boost (11%)	**No difference in OS. Significantly improved biochemical failure-free, metastatic-free survival and PCa-specific survival for ADT arm.**

ADT = androgen deprivation therapy; CI = confidence interval; EBRT = external beam radiotherapy in standard fractionation; HR = hazard ratio; ISUP = International Society of Urological Patholohy; LHRH = luteinising hormone-releasing hormone; mo. = months; n = number of patients; OS = overall survival; RP = radical prostatectomy; RT = radiotherapy; BT = brachytherapy; wk = week; yr. = year; 3D-CRT = three-dimensional conformal radiotherapy.

The question of the added value of EBRT combined with ADT has been clarified by 3 RCTs. All showed a clear benefit of adding EBRT to long-term ADT (Table 6.1.10).

Table 6.2.10: Selected studies of ADT in combination with, or without, RT for PCa

Study	TNM stage	n	Trial design	ADT	RT	Effect on OS
SPCG-7/ SFUO-3 2016 [686]	T1b-2 WHO Grade 1-3, T3 N0 M0	875	ADT ± EBRT	LHRH agonist for 3 mo. Plus continuous flutamide	70 Gy 3D-CRT vs. no RT	34% (95% CI: 29-39%) vs. 17% (95% CI: 13-22% CSM at 12 (15) yr. favouring combined treatment (p < 0.0001 for 15-yr. results) NCIC CTG PR.3/MRC

ADT = androgen-deprivation therapy; CSM = cancer-specific mortality; EBRT = external beam radiotherapy; HR = hazard ratio; LHRH = luteinising hormone-releasing hormone; mo. = months; n = number of patients; OS = overall survival; PSA = prostate-specific antigen; RT = radiotherapy; 3D-CRT = three-dimensional conformal radiotherapy; yr = years.

6.2.3.1.5 Combined dose-escalated radiotherapy and androgen-deprivation therapy

The combination of ADT with various forms of RT has been extensively studied, with extremely strong evidence for the use of such combined modality therapy in several settings. The MARCAP (Individual Patient Data Meta-Analysis of Randomised Trials in Cancer of the Prostate) consortium recently conducted a meta-analysis of trials using individual patient data (IPD), and a primary endpoint of MFS, a validated surrogate for OS. Trials were eligible if they studied the use or prolongation of ADT in patients receiving definitive RT, and included 12

trials with 10,853 patients. Median follow-up was over 11 years. The use of ADT was clearly associated with significant improvements in BCR, metastatic recurrence, MFS, and OS. The benefits of ADT were independent of RT dose, age, and risk groups comparing NCCN unfavourable intermediate-risk (see Sections 4.2 and 6.2.2.3), high-risk and locally-advanced disease. There were no demonstrable benefits from the extension of duration of neoadjuvant ADT [689].

Three RCTs have shown that the benefits of ADT are independent of dose escalation, and that the use of ADT would not compensate for a lower RT dose:

1. The GICOR study shows a better biochemical DFS in high-risk patients for 3D-CRT radiation dose > 72 Gy when combined with long-term ADT [690].
2. DART01/05 GICOR shows improved OS in high-risk patients after ten years if two years of adjuvant ADT is combined with high-dose RT [691].
3. The European Organisation for Research and Treatment of Cancer (EORTC) trial 22991 shows that six months ADT improves biochemical and clinical DFS irrespective of the dose (70, 74, 78 Gy) in intermediate-risk and low-volume high-risk localised PCa patients [692].

A meta-analysis based on IPD from two RCTs (RTOG 9413 and Ottawa 0101) has compared neoadjuvant/concomitant vs. adjuvant ADT (without substratifying between favourable- and unfavourable intermediaterisk disease) in conjunction with prostate RT and reported superior PFS with adjuvant ADT, but the data heterogeneity means that this observation is hypothesis-generating only [693].

In addition, a Canadian two-arm dose-escalated (76 Gy) RCT compared neoadjuvant and concomitant with adjuvant short-term ADT in 432 patients with intermediate-risk PCa. After ten years no significant difference in OS or RT-related grade ≥ 3 GI or GU toxicity was seen [694]. Therefore both regimen in combination with dose escalation are reasonable standards.

6.2.3.2 Proton beam therapy

In theory, proton beams are an attractive alternative to photon-beam RT for PCa, as they deposit almost all their radiation dose at the end of the particle's path in tissue (the Bragg peak), in contrast to photons which deposit radiation along their path. There is also a very sharp fall-off for proton beams beyond their deposition depth, meaning that critical normal tissues beyond this depth could be effectively spared. In contrast, photon beams continue to deposit energy until they leave the body, including an exit dose.

One RCT on dose escalation (70.2 vs. 79.2 Gy) has incorporated protons for the boost doses of either 19.8 or 28.8 Gy. This trial shows improved outcome with the higher dose but it cannot be used as evidence for the superiority of proton therapy [645]. Thus, unequivocal information showing an advantage of protons over IMRT photon therapy is still not available. Studies from the SEER database and from Harvard describing toxicity and patient-reported outcomes do not point to an inherent superiority of protons [695, 696]. In terms of longer-term GI toxicity, proton therapy might even be inferior to IMRT [696].

A RCT comparing equivalent doses of proton-beam therapy with IMRT is underway. Meanwhile, proton therapy must be regarded as an experimental alternative to photon-beam therapy.

6.2.3.3 Spacer during external beam radiation therapy

Biodegradable spacer insertion involves using a liquid gel or balloon to increase the distance between the prostate and rectum and consequently reduce the amount of radiation reaching the rectum. Various materials have been used with most evidence available for CE-marked hydrogel spacers [697]. A meta-analysis including one RCT and six cohort studies using the hydrogel spacer demonstrated a 5–8% reduction in the rectal volume receiving high-dose radiation, although heterogeneity between studies is found [698]. In the final analysis of the RCT with a median follow-up of 37 months and with approximately two-thirds of patients evaluable, those treated with spacer *in situ* had no deterioration from baseline bowel function whilst those treated without spacer had a lower mean bowel summary score of 5.8 points which met the threshold for a minimally important difference of 4–6 points [699].

This meta-analysis highlights inconsistent reporting of procedural complications. In addition, with more widespread clinical use safety reports describe uncommon, but severe and life changing, complications including prostatic abscess, fistulae and sepsis [700]. Implantation is associated with a learning curve and should only be undertaken by teams with experience of TRUS and transperineal procedures with robust audit reporting in place [701]. Its role in the context of moderate or extreme HFX is as yet unclear.

6.2.3.4 Brachytherapy

6.2.3.4.1 Low-dose rate brachytherapy

Low-dose rate (LDR) BT uses radioactive seeds permanently implanted into the prostate. In patients declining or unsuitable for AS LDR monotherapy [702] can be offered to those with low-risk or NCCN favourable intermediate-risk and good urinary function defined as an International Prostatic Symptom Score (IPSS) < 12 and maximum flow rate > 15 mL/min on urinary flow tests [703]. The RTOG Ph3 RCT compared LDR BT +/- EBRT in participants with Gleason grade 6 and PSA < 20 or Gleason grade 7 and PSA < 10 and found that the addition of EBRT resulted in increased toxicity but no improvement in freedom from progression [704].

Patients having had a previous TURP can undergo BT without an increase in risk of urinary toxicity with due attention to dose distribution. A minimal channel TURP is recommended, leaving at least 1 cm rim of prostate tissue around the post-TURP urethral defect at the postero-lateral sides of the prostate and there should be at least a 3-month interval between TURP and BT to allow for adequate healing [705-708].

The only available RCT comparing RP and LDR BT as monotherapy was closed due to poor accrual [709]. Outcome data are available from a number of large population cohorts with mature follow-up [710-714]. The biochemical DFS for ISUP grade group 1 patients after five and ten years has been reported to range from 71% to 93% and 65% to 85%, respectively [710-714]. A significant correlation has been shown between the implanted dose and biochemical control [715]. A D90 (dose covering 90% of the prostate volume) of > 140 Gy leads to a significantly higher biochemical control rate (PSA < 1.0 ng/mL) after four years (92 vs. 68%). There is no OS benefit in adding neoadjuvant or adjuvant ADT to LDR monotherapy [716].

Low-dose rate BT can be combined with EBRT in NCCN unfavourable intermediate-risk PCa and high-risk patients. External beam RT (total dose of 78 Gy) has been compared with EBRT (total dose 46 Gy) followed by LDR BT boost (prescribed dose 115 Gy) in intermediate-risk and high-risk patients in the ASCENDE-RT randomised trial with twelve months of ADT in both arms [717, 718]. The LDR boost resulted in 5-, 7-year and 10-year PSA PFS increase (89%,86% and 85% respectively, compared to 84%,75%, 70%) but with no impact on distant metastasis or OS. This improvement in biochemical control was achieved at a cost of increased late grade 3+ GU toxicity (18% compared to 8%) and 2 treatment related deaths [718, 719]. Urinary toxicity was mainly in the development of urethral strictures and incontinence and great care should be taken during treatment planning.

6.2.3.4.2 High-dose rate brachytherapy

High-dose rate (HDR) BT uses a radioactive source temporarily introduced into the prostate to deliver radiation. The technical differences are outlined in Table 6.1.11. The use of the GEC (Groupe Europeen de Curietherapie)/ ESTRO Guidelines is strongly recommended [720]. High-dose rate BT can be delivered in single or multiple fractions and is often combined with EBRT of at least 45 Gy, conventionally fractionated [721]. A retrospective analysis on 1641 intermediate and high-risk patients demonstrated a better distant-metastasis free survival when a HDR BT boost was added to 50 – 54 Gy EBRT. The difference mounted to 12% at ten years [722]. A SR of non-RCTs and data from population studies suggest outcomes with EBRT plus HDR BT are superior to EBRT alone [723, 724].

A single-centre RCT of EBRT (55 Gy in 20 fractions) vs. EBRT (35.75 Gy in 13 fractions), followed by HDR BT (17 Gy in two fractions over 24 hours) has been reported [725]. In 218 patients with T1–3 N0M0 PCa the combination of EBRT and HDR BT showed a significant improvement in the biochemical disease-free rate (p = 0.04) at five and ten years (75% and 46% compared to 61% and 39%). However, an unexpectedly high rate of early recurrences was observed in the EBRT arm alone, even after 2 years, possibly due to a dose lower than the current standard used [725].

Supporting, but not definitive, evidence of the benefit of HDR boost is available from the TROG 03.04 RADAR trial. This multi-centre study had upfront radiation dose escalation (non-randomised) with dosing options of 66, 70, or 74 Gy EBRT, or 46 Gy EBRT plus HDR BT boost and randomised men with locally-advanced PCa to 6 or 18 months ADT. After a minimum follow-up of ten years HDR boost significantly reduced distant progression, the study primary endpoint (sub HR: 0.68, 95% CI: 0.57–0.80; p < 0.0001), when compared to EBRT alone and, independent of duration of ADT, HDR boost was associated with increased IPSS of 3 points at 18 months post-treatment resolving by three years but decreased rectal symptoms when compared to EBRT [726]. Although radiation dose escalation using BT boost provides much higher biological doses, the TROG 03.04 RADAR RCT and SRs show ADT use independently predicts better outcomes regardless of radiation dose intensification [716, 726, 727]. Omitting ADT may result in inferior OS and based on current evidence ADT use and duration should be in line with that used when delivering EBRT alone.

Fractionated HDR BT as monotherapy can be offered to patients with low- and intermediate-risk PCa, who should be informed that results are only available from limited series in very experienced centres. Five-year PSA control rates of 97.5% and 93.5% for low- and intermediate-risk PCa, respectively, are reported, with late grade 3+ GU toxicity rates < 5% and no, or very minimal, grade 3+ GI toxicity rates [728]. Single fraction HDR monotherapy should not be used as it has inferior biochemical control rates compared to fractionated HDR monotherapy [729].

Table 6.2.11: Difference between LDR and HDR brachytherapy

	Differences in prostate brachytherapy techniques
Low dose rate (LDR)	• Permanent seeds implanted • Uses Iodine-125 (I-125) (most common), Palladium-103 (^{103}Pd-) or Cesium-131 isotopes • Radiation dose delivered over weeks and months • Acute side effects resolve over months • Radiation protection issues for patient and carers
High dose rate (HDR)	• Temporary implantation • Iridium-192 (IR-192) isotope introduced through implanted needles or catheters • Radiation dose delivered in minutes • Acute side effects resolve over weeks • No radiation protection issues for patient or carers

6.2.3.5 Acute side effects of external beam radiotherapy and brachytherapy

Gastro-intestinal and urinary side effects are common during and after EBRT. In the EORTC 22991 trial, approximately 50% of patients reported acute GU toxicity of grade 1, 20% of grade 2, and 2% grade 3. In the same trial, approximately 30% of patients reported acute grade 1 GI toxicity, 10% grade 2, and less than 1% grade 3. Common toxicities included dysuria, urinary frequency, urinary retention, haematuria, diarrhoea, rectal bleeding and proctitis [730]. In addition, general side effects such as fatigue are common. It should be noted that the incidence of acute side effects is greater than that of late effects (see Section 8.2.2.1), implying that most acute effects resolve. In a RCT of conventional dose EBRT vs. EBRT and LDR BT the incidence of acute proctitis was reduced in the BT arm, but other acute toxicities were equivalent [717]. Acute toxicity of HDR BT has not been documented in a RCT, but retrospective reports confirm lower rates of GI toxicity compared with EBRT alone and grade 3 GU toxicity in 10%, or fewer, patients, but a higher incidence of urinary retention [731]. Similar findings are reported using HFX; in a pooled analysis of 864 patients treated using extreme HFX and stereotactic RT, declines in urinary and bowel domains were noted at three months which returned to baseline, or better, by six months [732].

6.2.4 ***Investigational therapies***

6.2.4.1 Background

Besides RP, EBRT and BT, other modalities have emerged as potential therapeutic options in patients with clinically localised PCa [733-735]. These new modalities have been developed as minimally invasive procedures with the aim of providing equivalent oncological safety, reduced toxicity, and improved functional outcomes. In this section, both whole gland- and focal treatment [736, 737] will be considered, looking particularly at high-intensity focused US (HIFU), cryotherapeutic ablation of the prostate (cryotherapy) and focal photodynamic therapy (PDT), as sufficient data are available to form the basis of some initial judgements. Other options such as radiofrequency ablation (RFA) and electroporation, among others, are considered to be in the early phases of evaluation [736].

6.2.4.2 Whole-gland therapies

6.2.4.2.1 Cryotherapy for whole-gland treatment

Cryotherapy uses freezing techniques to induce cell death by dehydration resulting in protein denaturation, direct rupture of cellular membranes by ice crystals and vascular stasis and microthrombi, resulting in stagnation of the microcirculation with consecutive ischaemic apoptosis [733-735]. Freezing of the prostate is ensured by the placement of 17-gauge cryo-needles under TRUS guidance, placement of thermosensors at the level of the external sphincter and rectal wall, and insertion of a urethral warmer. Two freeze-thaw cycles are used under TRUS guidance resulting in a temperature of -40°C in the mid-gland and at the neurovascular bundle. Currently, third and fourth generation cryotherapy devices are mainly used. Since its inception, cryotherapy has been used for whole-gland treatment in PCa either as a primary or salvage treatment option.

The main adverse effects of whole-gland cryosurgery are ED (18%), urinary incontinence (2–20%), urethral sloughing (0–38%), rectal pain and bleeding (3%) and recto-urethral fistula formation (0–6%) [738]. There is a lack of prospective comparative data regarding oncological outcomes of whole-gland cryosurgery as a curative treatment option for men with localised PCa, with most studies being non-comparative single-arm case series with short follow-up [738].

6.2.4.2.2 High-intensity focused ultrasound for whole-gland treatment

High-intensity focused US consists of focused US waves emitted from a transducer that cause tissue damage by mechanical and thermal effects as well as by cavitation [739]. The goal of HIFU is to heat malignant tissue above 65°C, so that it is destroyed by coagulative necrosis. High-intensity focused US is performed under general or spinal anaesthesia, with the patient lying in the lateral or supine position. Since the ultrasound energy is most often delivered from the rectal cavity, HIFU faces challenges in delivering energy to the anterior part in large prostates.

High-intensity focused US has previously been widely used for whole-gland therapy with the following adverse effects: acute urinary retention (10%), ED (23%), urethral stricture (8%), rectal pain or bleeding (11%), recto-urethral fistula (0–5%) and urinary incontinence (10%) [738]. Combining the whole-gland HIFU treatment with TUR-P reduces the rate of urethral strictures, maintains the level of incontinence, but increases the rate of ED [740].

Overall, the lack of any long-term prospective comparative studies, and data to suggest poor long-term oncological outcomes for men with high-risk localised disease [741] prevents whole-gland HIFU from being considered as a reasonable alternative to the established curative treatment options [738]. In addition, the expected improvements in functional outcome failed to materialise with 12% of patient developing incontinence and 61% developing ED [742].

6.2.4.3 Focal therapy

During the past two decades, there has been a trend towards earlier diagnosis of PCa as a result of greater public and professional awareness leading to the adoption of both formal and informal screening strategies. The effect of this has been that men are identified at an earlier stage with smaller tumours, with a greater propensity for unifocal disease potentially suitable for focal therapy [743-745]. There is also greater awareness of the risks of the consequences of treatment leading to attempts to ablate only a region of the prostate containing the tumour thereby limiting toxicity by sparing the neurovascular bundles, sphincter, and urethra [746-748]. The question remains which if any of these small unifocal tumours need treatment.

A SR included data from 5,827 patients across 72 studies and covered different energy sources including HIFU, cryotherapy, PDT, laser interstitial thermotherapy, focal BT, irreversible electroporation (IRE) and radiofrequency ablation (RFA) [749]. The review favours HIFU and PDT for their higher quality data, over 95% of pad-free incontinence and 85–90% of patients without clinically significant cancer in short-term analysis. This has to be critically analysed, because 45% of all patients with a focal approach included in this SR had an ISUP Grade Group 1 cancer. The overall quality of the evidence was low, due to the majority of studies being single-centre, non-comparative and retrospective in design, heterogeneity of definitions and approaches, follow-up strategies, outcomes, and duration of follow-up. Although the review finds high quality evidence that focal therapy has favourable functional outcomes and minimises AEs, definitive proof of oncological effectiveness of focal therapy compared to standard treatments remains unavailable.

The currently largest analysis on oncologic outcomes following focal HIFU includes 625 patients, with 70% having ISUP grade group 2/3 disease, followed for five years with an 88% failure-free survival (FFS), defined as the need for salvage treatment or systemic therapy [750]. In this study one repeated focal HIFU session was allowed and performed in 25% of all patients. Follow-up was driven by PSA and clinics, with re-biopsies performed only in 36% of patients after a significant PSA rise and suspicious MRI.

The guideline panel acknowledges the challenges for interventional RCTs [751-753]. The interim analysis and meeting reports demonstrate slow recruitment, patients declining consent and rejecting their treatment allocation into the RP group. In an attempt to overcome this propensity-matched analysis using prospective multi-centre databases have been performed for comparison of focal therapy vs. radical therapy [754, 755]. Such analyses are always susceptible to unmeasured selection biases in who was selected for each treatment.

Oncological follow-up data up to 8 years can be used to counsel patients in treatment decisions [754]. Patients were managed by focal therapy had a HIFU or cryotherapy, with one retreatment, if needed. 17.1% of patients

in the focal arm received a retreatment. The primary outcome was FFS defined as "need for local or systemic salvage treatment or metastasis". Both groups included 246 patients with an average PSA of 7.9 ng/mL and 60% ISUP Grade Group 2/3 cancers. The cancer core length was 5–6 mm with 45% having bilateral cancer. The authors report similar cancer control 8 years after therapy, with FFS and BCR of 83% and 23.9% for focal therapy vs. 79% and 24.8% for RP, respectively. Similar results were demonstrated in a cohort-based analysis with a follow-up six years [755]. The use of different definitions for oncological failure in the two arms is another limitation of these studies. While any recurrence after RP was seen as failure, a second HIFU was permitted in the focal group. The current data from the HIFU Evaluation and Assessment of Treatment (HEAT) registry indicates that a repeat-HIFU does not significantly decrease urinary or erectile function [756]. However, this change of failure definition will have to be re-evaluated. It is important to note, that these results were achieved in centres with a dedicated focal program where all patients had a mpMRI with targeted and systematic biopsies or full template mapping biopsies.

The prospective HEAT registry analysed over 800 men undergoing focal HIFU for localised PCa [756]. The functional data indicate low treatment-related toxicity with less than 4% decrease in pad-free incontinence and a reduction in IIEF of 0.4 points. The impact of salvage therapies after focal therapy was investigated in small series [757, 758]. If a salvage RP is necessary, the reported functional and oncological outcomes are comparable to treatment-naive patients [802, 803].

One comparative RCT was conducted in a very-low risk population, for which there is currently a strong movement away from any form of active treatment. This study was comparing padeliporfin-based vascular targeted PDT vs. AS and found at a median follow-up of 24 months that less patients progressed in the PDT arm compared with the AS arm (adjusted HR: 0.34, 95% CI: 0.24–0.46), and needed less radical therapy (6% vs. 29%, $p < 0.0001$). Updated results were published in 2018 showing that these benefits were maintained after four years [759]. Nevertheless, limitations of the study include an unusually high observed rate of disease progression in the AS arm (58% in two years) and more patients in the AS arm chose to undergo radical therapy without a clinical indication which may have introduced confounding bias. Finally, the AS arm did not undergo any confirmatory biopsy or any MRI scanning, which is not representative of contemporary practice. A matched-pair analysis comparing focal cryo therapy to AS with 76% ISUP grade group 1 cancers failed to demonstrate any significant advantages for MFS and OS [760].

The available evidence indicates that focal therapy is associated with less AEs than whole gland or radical treatments. Many of the patients included in these trials would currently be considered to have been over treated. Robust prospective trials reporting standardised 15-year oncological outcomes [761] are needed in patients with clinically significant cancers before unrestricted recommendations in support of focal therapy for routine clinical practice can be made [736, 750, 761]. Currently, focal therapy using HIFU or cryotherapy should be performed within the context of a prospective registry. All other ablative modalities and treatment strategies should only be offered in well-designed prospective trial setting. In order to allow quality analysis of the collected data, the prospective registry should adhere to the EMA recommendations (Guideline on registry-based studies EMA/426390/2021), which emphasises the need for clear follow-up timelines and timely recording, completeness of core data of consecutive patients enrolled, an analysis plan in defined intervals and a data quality management. In near future the EAU will offer a quality registry within the PIONEER network.

*6.2.5 General guidelines for the treatment of prostate cancer**

Recommendations	Strength rating
Offer a watchful waiting (WW) policy to asymptomatic patients with clinically localised disease and with a life expectancy < ten years (based on comorbidities and age).	Strong
No active treatment modality has shown superiority over any other active management options or deferred active treatment in terms of overall- and PCa-specific survival for clinically localised low/intermediate-risk disease.	Strong
Inform patients that all local treatments have side effects.	Strong
Surgical treatment	
Inform patients that no surgical approach (open-, laparoscopic- or robotic RP) has clearly shown superiority in terms of functional or oncological results.	Weak
Consider avoiding nerve-sparing surgery when there is a risk of ipsilateral ex-tra-capsular extension (based on cT stage, ISUP grade group, magnetic reso-nance imaging, or with this information combined in a nomogram).	Weak

In patients undergoing a lymph node dissection you should perform an extended PLND.	Strong
Do not offer neoadjuvant androgen deprivation therapy before surgery.	Strong
Radiotherapeutic treatment	
Offer intensity-modulated radiation therapy (IMRT) or volumetric arc radiation therapy (VMAT) plus image-guided radiation therapy (IGRT) for definitive treatment of PCa by external-beam radiation therapy.	Strong
Offer moderate hypofractionation (HFX) with IMRT/VMAT plus IGRT to the prostate to patients with localised disease (60 Gy/20 fractions in 4 weeks or 70 Gy/28 fractions in 6 weeks).	Strong
Offer low-dose rate (LDR) brachytherapy monotherapy to patients with good urinary function and low-risk or NCCN favourable intermediate-risk disease.	Strong
Offer LDR or high-dose rate (HDR) brachytherapy boost combined with IMRT/VMAT plus IGRT to patients with good urinary function and NCCN unfa-vourable intermediate-risk or high-risk disease and/or locally-advanced disease.	Weak
Active therapeutic options outside surgery or radiotherapy	
Offer focal therapy with HIFU or cryotherapy within a clinical trial or prospective registry.	Strong

**All recommendations are based on conventional imaging with isotope bone scan and CT/MR abdomen/pelvis.*

Summary of evidence	**LE**
The AS strategy should be based on PSA (at least once every six months), serial DRE (at least once yearly) and repeated biopsy. Serial DRE may be omitted if MRI is stable.	3
Serial MRI can improve the detection of aggressive cancers during AS.	
A progression on MRI mandates a repeat biopsy before a change in treatment strategy.	
A stationary MRI does not make repeat biopsy superfluous (patients with low-risk tumour and a stable PSA-D < 0.15 may be excepted).	

Recommendations	**Strength rating**
Base the strategy of active surveillance (AS) on a strict protocol including digital rectal examination (at least once yearly), prostate-specific antigen (PSA) (at least once every six months) and repeated biopsy every 2 to 3 years.	Strong
Patients with a low risk PCa, a stable MRI (PRECISE 3) and a stable, low PSA density (< 0.15) may be excused from repeat biopsy.	Weak
Perform magnetic resonance imaging (MRI) and repeat biopsy if PSA is rising (PSA-doubling time < 3 years).	Strong
Base change in treatment on biopsy progression, not on progression on MRI and/or PSA.	Weak
Re-classify patients with low-volume ISUP grade group 2 disease included in AS protocols, if repeat non-MRI-based systematic biopsies performed during monitoring reveal > 3 positive cores or maximum core involvement > 50%/core of ISUP grade group 2 disease.	Weak

6.3 Treatment by disease stages

6.3.1 Treatment of low-risk disease

6.3.1.1 Active surveillance

The main risk for men with low-risk disease is over-treatment (see sections 6.1.1, 6.2.1); AS should therefore be considered SOC for all such patients with a life expectancy > ten years based on comorbidities and age) and where curative treatment would be considered in the case of disease progression.

6.3.1.1.1 Active surveillance - inclusion criteria

Guidance regarding selection criteria for AS is limited by the lack of data from prospective RCTs. As a consequence, the Panel undertook an international collaborative study involving healthcare practitioners and patients to develop consensus statements for deferred treatment with curative intent for localised PCa, covering all domains of AS (DETECTIVE Study) [330], as well as a formal SR on the various AS protocols [491]. The criteria most often published include: ISUP grade group 1, clinical stage cT1c or cT2a, PSA < 10 ng/mL and PSA-D < 0.15 ng/mL/cc, as based on systematic biopsy schemes [487, 492]. The latter threshold remains controversial [492, 493]. These criteria were supported by the DETECTIVE study consensus. There was no agreement on

the maximum number of systematic cores that can be involved with cancer or the maximum percentage core involvement (CI), although there was recognition that extensive disease on MRI should exclude men from AS, even though there is no firm definition on this, especially when targeted biopsies confirm ISUP grade group 1 [330]. A SR and meta-analysis found three clinico-pathological variables which were significantly associated with reclassification, high PSA-D, > 2 positive cores (on systematic biopsies) and African-American descent [495]. In addition, a previous pathology consensus group suggested excluding men from AS when any of the following features were present: predominant ductal carcinoma (including pure IDC), cribriform histology, sarcomatoid carcinoma, small cell carcinoma, EPE or LVI in needle biopsy [497] and perineural invasion [498].

A multi-disciplinary consensus conference on germline testing attempted to develop a genetic implementation framework for the management of PCa [154]. Based on consensus, *BRCA2*-gene testing was recommended for AS discussions and could be performed in men with family history of prostate, breast or ovarian cancers. However, the nature of such discussions and how a positive result influences management were beyond the scope of the project. Currently, *BRCA2* mutation does not exclude a patient from AS if tumour factors are otherwise favourable. Furthermore, if included in AS programmes, patients with a known *BRCA2* mutation should be cautiously monitored until such time that more robust data are available.

6.3.1.1.2 Tissue-based prognostic biomarker testing for selection for active surveillance

Biomarkers, including Oncotype Dx®, Prolaris®, Decipher®, PORTOS and ProMark® are promising (see Section 5.2.8.3). However, further data will be needed before such markers can be used in standard clinical practice [220].

6.3.1.1.3 Magnetic resonance imaging for selection for active surveillance

In men eligible for AS based upon systematic biopsy findings alone who did not have a pre-biopsy MRI, a re-biopsy within 6–12 months (usually referred to as 'confirmatory biopsy') seems mandatory to exclude sampling error. A large body of literature including two RCTs showed that adding MRI-targeted biopsy to systematic sampling at confirmatory biopsy improved detection of ISUP grade ≥ 2 cancers and thus, patient selection for AS [121, 499, 500, 502-504]. Adding MRI-targeted biopsy to systematic sampling at confirmatory biopsy improved upgrade detection by increments of 0-7.9 per 100 men depending on the series [499]. In a meta-analysis of 6 studies, the rate of upgrading to ISUP grade group ≥ 2 cancer increased from 20% (95% CI: 16–25%) to 27% (95% CI: 22–34%) when MRI-targeted biopsy was added to systematic biopsy [504]. The Active Surveillance MRI Study (ASIST) randomised men on AS scheduled for confirmatory biopsy to either 12-core systematic biopsy or to MRI with targeted biopsy (when indicated), combined with systematic biopsy (up to 12 cores in total). After two yearsof follow-up, use of MRI before confirmatory biopsy resulted in fewer failures of surveillance (19% vs. 35%, p = 0.017) and in fewer patients progressing to ISUP grade group ≥ 2 cancer (9.9% vs. 23%, p = 0.048) [502]. However, systematic biopsy retains its additional value, which argues for a combined biopsy approach [499, 504]. The DETECTIVE study agreed that men eligible for AS after combined systematic- and MRI-targeted biopsy do not require a confirmatory biopsy [330].

If the PCa diagnosis is made on MRI-targeted biopsy alone (recommended in some countries national guidelines, e.g., the Nordic countries [762] in order to lower the risk of over-detection of insignificant tumours, a confirmative systematic biopsy should be performed before definite decision of AS to rule out more widespread cancer growth in the prostate.

6.3.1.1.4 Follow-up during active surveillance

Based on the DETECTIVE consensus study, the follow-up strategy should be based on serial DRE (at least once yearly), PSA (at least once, every six months) and repeated biopsy. It was also agreed that PSA progression or change in PSA kinetics alone should lead to reclassification only if accompanied by changes in histology on repeat biopsy [330].

Yerram *et al.*, analysed a prospectively-maintained AS cohort of 369 patients (272 with ISUP grade group 1 cancer and 97 with ISUP grade group 2 cancer) who had been selected for AS after combined systematic and MRI-targeted sampling during confirmatory biopy. At two years, systematic biopsy, MRI-targeted biopsy and combined biopsy detected grade progression in 44 patients (15.9%), 73 patients (26.4%) and 90 patients (32.5%), respectively. This suggests that both biopsy approaches retain added value, not only for confirmatory biopsy, but also during AS [763].

In 2016, the Prostate Cancer Radiological Estimation of Change in Sequential Evaluation (PRECISE) criteria were established to standardise the assessment of tumour progression on serial MRI [507]. Progression on MRI, defined using the PRECISE criteria, or not, is a strong predictor of histological upgrading [508, 509]. Two independent meta-analyses assessed the value of MRI progression criteria for predicting histological progression (mostly defined as progression to ISUP grade group ≥ 2). The pooled histological progression rate was 27% in both reviews. If biopsies were triggered only by MRI progression findings, approximately two thirds of the biopsies would be avoided, at the cost of missing 40% of men with histological progression. In addition, at least half of biopsied men would have had negative findings for histological progression and thus would have undergone unnecessary biopsies. If histological progression was restricted to progression to ISUP grade group > 3, approximately 30% of histological progression would be missed and approximately 80% of the biopsies performed would be unnecessary. The use of the PRECISE criteria did not seem to change these results [510, 511]. This supports maintaining protocol-mandated follow-up biopsies during the course of AS.

However, several factors have been found to be associated with low re-classification rates and long PFS; negative baseline or follow-up MRI [505, 512-518], low PSA-D [505, 513, 515, 518], low PSA velocity [519, 520] or negative biopsy (i.e., no cancer at all) at confirmatory or follow-up biopsy [521]. In patients with stable (PRECISE 3) follow-up MRI, a low PSA-D may be associated with a low rate of progression [522]. Using these criteria, it might be possible, in the future, to create risk-based personalised AS biopsy schedules.

A Panel SR incorporating 263 surveillance protocols showed that 78.7% of protocols mandated per-protocol confirmatory biopsies within the first two yearsand that 57.7% of the protocols performed repeat biopsy at least every three years for ten years after the start of AS [491]. In another review it was concluded that a negative follow-up biopsy was associated with a 50% decrease in the risk of future reclassification and upgrading [523]. In a single-centre AS cohort of 514 patients who underwent at least three protocol-mandated biopsies after diagnosis (the confirmatory biopsy and at least two additional surveillance biopsies), men with one negative biopsy (i.e., no cancer at all) at confirmatory or second biopsy, or men with two consecutive negative biopsies had a lower likelihood of a positive third biopsy and significantly better 10-year treatmentfree survival [521]. This suggests that men with repetitive negative biopsies may pursue AS with at least less frequent untriggered biopsies.

6.3.1.1.5 Active Surveillance - change in treatment

Men may remain on AS whilst they continue to consent, have a life expectancy of > ten years and the disease remains indolent. Patient anxiety about continued surveillance occurs in around 10% of patients on AS [524] and was recognised as a valid reason for active treatment [330]. A thorough discussion on pros/cons of AS vs. active treatment already at the time of diagnosis is therefore of outmost importance. More common is the development of other comorbidities which may result in a decision to transfer to a WW strategy.

A PSA change alone (including PSA-DT < 3 years) should not change management based on its weak link with grade progression [527, 528] but rather trigger further investigation. There was clear agreement in the DETECTIVE consensus meeting that a change in PSA should lead to repeat-MRI and repeat-biopsy. It was also agreed that changes on follow-up MRI needed a confirmatory biopsy before considering active treatment [330].

However, the histopathology criteria required to trigger a change in management in the targeted biopsy era remain debated. Magnetic resonance imaging-targeted biopsy induces a grade shift and ISUP grade group 2–3 cancers detected by MRI-targeted biopsy have, on average, a better prognosis than those detected by systematic sampling (see Section 5.2.4.2.6.4). As an increasing number of men with favourable intermediate-risk disease are managed with AS (see section 6.2.2.1), it seems illogical to use progression to ISUP grade group 2 based on targeted biopsies as the sole criterion for reclassification. In addition, as acknowledged in the DETECTIVE consensus meeting, the number of positive cores is not an indicator of tumour volume anymore if targeted biopsies are performed [330, 529]. No agreement could be reached on the pathological criteria required to trigger a change in management during the DETECTIVE consensus meeting [330]. However, based on the findings of a SR incorporating 271 reclassification protocols, patients with low-volume ISUP grade group 2 disease at recruitment, and with increased systematic core positivity (> 3 cores involvement [> 50% per core]) on repeat systematic biopsies not using MRI, should be reclassified [491].

6.3.1.2 Alternatives to active surveillance

For patients with a life expectancy of < ten years (based on comorbidities and age), where curative treatment would not be an option in the case of progression, WW is SOC rather than AS.

In terms of alternatives to AS in the management of patients with low-risk disease there is some data from randomised studies. In the PIVOT trial (Section 6.1.1) which compared surgery vs. observation, only 42%

of patients had low-risk disease [482]. Sub-group analysis revealed that for low-risk disease there was no statistically significant difference in all-cause mortality between surgery vs. observation (RR: 0.93, 95% CI: 0.78–1.11). In the ProtecT study (Section 6.1.1) which compared the less organised strategy of "active monitoring" (i.e. repeat PSA management only) vs. surgery vs. EBRT, 66% of patients had a D'Amico low-risk disease [474]. The study found, after 15 years follow-up, no difference between the three arms in terms of OS and CSS, but AM had higher metastatic progression (9.4%) compared with surgery (4.7%) or EBRT (5.0%). There are no robust data comparing contemporary AS protocols with either surgery or EBRT in patients with low-risk disease. Active surveillance should be considered SOC in patients with low- to intermediate risk disease and a life expectancy > ten years. Surgery and EBRT should only be considered as alternatives to AS in patients suitable for such treatments after thorough information on pros and cons of AS and active treatment, and who after such information refuse or for some other reason are deemed unfit for AS, and who accept a trade-off between toxicity and prevention of disease progression.

Other treatments such as whole-gland ablative therapy (e.g. cryotherapy or HIFU) or focal ablative therapy remain unproven in the setting of localised low-risk disease compared with AS or radical treatment options and should not be used outside a trial setting or well-designed prospective cohort setting. These treatments are discussed in detail in Section 6.1.5.

6.3.1.2.1 Androgen deprivation monotherapy

Data regarding the use of ADT monotherapy in men with low-risk localised disease may be inferred indirectly from the Early Prostate Cancer (EPC) Trial Programme which published its findings in 2006 [764]. The EPC programme comprises three large RCTs including 8,113 men with localised (cT1–2, N0/NxM0) or locally advanced (cT3–4, any N; or any T, N+, M0) PCa. The intervention was oral bicalutamide 150 mg monotherapy vs. placebo following standard care (defined as RP, radical EBRT or WW). The primary endpoints were PFS and OS. Patients were stratified according to clinical stage only; data regarding PSA and GS were not assessed. The authors found in patients with localised disease, ADT monotherapy did not improve PFS nor OS in any of the subgroups, compared with placebo. Instead, there was a statistically insignificant numerical trend towards worse OS with ADT in the WW sub-group (HR: 1.16, 95% CI: 0.99–1.37; p = 0.07). Although the trial did not directly address men with low-risk disease, it offered some evidence suggesting that otherwise asymptomatic men with localised disease should not receive ADT monotherapy. A phase 2 RCT addressed a similar approach, where patients were randomised to enzalutamide plus AS or AS alone. This study indicated that PSA progression could be delayed, and the odds of a negative biopsy increased during the median follow-up time of 1.3 years, but patients had more side effects of the treatment without showing any long-term benefits of the treatment [765]. Hence, there is no evidence supporting the use of any hormonal treatment in asymptomatic men with low-risk disease who are not eligible for any local/radical treatment; these men should simply be offered AS or WW alone.

*6.3.1.3 Summary of evidence and guidelines for the management of low-risk disease**

Summary of evidence	**LE**
WW or AS is SOC, based on life expectancy.	2a
All active treatment options present a risk of over-treatment.	1a

Recommendations	**Strength rating**
Watchful Waiting	
Manage patients with a life expectancy < ten years by watchful waiting.	Strong
Active surveillance (AS)	
Manage patients with a life expectancy > ten years and low-risk disease by AS.	Strong
Selection of patients	
Patients with cribriform or intraductal histology on biopsy should be excluded from AS.	Strong
Perform magnetic resonance imaging (MRI) before a confirmatory biopsy if no MRI has been performed before the initial biopsy.	Strong
Take both targeted biopsy (of any PI-RADS ≥ 3 lesion) and systematic biopsy if a confirmatory biopsy is performed.	Strong
If MRI is not available, per-protocol confirmatory prostate biopsies should be performed.	Weak

If a patient has had upfront MRI followed by systematic and targeted biopsies there is no need for confirmatory biopsies.	Weak
Strategy of surveillance	
Repeat biopsies should be performed at least once every three years for ten years.	Weak
In case of prostate-specific antigen progression or change in digital-rectal exam-ination or MRI findings, do not progress to active treatment without a repeat biopsy.	Strong

6.3.2 Treatment of intermediate-risk disease

When managed with non-curative intent, intermediate-risk PCa is associated with 10-year and 15-year PCSM rates of 13.0% and 19.6%, respectively [841]. These estimates are based on systematic biopsies and may be overestimated in the era of MRI-targeted biopsies.

6.3.2.1 Active Surveillance

In the ProtecT trial, where 34% of the randomised patients had a D'Amico intermediate- or high-risk disease, there was no statistically significant difference in CSS at 15 years [474]. In the comprehensive characterisation of the patients in the ProtecT trial, treatment received, PSA, ISUP grade group at diagnosis, cT stage, risk group, number of PCa-involved biopsy cores, maximum length of tumour (median 5.0 vs. 3.0 mm), aggregate length of tumour (median 8.0 vs. 4.0 mm), and presence of perineural invasion were each associated with increased risk of disease progression ($p < 0.001$ for each). However, these factors could not reliably predict progression in individuals [487].

The outcomes of AS in intermediate-risk PCa has also been analysed in three SRs and meta-analyses, summarising available data on its oncological outcomes and comparing patients with intermediate-risk PCa to patients with low-risk disease [766-768]. The definition of AS was not strictly defined in either of the reviews: instead, the search strategies included 'active surveillance' as a search term, and no *a priori* study protocol was available. The primary outcome was the proportion of patients who remained on AS, whilst secondary outcomes included CSS, OS, and MFS in all three studies. In the first review 17 studies were included, incorporating 6,591 patients with intermediate risk disease. Sixteen studies included patients with low- and intermediate-risk disease, hence enabling comparative outcome assessment via pooled analysis. Only one study performed MRI at recruitment and during AS. There was significant clinical heterogeneity in terms of inclusion criteria for intermediate-risk disease. The results showed the proportion of patients who remained on AS was comparable between the low- and intermediate-risk groups after ten- and fifteen-years' follow-up (OR: 0.97, 95% CI: 0.83–1.14; and OR: 0.86, 95% CI: 0.65–1.13, respectively). Cancer-specific survival was worse in the intermediate-risk group after ten years (OR: 0.47, 95% CI: 0.31–0.69) and 15 years (OR: 0.34, 95% CI: 0.2–0.58). Overall survival was not statistically significantly different at five years' follow-up (OR: 0.84, 95% CI: 0.45–1.57) but was significantly worse in the intermediate-risk group after ten years (OR: 0.43, 95% CI: 0.35–0.53). Metastases-free survival did not significantly differ after five years (OR: 0.55, 95% CI: 0.2–1.53) but was worse in the intermediate-risk group after ten years (OR: 0.46, 95% CI: 0.28–0.77) [768]. The second review, including 25 studies and a total of 29,673 low- or intermediate-risk patients, showed similar results in terms of treatment-free survival at ten years (RR: 1.16, 95% CI: 0.99-1.36), risk of developing metastases (RR: 5.79, 95% CI: 4.61-7.29), risk of dying from PCa (RR: 3.93, 95% CI: 2.93-5.27) and risk of dying from any cause (RR: 1.44, 95% CI: 1.11-1.86) [766]. The third, most recent, review included 25 studies of which thirteen studies provided data on treatment free survival, six on CSS and seven on OS. Treatment free survival was not statistically significantly different in the intermediate risk group after 5 (RR: 0.92, 95% CI: 0.82-1.02), 10 (RR: 0.83, 95% CI: 0.55-1.23) or 15 years (RR: 0.54, 95% CI: 0.21-1.39). Cancer-specific survival was significantly lower after 15 years (RR: 0.92, 95% CI: 0.89-0.96) and OS was significantly lower after ten years (RR: 0.87, 95% CI: 0.82-0.93) in the intermediate risk group. It should be noted that many of the studies included patients with ISUP grade group 3 disease. When these studies were excluded no difference in treatment free, cancer specific or OS could be observed [767].

In a subgroup analysis of four studies comparing outcomes of patients with intermediate- and low-risk PCa of ISUP grade group ≤ 2 (n = 1,900) no statistically significant difference could be found in terms of treatment free survival or risk of developing metastases (RR: 1.03, 95% CI: 0.62-1.71 and RR: 2.09, 95% CI: 0.75-5.82, respectively). Both reviews indicate that AS in unselected intermediate-risk patients implies a higher risk of progression over time. It remains unclear whether this difference only reflects the inborne difference in outcome, that can also be seen when comparing immediate treatment of low- and intermediate-risk PCa, or if the delay in treatment caused any worsening of the outcomes in the intermediate-risk group in any way. All three reviews conclude that AS could be offered to patients with intermediate-risk disease, but they should be informed of a higher risk of progression and the latter two reviews suggests limiting the inclusion of intermediate-risk patients to those with low-volume ISUP grade group 2 disease.

A Canadian consensus group proposes that low volume ISUP grade group 2 (< 10% Gleason pattern 4 on systematic biopsies) may also be considered for AS. These recommendations have been endorsed by the ASCO [225] and the DETECTIVE study consensus [330] for those patients with a PSA < 10 ng/mL and low core positivity. The DETECTIVE Study concluded that men with favourable ISUP grade group 2 PCa (PSA < 10 ng/mL, low density, clinical stage ≤ cT2a and a low number of positive systematic cores) should also be considered for deferred treatment [330]. In this setting, re-biopsy within six to twelve months to exclude sampling error is even more relevant than in low-risk disease [492, 769]. The DETECTIVE Study-related qualitative SR aimed to determine appropriate criteria for inclusion of intermediate-risk disease into AS protocols [491]. Out of 371 AS protocols included in the review, more than 50% included patients with intermediate-risk disease on the basis of PSA up to 20 ng/mL (25.3%), ISUP grade group 2 or 3 (27.7%), clinical stage cT2b/c (41.6%) and/or direct use of D'Amico risk grouping of intermediate risk or above (51.1%). The DETECTIVE study reached consensus that patients with ISUP grade group 3, or patients with intraductal or cribriform histology, should not be considered for AS. The presence of any grade 4 pattern is associated with a 3-fold increased risk of metastases compared to ISUP grade group 1, while a PSA up to 20 ng/mL might be an acceptable threshold [769-771], especially in the context of low PSA-D. In addition, it is likely that MRI and targeted biopsies will detect small foci of Gleason grade 4 cancer that might have been missed with systematic biopsy. Therefore, care must be taken when explaining this treatment strategy, especially to patients with the longest life expectancy.

There is no clear consensus on how to interpret MRI and targeted biopsies for AS but the DETECTIVE study consensus was that if targeted biopsies based upon mpMRI images are performed, the number of positive cores of the targeted biopsies are not an indicator of the extent of disease or tumour volume. Indicator of the tumour volume may be either the number of positive cores, and the length of cancer in each core, based on systematic biopsies, or the volume of the dominant lesion seen on mpMRI [330].

In summary, AS can be considered in patients with a life expectancy of more than ten years and low-volume ISUP grade group 2 (defined as ≤ 3 positive systematic cores and ≤ 50% core involvement) or another single element of intermediate-risk disease (i.e. favourable intermediate-risk disease). Patients with ISUP grade group 3 disease, or patients with intraductal or cribriform histology, should be excluded. The monitoring schedule should be diligent, given the potential higher risk of progression, development of regional or distant metastases and death of this group compared with patients with low-risk disease. During monitoring, if repeat non-MRI-based systematic biopsies reveal > 3 positive cores or maximum CI > 50%/core of ISUP grade group 2 disease, patients should be reclassified (i.e., actively treated). For patients with a life expectancy of less than ten years, and not suitable for curative treatment, WW is a valid option and should be discussed with the patient.

6.3.2.2 Radical prostatectomy

Patients with intermediate-risk PCa should be informed about the results of two RCTs (SPCG-4 and PIVOT) comparing RRP vs. WW in localised PCa. In the SPCG-4 study, death from any cause (RR: 0.71, 95% CI: 0.53–0.95), death from PCa (RR: 0.38, 95% CI: 0.23–0.62) and distant metastases (RR: 0.49, 95% CI: 0.32–0.74) were significantly reduced in intermediate-risk PCa at 18 years. In the PIVOT trial, according to a pre-planned subgroup analysis among men with intermediate-risk tumours, RP significantly reduced all-cause mortality (HR: 0.69, 95% CI: 0.49–0.98), but not death from PCa (0.50, 95% CI: 0.21–1.21) at ten years. A meta-analysis based on the findings of SPCG-4, PIVOT and ProtecT demonstrated a benefit from RP over observation with a significantly decreased risk of death of 9% and of disease progression of 43% [772]. However, no stratification by disease stages was performed. The risk of having positive LNs in intermediate-risk PCa is between 3.7–20.1% [773]. A large study only found 2.9% of LN invasion in a contemporary cohort of 6,883 patients undergoing RP and LND for intermediate risk PCa [774]. Nerve sparing surgery is discussed in Section 6.1.2.3.5.

6.3.2.3 Radiation therapy

6.3.2.3.1 Recommended IMRT/VMAT for intermediate-risk PCa

Patients suitable for ADT can be given combined IMRT/VMAT with short-term ADT (four to six months) [775-777]. The RTOG 0815 RCT demonstrated improved BFSR, metastasis free and prostate CSS with the addition of six months ADT to dose escalated RT [685]. For adjuvant RT of the pelvic lymphatics (45-50 Gy) for NCCN unfavourable intermediate risk (cN0) see Section 6.2.3.2.1 - Radiotherapy for localised high-risk PCa. For patients unsuitable (e.g., due to comorbidities) or unwilling to accept ADT (e.g., to preserve their sexual health) the recommended treatment is IMRT/VMAT (76–78 Gy or equivalent moderate HFX) or a combination of IMRT/VMAT and BT as described below (see Section 6.2.2.3.2). A secondary analysis of the PCS III trial has suggested that patients with NCCN favourable intermediate-risk disease (see Section 4.4) can safely omit ADT if their RT dose is 76 Gy, but this is based on an unplanned subgroup analysis and only 138 patients had favourable intermediate-risk disease. An individual discussion between the physician and the patient of the possible benefits and harms of omitting ADT in this group is essential [778].

6.3.2.3.2 Brachytherapy for intermediate-risk PCa

Systematic review recommends LDR BT monotherapy can be offered to patients with NCCN favourable intermediate-risk disease and good urinary function (see Section 4.4) [779]. Fractionated HDR BT as monotherapy can be offered to selected patients with intermediate-risk PCa although they should be informed that results are only available from small series in very experienced centres. Five-year PSA control rates over 90% are reported, with late grade 3+ GU toxicity rates < 5% and no, or very minimal, grade 3+ GI toxicity rates [728]. There are no direct data to inform on the use of ADT in this setting. Trimodality therapy with IMRT plus BT boost and short-term ADT can be considered for NCCN unfavourable intermediate-risk PCa (see Section 4.4) but patients should be made aware that the potential improvements in biochemical control are accompanied with an increased risk of long-term urinary problems [717, 719, 724].

6.3.2.4 Other options for the primary treatment of intermediate-risk PCa (experimental therapies)

6.3.2.4.1 Focal therapy

A prospective study on focal therapy using HIFU in patients with localised intermediate-risk disease was published but the data was derived from an uncontrolled single-arm case series [750]. There is a paucity of high-certainty data for either whole-gland or focal ablative therapy in the setting of intermediate-risk disease. Consequently, neither whole-gland ablative treatment nor focal treatment can be considered as standard therapy for intermediate-risk patients and, if offered, it should only be in the setting of clinical trials or prospective registries [736].

6.3.2.4.2 Androgen deprivation therapy monotherapy

Data regarding the use of ADT monotherapy for intermediate-risk disease have been inferred indirectly from the EORTC 30891 trial, which was a RCT comparing deferred ADT vs. immediate ADT in 985 patients with T0–4 N0–2 M0 disease [773]. The trial showed a small, but statistically significant, difference in OS in favour of immediate ADT monotherapy but there was no significant difference in CSS, predominantly because the risk of cancer-specific mortality was low in patients with PSA < 8 ng/mL. Consequently, the use of ADT monotherapy for this group of patients is not considered as standard, even if they are not eligible for radical treatment.

*6.3.2.5 Guidelines for the treatment of intermediate-risk disease**

Recommendations	**Strength rating**
Watchful Waiting (WW)	
Offer WW in asymptomatic patients with life expectancy < ten years (based on comorbidities and age).	Strong
Active surveillance (AS)	
Offer AS to selected patients with ISUP grade group 2 disease (e.g. < 10% pattern 4, PSA < 10 ng/mL, ≤ cT2a, low disease extent on imaging and low extent of tu-mour in biopsies (≤ 3 positive cores with Gleason score 3+4 and ≤ 50% cancer involvement/core), or another single element of intermediate-risk disease with low disease extent on imaging and low biopsy extent, accepting the potential increased risk of metastatic progression.	Weak
Patients with ISUP grade group 3 disease should be excluded from AS protocols.	Strong
Re-classify patients with low-volume ISUP grade group 2 disease included in AS protocols, if repeat non-MRI-based systematic biopsies performed during moni-toring reveal > 3 positive cores or maximum CI > 50%/core of ISUP grade group 2 disease.	Weak
Radical prostatectomy (RP)	
Offer RP to patients with a life expectancy of > ten years.	Strong
Radical prostatectomy can be safely delayed for at least three months.	Weak
Offer nerve-sparing surgery to patients with a low risk of extra-capsular disease on that side.	Strong

Radiotherapeutic treatment	
Offer low-dose rate (LDR) brachytherapy to patients with good urinary function and NCCN favourable intermediate-risk disease.	Strong
Offer intensity-modulated radiotherapy (IMRT)/volumetric modulated arc therapy (VMAT) plus image-guided radiotherapy (IGRT), with a total dose of 76–78 Gy or moderate hypofractionation (60 Gy/20 fx in 4 weeks or 70 Gy/28 fx in 6 weeks), in combination with short-term androgen deprivation therapy (ADT) (four to six months).	Strong
Offer focal boosting to MRI-defined dominant intra-prostatic tumour when using conventionally fractionated IMRT/IGRT (1.8-2.0 Gy per fraction) ensuring that Organ at Risk constraints are not exceeded	Weak
Offer ultra-hypofractionated IMRT/IGRT or SBRT, using either 36.25 Gy (40 Gy to prostate) in 5 fx or 42.7 Gy in 7 fx delivered alternate days.	Weak
Offer LDR brachytherapy boost combined with IMRT/VMAT plus IGRT to pa-tients with good urinary function and NCCN unfavourable intermediate-risk disease, in combination with short-term ADT (four to six months).	Weak
Offer high-dose rate (HDR) brachytherapy boost combined with IMRT/VMAT plus IGRT to patients with good urinary function and NCCN unfavourable in-termediate-risk disease, in combination with short-term ADT (four to six months).	Weak
Other therapeutic options	
Only offer whole-gland ablative therapy (such as cryotherapy, high-intensity focused ultrasound, etc.) or focal ablative therapy within clinical trials or registries.	Strong
Do not offer ADT monotherapy to asymptomatic men not able to receive any local treatment.	Weak

**All recommendations are based on conventional imaging with isotope bone scan and CT/MR abdomen/pelvis.*

*6.3.3 **Treatment of high-risk localised disease***

Patients with high-risk PCa are at an increased risk of PSA failure, need for secondary therapy, metastatic progression and death from PCa. Nevertheless, not all high-risk PCa patients have a uniformly poor prognosis after RP [780]. When managed with non-curative intent, high-risk PCa is associated with 10-year and 15-year PCSM rates of 28.8 and 35.5%, respectively [781]. There is no consensus regarding the optimal treatment of men with high-risk PCa.

Some evidence suggests that radical treatment for high-risk PCa can be delayed up to three months after the diagnosis without any oncological consequences [782, 783]. Systematic reviews suggest that there is a higher risk of biochemical recurrence and worse pathological outcomes when definitive treatment is given beyond a 6 to 9 months delay. However, there is no conclusive data regarding stronger endpoints (CSS or OS).

6.3.3.1 Radical prostatectomy

Provided that the tumour is not fixed to the pelvic wall or there is no invasion of the urethral sphincter, RP is a standard option in selected patients with a low tumour volume. ePLND provides accurate LN staging. Pre-operative PSMA-PET/CT is more accurate for staging generally, but can miss smaller LNs (especially LNs <5mm). ePLND may also miss LN metastasis [539, 784]. Risks and benefits of pelvic LN dissection vs. PSMA PET/CT should be discussed with the patient pre-operatively. Patients should be aware pre-operatively that surgery may be part of multi-modal treatment, with adjuvant or SRT or ADT. Neoadjuvant therapy using ADT with or without new generation HT or docetaxel is not indicated. (See Section 6.1.2.2.4) [785, 786]. Nerve sparing management is discussed in Section 6.1.2.3.5.

At 15 years follow-up cN0 patients who undergo RP but who were found to have pN1 were reported to have an overall CSS and OS of 45% and 42%, respectively [787, 788]. A SR has reported 10-year BCR-free, CSS, and OS rates ranging from 28% to 56%, 72% to 98%, and 60% to 87.6%, respectively, in pN1 patients [789]. These findings highlight that pN1 patients represent a very heterogeneous patient group and further treatment must be individualised based on risk factors (see Sections 6.2.5.2 and 6.2.5.6).

6.3.3.2 External beam radiation therapy

For high-risk localised PCa, a combined modality approach should be used consisting of IMRT/VMAT plus long-term ADT. The duration of ADT has to take into account PS, comorbidities and the number of poor prognostic factors. It is important to recognise that in several studies EBRT plus short-term ADT did not improve OS in high-risk localised PCa and long-term ADT (at least 2 to 3 years) is currently recommended for these patients [677, 678, 689]. Moderate HFX is an option in selected high-risk patients with localised disease. The CHHiP study included 12% high-risk patients (n = 386) but limited entry to those with a PSA < 30 ng/mL and a Roach formula

risk of SV involvement < 30% [661]. Patients were ineligible if they had both T3a tumours and ISUP grade group 4 or higher.

6.3.3.2.1 Lymph node irradiation in cN0

There is no clear evidence for prophylactic irradiation of the pelvic LNs in intermediate- and high-risk disease. The long-term results of the NRG/RTOG 9413-trial which randomised intermediate-risk and high-risk localised PCa patients (1,322 cN0 patients were enrolled), showed that neoadjuvant HT plus whole pelvic RT improved PFS only compared with neoadjuvant ADT plus prostate RT and whole pelvic RT plus adjuvant ADT [790]. However, at the increased risk of ≥ grade 3 GI-toxicity.

A well-conducted single-centre RCT randomised 224 patients comparing prostate-only RT (PORT) vs. whole pelvic RT (WPRT) in localised high-risk- and locally-advanced tumours (cN0) with a risk of > 20% of positive nodes (Roach formula). With a median follow-up of 68 months there was a significant improvement of distant MFS (95.9% vs. 89.2%, HR: 0.35, p = 0.01) and DFS (89.5% vs.77.2%, p = 0.02). However, there was a significant higher rate of late GU ≥ 2 effects (17.7% vs. 7.5%, p = 0.02), the trial was relatively small in size with additional limitations and these findings are therefore insufficient to define a change in practice [791, 792]. The benefits of pelvic nodal irradiation using IMRT/VMAT merit further investigation in large scale RCTs as conducted by the RTOG or the UK National Cancer Research Institute (NCRI).

6.3.3.2.2 Brachytherapy boost

In men with NCCN unfavourable intermediate- or high-risk PCa, BT boost with supplemental EBRT and HT may be considered. See Sections 6.1.3.4.1 and 6.1.3.4.2 for details on RCTs comparing EBRT alone and EBRT with LDR or HDR boost, respectively.

6.3.3.3 Options other than surgery or radiotherapy for the primary treatment of localised PCa

Currently there is a lack of evidence supporting any other treatment option apart from RP and radical RT in localised high-risk PCa. The use of ADT monotherapy was addressed by the EORTC 30891 trial [773] (see Section 6.2.4.4.2). Immediate ADT may only benefit patients with a PSA-DT < twelve months, and either a PSA > 50 ng/mL or a poorly-differentiated tumour [773, 793].

*6.3.3.4 Guidelines for radical and palliative treatment of high-risk localised disease**

Recommendations	Strength rating
Watchful Waiting (WW)	
Offer WW to asymptomatic patients with life expectancy < ten years.	Strong
Radical prostatectomy (RP)	
Offer RP to selected patients as part of potential multi-modal therapy.	Weak
Extended pelvic lymph node dissection (ePLND)	
In patients undergoing a lymph node dissection you should perform an extended PLND.	Strong
Do not perform a frozen section of nodes during RP to decide whether to proceed with, or abandon, the procedure (see Section 6.2.4.1).	Strong
Radiotherapeutic treatment	
Offer patients intensity-modulated radiation therapy (IMRT)/volumetric modu-lated arc therapy (VMAT) plus image-guided radiation therapy (IGRT) with 76–78 Gy in combination with long-term androgen deprivation therapy (ADT) (2 to 3 years).	Strong
Offer focal boosting to MRI-defined dominant intra-prostatic tumour when using normo-fractionated IMRT/IGRT (1.8-2.0 Gy per fraction) ensuring that Organ at Risk constraints are not exceeded.	Weak
Offer patients with good urinary function IMRT/VMAT plus IGRT with brachy-therapy boost (either high-dose rate or low-dose rate), in combination with long-term ADT (2 to 3 years).	Weak
Therapeutic options outside surgery or radiotherapy	
Do not offer either whole gland or focal therapy.	Strong
Only offer ADT monotherapy to those patients unwilling or unable to receive any form of local treatment if they have a prostate-specific antigen (PSA)-doubling time < twelve months, and either a PSA > 50 ng/mL or a poorly-differentiated tumour.	Strong

**All recommendations are based on conventional imaging with isotope bone scan and CT/MR abdomen/pelvis.*

6.3.4 *Treatment of locally-advanced PCa*

In the absence of high-level evidence, a SR could not define the most optimal treatment option [794]. Randomised controlled trials are only available for EBRT. A local treatment combined with a systemic treatment provides the best outcome, provided the patient is fit enough to receive both. The initial results of the SCPG-15 trials suggested that randomisation between surgery and EBRT is feasible, but oncologic outcomes are awaited [795].

6.3.4.1 *Radical prostatectomy*

Surgery for locally-advanced disease as part of a multi-modal therapy has been reported [781, 796, 797]. However, the comparative oncological effectiveness of RP as part of a multi-modal treatment strategy vs. upfront EBRT with ADT for locally-advanced PCa remains unknown, although a prospective phase III RCT (SPCG-15) comparing RP (with or without adjuvant or salvage EBRT) against primary EBRT and ADT among patients with locally-advanced (T3) disease is currently recruiting [798]. Data from retrospective case series demonstrated over 60% CSS at 15 years and over 75% OS at ten years [781, 796, 797, 799-802]. For cT3b–T4 disease, PCa cohort studies showed 10-year CSS of over 87% and OS of 65% [803, 804]. The indication for RP in all previously described stages assumes the absence of clinically detectable nodal involvement (cN0), based on conventional imaging. In case of suspected positive LNs during RP (initially considered cN0) the procedure should not be abandoned since RP may have a survival benefit in these patients. Intra-operative frozen section analysis is not justified in this case [541].

6.3.4.2 *Treatment of cN1 M0 PCa*

Lymph-node metastasised PCa is an entity where options for local therapy and systemic therapies overlap. Approximately 5% to 10% of newly diagnosed PCa patients have synchronous suspected pelvic nodal metastases on conventional imaging (CT/bone scan) without bone or visceral metastases (cN1 M0 stage). Meta-analyses have shown that PSMA-PET/CT prior to primary treatment in advanced PCa detected disease outside the prostate in 32% of cases despite prior negative conventional imaging using bone scan and pelvic CT/MRI [412]. A RCT assessing PSMA-PET/CT as staging tool in high-risk PCa confirmed these findings and showed a 32% increase in accuracy compared with conventional imaging for the detection of pelvic nodal metastases [429]. Notably, more sensitive imaging also caused a stage shift with more cases classified as miN1, but with, on average, lower nodal disease burden.

The management of cN1M0 PCa is historically based on long-term ADT combined with a local treatment. The benefit of adding local treatment has been assessed in various retrospective studies, summarised in one SR [805] including five studies only [806-810]. The results of this SR were confirmed [811]. The findings of this retrospective analysis suggested an advantage in both OS and CSS after local treatment (RT or RP) combined with ADT as compared to ADT alone. Only limited evidence exists supporting RP for cN1 patients. Moschini *et al.*, compared the outcomes of 50 patients with cN+ with those of 252 patients with pN1, but cN0 at pre-operative staging. cN+ was not a significant predictor of CSS [812].

The addition of a brachytherapy boost to ADT plus EBRT was not associated with improved OS in a retrospective study of 1,650 cN1 patients after multivariable adjustment and propensity score matching [813].

The intensification of systemic treatment (abiraterone acetate, docetaxel, zoledronic acid) has been assessed in unplanned sub-group analyses from the STAMPEDE multi-arm RCT by stratifying for cN1 and M1 status [809, 814]. The analyses were balanced for nodal involvement and for planned RT use in STAMPEDE at randomisation and at analysis. Abiraterone acetate was associated with a non-significant OS improvement (HR: 0.75, 95% CI: 0.48–1.18) in non-metastatic patients (N0/N+M0), but OS data were still immature with a low number of events. Furthermore, this was an underpowered subgroup analysis and hypothesis generating at best. Moreover, subgroup analyses were performed according to the metastatic/non-metastatic status and to the nodal status (any M) without specific data for the N1M0 population (n = 369; 20% of the overall cohort). The same would apply for the docetaxel arm in the STAMPEDE trial for which no specific subgroup analysis of newly diagnosed N1M0 PCa (n = 171, 14% of the overall cohort) was performed. However, the addition of docetaxel, zoledronic acid, or their combination, did not provide any OS benefit when stratifying by M0 and N+ status.

In the AFU-GETUG 12 trial comparing the impact of docetaxel plus estramustine in addition to ADT, 29% of included high-risk non-metastatic PCa patients had a nodal involvement (pN1) at randomisation [815]. A non-significant trend towards better relapse-free survival rates was reported in the treatment arm (HR 0.66; 86 0.43–1.01) without OS benefit. A meta-analysis of docetaxel trials in N0/N1-M0 patients concluded to an 8% 4-year survival advantage for docetaxel compared with ADT alone in terms of failure-free survival without OS benefit [816]. Two RCTs from the STAMPEDE platform protocol reported on men with *de novo* high-risk/locally-

advanced M0 disease, or relapse after primary curative therapy with high-risk features. Thirty-nine percent of patients (n = 774) were N1 on conventional imaging [817]. Radiotherapy in addition to long-term ADT was administered in 71% of these patients. Given the MFS and OS benefits observed in the overall population (see Section 6.3.4.2), combined ADT (for 3 years) and additional abiraterone (for 2 years) should be a SOC in cN1 patients in addition to prostate- and WPRT.

Table 6.3.4.1: Selected studies assessing local treatment in (any cT) cN1 M0 prostate cancer patients

Study	n	Design	Study period/ follow-up	Treatment arms	Effect on survival
Bryant, *et al.* 2018 [818]	648	Retrospective (National Veterans Affairs)	2000-2015 61 mo.	ADT ± EBRT	Significant benefit for combined treatment only if PSA levels less than the median (26 ng/mL) All-cause mortality HR: 0.50 CSS, HR: 0.38
Sarkar, *et al.* 2019 [819]	741	Retrospective (National Veterans Affairs)	2000-2015 51 mo.	ADT ± local treatment (surgery or RT)	Significant benefit for RP All cause mortality HR 0.36 CSS, HR: 0.32 No statistical difference for RP vs. RT (p ≥ 0.1) All-cause mortality HR: 047 CSS, HR: 0.88
Lin, *et al.* 2015 [807]	983 before propensity score matching	Retrospective (NCDB)	2004-2006 48 mo.	ADT ± EBRT	Significant benefit for combined treatment 5-yr OS: 73% vs. 52% HR: 0.5
Tward, *et al.* 2013 [806]	1,100	Retrospective (SEER)	1988-2006 64 mo.	EBRT (n = 397) vs. no EBRT (n = 703) No information on ADT)	Significant benefit for EBRT 5-yr CSS 78% vs. 71% HR: 0.66 5-yr. OS: 68% vs. 56%, HR: 0.70
Rusthoven, *et al.* 2014 [810]	796	Retrospective (SEER)	1995-2005 61 mo.	EBRT vs. no EBRT (no information on ADT)	Significant benefit for EBRT 10-yr OS: 45% vs. 29% HR: 0.58
Seisen, *et al.* 2018 [808]	1,987	Retrospective (NCDB)	2003-2011 50 mo.	ADT ± local treatment (surgery or RT)	Significant benefit for combined treatment 5-yr OS: 78.8% vs. 49.2% HR: 0.31 No difference between RP and RT
James, *et al.* 2016 [809]	177	Unplanned sub-group analysis RCT	2005-2014 17 mo.	ADT ± EBRT	Significant benefit for combined treatment 5-yr OS: 93% vs. 71% 2-yr FFS: 81% vs 53% FFS, HR: 0.48

ADT = androgen deprivation therapy; CSS = cancer-specific survival; EBRT = external beam radiotherapy; FFS = failure-free survival; HR = hazard ratio; mo = months; n = number of patients; OS = overall survival; RP = radical prostatectomy; RT = radiotherapy; yr = year.

6.3.4.3 Options other than surgery or radiotherapy for primary treatment

6.3.4.3.1 Investigational therapies

Currently cryotherapy, HIFU or focal therapies have no place in the management of locally-advanced PCa.

6.3.4.3.2 Androgen deprivation therapy monotherapy

The deferred use of ADT as single treatment modality has been answered by the EORTC 30891 trial [773]. Nine hundred and eighty-five patients with T0–4 N0–2 M0 PCa received ADT alone, either immediately or after symptomatic progression or occurrence of serious complications. After a median follow-up of 12.8 years, the OS favoured immediate treatment (HR: 1.21, 95% CI: 1.05–1.39). Surprisingly, no different disease-free or symptom-free survival was observed, raising the question of survival benefit. In locally-advanced T3–T4 M0 HSPC unsuitable for surgery or RT, immediate ADT may only benefit patients with a PSA > 50 ng/mL and a PSA-DT < twelve months or those that are symptomatic [773, 793]. The median time to start deferred treatment was 7 years. In the deferred treatment arm 25.6% of patients died without needing treatment.

*6.3.4.4 Guidelines for radical- and palliative treatment of locally-advanced disease**

Recommendations	Strength rating
Radical prostatectomy (RP)	
Offer RP to patients with cN0 disease as part of multi-modal therapy.	Weak
Extended pelvic lymph node dissection (ePLND)	
In patients undergoing a lymph node dissection you should perform an extended PLND.	Strong
Radiotherapeutic treatments	
Offer patients with cN0 disease intensity-modulated radiation therapy (IMRT)/volumetric modulated arc therapy (VMAT) plus image-guide radiation therapy in combination with long-term androgen deprivation therapy (ADT).	Strong
Offer patients with cN0 disease and good urinary function, IMRT/VMAT plus IGRT with brachytherapy boost (either high-dose rate or low-dose rate), in combination with long-term ADT.	Weak
Offer long-term ADT for at least 2 years.	Strong
Offer IMRT/VMAT plus IGRT to the prostate in combination with long-term ADT and two years of abiraterone to cN0M0 patients with ≥ 2 high-risk factors (cT3-4, Gleason ≥ 8 or PSA ≥ 40 ng/mL).	Strong
Offer IMRT/VMAT plus IGRT to the prostate plus pelvis in combination with long-term ADT and two years of abiraterone to cN1M0 patients.	Strong
Therapeutic options outside surgery or radiotherapy	
Do not offer whole gland treatment or focal treatment.	Strong

**All recommendations are based on conventional imaging with isotope bone scan and CT/MR abdomen/pelvis.*

*6.3.5 **Adjuvant treatment after radical prostatectomy***

6.3.5.1 Introduction

Adjuvant treatment is by definition additional to the primary or initial therapy with the aim of decreasing the risk of relapse, despite the apparent full control following surgery. A post-operative detectable PSA is an indication of persistent prostate cells (see Section 6.3.6). All information listed below refers to patients with a post-operative undetectable PSA.

6.3.5.2 Risk factors for relapse

Patients with ISUP grade group > 2 in combination with EPE (pT3a) and particularly those with SV invasion (pT3b) and/or positive surgical margins are at high risk of progression, which can be as high as 50% after five years [820]. Irrespective of the pT stage, the number of removed nodes [821-828], tumour volume within the LNs and capsular perforation of the nodal metastases are predictors of early recurrence after RP for pN1 disease [829]. A LN density (defined as 'the percentage of positive LNs in relation to the total number of analysed/removed LNs') of over 20% was found to be associated with poor prognosis [830]. The number of involved nodes seems to be a major factor for predicting relapse [823, 824, 831]; the threshold considered is less than 3 positive nodes from an ePLND [540, 823, 831]. However, prospective data are needed before defining a definitive threshold value.

6.3.5.2.1 Biomarker-based risk stratification after radical prostatectomy

The Decipher® gene signature consists of a 22-gene panel representing multiple biological pathways and was developed to predict systemic progression after definitive treatment. A meta-analysis of five studies analysed the performance of the Decipher® Genomic Classifier (GC) test on men post-RP. The authors showed in multivariable analysis that Decipher® GC remained a statistically significant predictor of metastasis (HR: 1.30, 95% CI: 1.14–1.47, p < 0.001) per 0.1 unit increase in score and concluded that it can independently improve prognostication of patients post-RP within nearly all clinicopathologic, demographic, and treatment subgroups [832]. A SR of the evidence for the Decipher® GC has confirmed the clinical utility of this test in post-RP decision-making [833]. Further studies are needed to establish how to best incorporate Decipher® GC in clinical decision-making.

6.3.5.3 Immediate (adjuvant) post-operative external irradiation after RP (cN0 or pN0)

Four prospective RCTs have assessed the role of immediate post-operative RT (adjuvant RT [ART]) (undetectable PSA mostly defined as PSA < 0.1 ng/mL), demonstrating an advantage (endpoint, development of BCR) in high-risk patients (e.g., pT2 with positive surgical margins and ISUP grade group 3–5 or pT3/4 with- or without positive surgical margins and ISUP grade group 3–5) post-RP (Table 6.3.5.1). In the ARO 96-02 trial, 80% of the pT3/R1/GS 8–10 patients randomised to observation developed BCR within ten years [834]. It must be emphasised that PSA was undetectable at inclusion only in the ARO 96-02 trial which presents a major limitation interpreting these findings as patients with a detectable PSA would now be considered for salvage therapy rather than ART [834].

Table 6.3.5.1: Overview of all four randomised trials for adjuvant surgical bed radiation therapy after RP* (without ADT)

Study	n	Inclusion criteria	Randomisation	Definition of BCR PSA (ng/mL)	Median FU (mo)	Biochemical Progression-free survival	Overall survival
SWOG 8794 2009 [835]	431	pT3 cN0 ± involved SM	60-64 Gy vs. observation	> 0.4	152	10 yr.: 53% vs. 30% (p < 0.05)	**10 yr.: 74% vs. 66%** Median time: 15.2 vs. 13.3 yr., p = 0.023
EORTC 22911 2012 [836]	1,005	pT3 ± involved SM pN0 pT2 involved SM pN0	60 Gy vs. observation	> 0.2	127	10 yr.: 60.6% vs. 41% (p < 0.001)	**81% vs. 77% n.s.**

**See Section 6.3.5.1 for delayed (salvage) post-radical prostatectomy external irradiation.*
BCR = biochemical recurrence; FU = follow-up; mo = months; n = number of patients; n.s. = not significant; OS = overall survival; PSA = prostate-specific antigen; RP = radical prostatectomy; SM = surgical margin; SRT = salvage radiotherapy.

6.3.5.4 Comparison of adjuvant- and salvage radiotherapy

Two retrospective matched studies (510 and 149 patients receiving ART) failed to show an advantage for MFS [838, 839]. However, both studies were underpowered for high-risk patients (pT3b/R1/ISUP grade group 4–5 PCa). In contrast to these studies, a propensity score-matched retrospective analysis of two cohorts of 366 pT3 and/or R1 patients found that compared to SRT at a PSA between 0.1 and 0.5 ng/mL, ART given at an undetectable PSA (< 0.1 ng/mL) improved all three endpoints; BCR, MFS, and OS [840].

Both approaches (ART and early SRT) together with the efficacy of adjuvant ADT are compared in three prospective RCTs: the Medical Research Council (MRC) Radiotherapy and Androgen Deprivation In Combination After Local Surgery (RADICALS) trial [841], the Trans-Tasman Oncology Group (TROG) Radiotherapy Adjuvant Versus Early Salvage (RAVES) trial [842], and the Groupe d'Etude des Tumeurs Uro- Genitales (GETUG-AFU 17) trial [843]. In addition, a pre-planned meta-analysis of all three trials has been published (Table 6.3.5.2) [844].

Two trials closed early after randomising 333/470 patients (RAVES) and 424/718 (GETUG-AFU-17) patients. RADICALS-RT included 1,396 patients with the option of subsequent inclusion in RADICALS-HT; 154/649 (24%) of patients starting in the adjuvant RT group also received neoadjuvant or adjuvant HT; 90 patients for six months/45 for 2 years/19 patients outside RADICALS-HT. From the SRT group, 61/228 (27%) received neoadjuvant or adjuvant HT for six months (n = 33) and two years (n = 13). Fifteen of these patients were treated outside the trial [841]. All men in the GETUG-AFU-17 trial (n = 424) received six months of HT. All together, 684 out of 2,153 patients received additional ADT for at least six months across both trials [844]. Radiotherapy to the pelvic lymphatics was allowed in the GETUG-AFU and in the RADICALS-RT trials.

The primary endpoint for RAVES and GETUG-AFU 17 was biochemical PFS, and for RADICALS-RT MFS. So far only PFS data has been reported, and not MFS- or OS data. With a median follow-up between 4.9 years and 6.25 years there was no statistically significant difference for biochemical PFS for both treatments in all three trials (see Table 6.2.5.2) indicating that in the majority of patients adjuvant irradiation should be avoided. Additionally, there was a significant lower rate of grade ≥ 2 GU late side effects and grade 3–4 urethral strictures in favour of early SRT; which may also be caused by the low number of patients with PSA-progression and subsequent need for early SRT at the time of analysis (40% of patients).

It is important to note that the indication for ART changed over the last ten years with the introduction of ultra-sensitive PSA-tests, favouring early SRT. Therefore many patients, randomised in these three trials (accruing 2006–2008) are not likely to benefit from ART as there is a low risk of biochemical progression (~20–30%) in, for example, pT3R0 or pT2R1-tumours. The median pre-SRT PSA in all 3 trials was 0.24 ng/mL. Therefore, patients with 'low-risk factors' of biochemical progression after RP should be closely followed up with ultra-sensitive assays and SRT should be discussed if needed as soon as PSA starts to rise, which has to be confirmed by a second PSA measurement (see Section 6.3). The proportion of patients with adverse pathology at RP (ISUP grade group 4–5 and pT3 with or without positive margins) in all three trials was low (between 10–20%) and therefore even the meta-analysis may be underpowered to show an outcome in favour of SRT [844]. In addition, the side-effect profile may have been impacted with a larger proportion of ART patients receiving treatment with older 3D-treatment planning techniques as compared to SRT patients (GETUG-AFU 17: ART, 69% 3D vs. 46% SRT) and patients treated more recently were more likely to undergo IMRT techniques with a proven lower rate of late side effects [634].

For these reasons, 10-year OS and MFS endpoints results should be awaited before drawing final conclusions. Due to the small number of patients with adverse pathology (ISUP grade group 4–5 and pT3) included in these three trials (between 10–20%), ART remains a recommended treatment option in highly selected patients with adverse pathology ('high-risk patients') i.e. ISUP grade group 4–5 and pT3 with or without positive margins [845, 846]. This recommendation was supported by a published retrospective multi-centre study comparing ART and SRT in patients with high-risk features (pN1 or ISUP grade group 4–5 and pT3/4-tumours) after RP [847]. After a median follow-up of 8.2 years of the 26,118 men included in the study, 2,104 patients died, 25.62% from PCa (n = 539) and 2,424 patients had adverse pathology compared with 23.694 who did not. After excluding men with persistent PSA after RP, ART when compared with early SRT showed a significantly lower acute mortality risk (p = 0.02, HR: 0.33).

Table 6.3.5.2: Overview of all three randomised trials and one meta-analysis for patients treated with adjuvant vs. early salvage RT after RP

Study	n	Inclusion criteria	Randomisation	Definition of BCR PSA (ng/mL)	Median FU (yr)	BPFS	OS or MFS	Side effects

ART = adjuvant radiotherapy; BCR = biochemical recurrence; BPFS = biochemical progression-free survival; ED = erectile dysfunction; FU = follow-up; Fx = fraction; GU = genito-urinary; LHRH = luteinising hormonereleasing hormone; LT = late toxicity; mo = months; med = median; MFS = metastasis-free survival; n.r. = not reported; OS = overall survival; PSA = prostate-specific antigen; RP = radical prostatectomy; RT = radiotherapy; SRT = salvage radiotherapy; + = positive; yr = year.

6.3.5.5 Adjuvant systemic therapy in N0 disease

Adjuvant androgen ablation with bicalutamide 150 mg daily did not improve PFS in localised disease while it did for locally-advanced disease after RT. However, this never translated to an OS benefit [848]. A SR showed a possible benefit for PFS but not OS for adjuvant androgen ablation [786].

The TAX3501 trial comparing the role of leuprolide (18 months) with and without docetaxel (6 cycles) ended prematurely due to poor accrual. A phase III RCT comparing adjuvant docetaxel against surveillance after RP for locally-advanced PCa showed that adjuvant docetaxel did not confer any oncological benefit [849]. Consequently, adjuvant chemotherapy after RP should only be considered in a clinical trial [850].

6.3.5.6 Adjuvant treatment in pN1 disease

6.3.5.6.1 Adjuvant androgen ablation alone

The combination of RP and early adjuvant HT in pN+ PCa has been shown to achieve a 10-year CSS rate of 80% and has been shown to significantly improve CSS and OS in prospective RCTs [851, 852]. However, these trials included mostly patients with high-volume nodal disease and multiple adverse tumour characteristics and these findings may not apply to men with less extensive nodal metastases.

6.3.5.6.2 Adjuvant radiotherapy combined with ADT in pN1 disease

In a retrospective multi-centre cohort study, maximal local control with RT to the prostatic fossa appeared to be beneficial in PCa patients with pN1 after RP, treated 'adjuvantly' with continuous ADT (within six months after surgery irrespective of PSA). The beneficial impact of adjuvant RT on survival in patients with pN1 PCa was highly influenced by tumour characteristics. Men with low-volume nodal disease (< 3 LNs), ISUP grade group 2–5 and pT3–4 or R1, as well as men with 3 to 4 positive nodes were more likely to benefit from RT after surgery, while the other subgroups did not [853]. In contrast, a retrospective multi-centre study including 1,614 patients and a median follow-up of 7,02 years assessed ART + ADT. Adjuvant RT compared to SRT was associated with a decreased all-cause mortality and this reduction increased with each additional positive pelvic LN, from the first one on and the highest effect was for more than 3 positive nodes [854]. These data are in agreement with a US National Cancer Database analysis based on 5,498 patients [855]. Another US National Cancer Database study including 8,074 pN1 patients reports improved OS after ADT plus EBRT (including pelvic LNs) vs. observation and vs. ADT alone in all men with single or multiple adverse pathological features. Men without any adverse pathological features did not benefit from immediate adjuvant therapy [856].

In a SR of the literature, RT with or without ADT was associated with improved survival in men with locally-advanced disease and a higher number of positive nodes [789]. Radiotherapy to the pelvic lymphatics and the prostate fossa plus long-term ADT can be offered to patients with pN1 disease. [853, 857]. However, the optimal duration of ADT is still unkown.

6.3.5.6.3 Observation of pN1 patients after radical prostatectomy and extended lymph node dissection

Several retrospective studies and a SR addressed the management of patients with pN1 PCa at RP [789, 831, 853, 857, 858]. A subset of patients with limited nodal disease (1–2 positive LNs) showed favourable oncological outcomes and did not require additional treatment.

An analysis of 209 pN1 patients with one or two positive LNs at RP showed that 37% remained metastasis-free without need of salvage treatment at a median follow-up of 60.2 months [858]. Touijer *et al.*, reported their results of 369 pN1-positive patients (40 with and 329 without adjuvant treatment) and showed that higher pathologic grade group and > 3 positive LNs were significantly associated with an increased risk of BCR on multivariable analysis [831]. Biochemical-free survival rates in pN1 patients without adjuvant treatment ranged from 43% at four years to 28% at ten years [789]. Reported CSS rates were 78% at five years and 72% at ten years. The majority of these patients were managed with initial observation after surgery, had favourable disease characteristics, and 63% had only one positive node [789]. Initial observation followed by early salvage treatment at the time of recurrence may represent a safe option in selected patients with a low disease burden [789].

*6.3.5.7 Guidelines for adjuvant treatment for pN0 and pN1 disease after radical prostatectomy**

Recommendations	Strength rating
Do not prescribe adjuvant androgen deprivation therapy (ADT) to pN0 patients.	Strong
In pN0 patients with ISUP grade group 4–5 and pT3 ± positive margins, offer adjuvant intensity-modulated radiation therapy (IMRT)/volumetric modulated arc therapy (VMAT) plus image-guided radiation therapy (IGRT).	Strong
In pN1 patients, after an extended lymph node dissection, discuss three management options, based on nodal involvement characteristics: 1. Offer adjuvant ADT; 2. Offer adjuvant ADT with additional IMRT/VMAT plus IGRT; 3. Offer observation (expectant management) to a patient after eLND and ≤ 2 nodes and a PSA < 0.1 ng/mL.	Weak

**All recommendations are based on conventional imaging with isotope bone scan and CT/MR abdomen/pelvis.*

*6.3.6 **Persistent PSA after radical prostatectomy***

Between five and 20% of men continue to have detectable or persistent PSA after RP (when defined in the majority of studies as detectable post-RP PSA of ≥ 0.1 ng/mL within 4 to 8 weeks of surgery) [859, 860]. It may result from persistent local disease, pre-existing metastases or residual benign prostate tissue.

6.3.6.1 Natural history of persistently elevated PSA after RP

Several studies have shown that persistent PSA after RP is associated with more advanced disease (such as positive surgical margins, pathologic stage ≥ T3a, positive nodal status and/or pathologic ISUP grade group > 3) and poor prognosis. Initially defined as ≥ 0.1 ng/mL, improvements in the sensitivity of PSA assays now allow for the detection of PSA at much lower levels.

Moreira *et al.*, demonstrated that failure to achieve a PSA of less than 0.03 ng/mL within six months of surgery was associated with an increased risk of BCR and overall mortality [861, 862]. However, since the majority of the published literature is based on the 0.1 ng/mL PSA cut-off, there is significantly more longterm data for this definition. Predictors of PSA persistence were higher BMI, higher pre-operative PSA and ISUP grade group ≥ 3 [862]. In patients with PSA persistence, one and 5-year BCR-free survival were 68% and 36%, compared to 95% and 72%, respectively, in men without PSA persistence [861]. Ten-year OS in patients with and without PSA persistence was 63% and 80%, respectively.

Spratt *et al.*, confirmed that a persistently detectable PSA after RP represents one of the worst prognostic factors associated with oncological outcome [863]. Of 150 patients with a persistent PSA, 95% received RT before detectable metastasis. In a multi-variable analysis the presence of a persistently detectable PSA post-RP was associated with a 4-fold increase in the risk of developing metastasis. This was confirmed by data from Preisser *et al.*, who showed that persistent PSA is prognostic of an increased risk of metastasis and death [864]. At 15 years after RP, MFS rates, OS and CSS rates were 53.0 vs. 93.2% (p < 0.001), 64.7 vs. 81.2%

(p < 0.001) and 75.5 vs. 96.2% (p < 0.001) for persistent vs. undetectable PSA, respectively. The median follow-up was 61.8 months for patients with undetectable PSA vs. 46.4 months for patients with persistent PSA. In multivariable Cox regression models, persistent PSA represented an independent predictor for metastasis (HR: 3.59, p < 0.001), death (HR: 1.86, p < 0.001) and cancer-specific death (HR: 3.15, p < 0.001).

However, not all patients with persistent PSA after RP experience disease recurrence. Xiang *et al.*, showed a 50% 5-year BCR-free survival in men who had a persistent PSA level > 0.1 but ≤ 0.2 ng/mL at 6–8 weeks after RP [865].

Rogers *et al.*, assessed the clinical outcome of 160 men with a persistently detectable PSA level after RP [866]. No patient received adjuvant therapy before documented metastasis. In their study, 38% of patients had no evidence of metastases for ≥ 7 years while 32% of the patients were reported to develop metastases within 3 years. Noteworthy is that a significant proportion of patients had low-risk disease. In multi-variable analysis the PSA slope after RP (as calculated using PSA levels 3 to twelve months after surgery) and pathological ISUP grade group were significantly associated with the development of distant metastases.

6.3.6.2 Imaging in patients with persistently elevated PSA after RP

Standard imaging with bone scan and MRI has a low detection rate in men with a PSA below 2 ng/mL. However, PSMA PET/CT has been shown to identify residual cancer with positivity rates of 33%, 46%, 57%, 82%, and 97%, in men with post-RP PSA ranges of 0–0.19, 0.2–0.49, 0.5–0.99, 1–1.99, and ≥ 2 ng/mL, respectively [867-872] which can guide SRT planning [873]. Based on these post-RP PSA ranges, Schmidt-Hegemann *et al.*, studied 129 patients who had either persistent PSA (52%) or BCR (48%) after RP, showing that men with a persistent PSA had significantly more pelvic nodal involvement on PSMA PET/CT than those developing a detectable PSA [874]. In a multi-centre retrospective study including 191 patients, ^{68}Ga-PSMA localised biochemical persistence after RP in more than two-thirds of patients with high-risk PCa features. The obturator and presacral or mesorectal nodes were identified as high risk for residual disease [875]. Another retrospective study included 150 patients with persistent PSA after RARP who were re-staged with both ^{68}Ga-PSMA and ^{18}F-DCFPyL PSMA. The authors found that in the presence of persistent PSA the majority of patients already had metastatic pelvic LNs or distant metastases which would support a role of PSMA PET/ CT imaging in guiding (salvage) treatment strategies [876]. At present there is uncertainty regarding the best treatment if PSMA PET/CT shows metastatic disease outside the pelvis.

6.3.6.3 Impact of post-operative RT and/or ADT in patients with persistent PSA

The benefit of SRT in patients with persistent PSA remains unclear due to a lack of RCTs, however, it would appear that men with a persistent PSA do less well than men with BCR undergoing RT.

Preisser *et al.*, compared oncological outcomes of patients with persistent PSA who received SRT vs. those who did not [864]. In the subgroup of patients with persistent PSA, after 1:1 propensity score matching between patients with SRT vs. no RT, OS rates at ten years after RP were 86.6 vs. 72.6% in the entire cohort (p < 0.01), 86.3 vs. 60.0% in patients with positive surgical margin (p = 0.02), 77.8 vs. 49.0% in pT3b disease (p < 0.001), 79.3 vs. 55.8% in ISUP grade group 1 disease (p < 0.01) and 87.4 vs. 50.5% in pN1 disease (p < 0.01), respectively. Moreover, CSS rates at ten years after RP were 93.7 vs. 81.6% in the entire cohort (p < 0.01), 90.8 vs. 69.7% in patients with positive surgical margin (p = 0.04), 82.7 vs. 55.3% in pT3b disease (p < 0.01), 85.4 vs. 69.7% in ISUP grade group 1 disease (p < 0.01) and 96.2 vs. 55.8% in pN1 disease (p < 0.01), for SRT vs. no RT, respectively. In multivariable models, after 1:1 propensity score matching, SRT was associated with lower risk of death (HR: 0.42, p = 0.02) and lower cancer-specific death (HR: 0.29, p = 0.03). These survival outcomes in patients with persistent PSA who underwent SRT suggest they benefit but outcomes are worse than for men experiencing BCR [877].

It is clear from a number of studies that poor outcomes are driven by the level of pre-RT PSA, the presence of ISUP grade group ≥ 4 in the RP histology and pT3b disease [878-883]. Fossati *et al.*, suggested that only men with a persistent PSA after RP and ISUP grade group ≤ 3 benefit significantly [884], although this is not supported by Preisser *et al.* [864]. The current data do not allow making any clear treatment decisions.

Addition of ADT may improve PFS [879]. Choo *et al.*, studied the addition of 2-year ADT to immediate RT to the prostate bed in patients with pT3 and/or positive surgical margins after RP [879]. Twenty-nine of the 78 included patients had persistently detectable post-operative PSA. The relapse-free rate was 85% at five years and 68% at 7 years, which was superior to the 5-year progression-free estimates of 74% and 61% in the post-operative RT arms of the EORTC and the SWOG studies, respectively, which included patients with undetectable PSA after RP [835, 836]. Patients with persistently detectable post-operative PSA comprised approximately 50% and 12%, respectively, of the study cohorts in the EORTC and the SWOG studies.

In the ARO 96-02, a prospective RCT, 74 patients with PSA persistence (20%) received immediate SRT only (66 Gy per protocol [arm C]). The 10-year clinical relapse-free survival was 63% [878]. The GETUG-22 trial comparing RT with RT plus short-term ADT for post-RP PSA persistence (0.2–2.0 ng/mL) reported good tolerability of the combined treatment. The oncological endpoints are yet to be published [885].

Two SRs addressing persistent PSA confirmed a strong correlation of PSA persistence with poor oncologic outcomes [859, 860]. Ploussard *et al.*, also reported that SRT was associated with improved survival outcomes, although the available evidence is of low quality [860].

6.3.6.4 Conclusion

The available data suggest that patients with PSA persistence after RP may benefit from early aggressive multi-modality treatment, however, the lack of prospective RCTs makes firm recommendations difficult.

6.3.6.5 Recommendations for the management of persistent PSA after radical prostatectomy

Recommendations	Strength rating
Offer a prostate-specific membrane antigen (PSMA) positron emission tomography/ computed tomography (PET/CT scan to men with a persistent prostate-specific antigen (PSA) > 0.2 ng/mL if the results will influence subsequent treatment decisions.	Weak
Treat men with no evidence of metastatic disease with salvage radiotherapy and additional hormonal therapy.	Weak

6.4 Management of PSA-only recurrence after treatment with curative intent

Follow-up will be addressed in Chapter 7 and is not discussed in this section.

*6.4.1 **Background***

Between 27% and 53% of all patients undergoing RP or RT develop a rising PSA (PSA recurrence). Whilst metastatic progression is universally preceded by rising PSA levels, physicians must inform the patient that the natural history of PSA-only recurrence may be prolonged and that a measurable PSA may not necessarily lead to clinically apparent metastatic disease. Physicians treating patients with PSA-only recurrence face a difficult set of decisions in attempting to delay the onset of metastatic disease and death while avoiding overtreating patients whose disease may never affect their OS or QoL. It should be emphasised that the treatment recommendations for these patients should be given after discussion in a multi-disciplinary team.

6.4.1.1 PSA velocity and doubling time

Various PSA kinetics definitions have been proposed with different methods of calculation (log transformed or not) and eligible PSAs:

- PSA velocity (PSAV): absolute annual increase in serum PSA (ng/mL/year);
- PSA doubling time (PSA-DT): which measures the exponential increase in serum PSA over time.

Prostate-specific antigen velocity is more simple to calculate by subtracting the initial value from the final value, dividing by time. However, by ignoring middle values, not all PSA values are accurately taken into account.

Prostate-specific antigen-DT is calculated assuming an exponential rise in serum PSA. The formula takes into account the natural logarithm of 2 divided by the slope obtained from fitting a linear regression of the natural log of PSA over time [886]. However, many different PSA-DT calculations have been assessed according to the mathematical formula used and to the included PSA values (number, time period, intervals) [887]. For example, the 'MSKCC' method calculates a regression slope integrating all PSA values. Other methods transform PSA before calculating the slope and do not include all PSA values (different time frames and minimal intervals) [888]. O'Brien and colleagues identified more than 20 different definitions of PSAV and PSA-DT and demonstrated that obtained values could vary widely between definitions [888].
However, some rules can be considered for PSA-DT calculation [886]:

- At least 3 PSA measurements are required;
- A minimum time period between measurements (4 weeks) is preferable due to potential
- statistical 'noise' when PSA values are obtained too close together (this statement can be
- reconsidered in case of very active disease);
- All included PSA values should be obtained within the past twelve months at most, to reflect the current disease activity;
- PSA-DT is often mentioned in months, or in weeks in very active disease.

These measurements do not provide additional information compared with PSA alone [479, 888-890]. In the post-local therapy relapse setting, PSA-DT has been correlated with distant progression and with poorer outcomes after salvage treatments [891, 892]. Prostate-specific antigen-DT has been linked with metastasis-free- and OS in non-metastatic CRPC (nmCRPC) and identifies patients with high-risk nmCRPC who benefit from intensified therapy (PSA-DT threshold < ten months) [893].

6.4.2 Controversies in the definitions of clinically relevant PSA relapse

The PSA level that defines treatment failure depends on the primary treatment. Patients with rising PSA after RP or primary RT have different risks of subsequent symptomatic metastatic disease based on various parameters, including the PSA level. Therefore, physicians should carefully interpret BCR endpoints when comparing treatments. Clinicians should interpret a PSA rise in light of the EAU BCR risk groups (see Section 6.3.3).

After RP, the threshold that best predicts further metastases is a PSA > 0.4 ng/mL and rising [894-896]. However, with access to ultra-sensitive PSA testing, a rising PSA much below this level will be a cause for concern for patients.

After primary RT, with or without short-term hormonal manipulation, the RTOG-ASTRO Phoenix Consensus Conference definition of PSA failure (with an accuracy of > 80% for clinical failure) is 'any PSA increase > 2 ng/mL higher than the PSA nadir value, regardless of the serum concentration of the nadir' [897].

After HIFU or cryotherapy no endpoints have been validated against clinical progression or survival; therefore, it is not possible to give a firm recommendation of an acceptable PSA threshold after these alternative local treatments [898].

6.4.3 Natural history of biochemical recurrence

Once a PSA recurrence has been diagnosed, it is important to determine whether the recurrence has developed at local or distant sites. A SR and meta-analysis investigated the impact of BCR on clinical endpoints and concluded that patients experiencing BCR are at an increased risk of developing distant metastases, PCa-specific and overall mortality [898]. However, the effect size of BCR as a risk factor for mortality is highly variable. After primary RP its impact ranges from HR 1.03 (95% CI: 1.004–1.06) to HR 2.32 (95% CI: 1.45–3.71) [899, 900]. After primary RT, OS rates are approximately 20% lower at eight to ten years follow-up even in men with minimal co-morbidity [901, 902]. Still, the variability in reported effect sizes of BCR remains high and suggests that only certain patient subgroups with BCR might be at an increased risk of mortality.

The risk of subsequent metastases, PCa-specific- and overall mortality may be predicted by the initial clinical and pathologic factors (e.g., T-category, PSA, ISUP grade group) and PSA kinetics (PSA-DT and interval to PSA failure), which was further investigated by the SR [898].

For patients with BCR after RP, the following outcomes were found to be associated with significant prognostic factors:

- distant metastatic recurrence: positive surgical margins, high RP specimen pathological ISUP grade group, high pT category, short PSA-DT, high pre-SRT PSA;
- prostate-cancer-specific mortality: high RP specimen pathological ISUP grade group, short interval to biochemical failure as defined by investigators, short PSA-DT;
- overall mortality: high RP specimen pathological ISUP grade group, short interval to biochemical failure, high PSA-DT.

For patients with BCR after RT, the corresponding outcomes are:

- distant metastatic recurrence: high biopsy ISUP grade group, high cT category, short interval to biochemical failure;
- prostate-cancer-specific mortality: short interval to biochemical failure;
- overall mortality: high age, high biopsy ISUP grade group, short interval to biochemical failure, high initial (pre-treatment) PSA.

Based on this meta-analysis, proposal is to stratify patients into two risk categories since not all patients with BCR will have similar outcomes (see Table 6.4.1). The stratification into 'EAU Low-Risk' or 'EAU High-Risk' BCR after RP has recently been validated in a European cohort [903].

Table 6.4.1: EAU risk categories for patients developing biochemical recurrence

	EAU Low Risk BCR	EAU High Risk BCR
After RP	PSA-DT > 1 yr AND pathological ISUP grade group < 4	PSA-DT ≤ 1 yr OR pathological ISUP grade group 4–5
After RT	interval to biochemical failure > 18 mo AND biopsy ISUP grade group < 4	interval to biochemical failure ≤ 18 mo OR biopsy ISUP grade group 4–5

*6.4.4 **The role of imaging in PSA-only recurrence***

Imaging is only of value if it leads to a treatment change which results in an improved outcome. In practice, however, there are very limited data available regarding the outcome's consequent on imaging at recurrence.

6.4.4.1 Assessment of metastases (including nodal)

6.4.4.1.1 Bone scan and abdominopelvic CT

Because BCR after RP or RT precedes clinical metastases by seven to eight years on average [825, 904], the diagnostic yield of conventional imaging techniques (bone scan and abdominopelvic CT) is low in asymptomatic patients [905]. In men with PSA-only recurrence after RP the probability of a positive bone scan is < 5%, when the PSA level is < 7 ng/mL [906, 907]. Only 11–14% of patients with BCR after RP have a positive CT [906]. In a series of 132 men with BCR after RP the mean PSA level and PSA velocity associated with a positive CT were 27.4 ng/mL and 1.8 ng/mL/month, respectively [908].

6.4.4.1.2 Choline PET/CT

In two different meta-analyses the combined sensitivities and specificities of choline PET/CT for all sites of recurrence in patients with BCR were 86–89% and 89–93%, respectively [909, 910]. Choline PET/CT may detect multiple bone metastases in patients showing a single metastasis on bone scan [911] and may be positive for bone metastases in up to 15% of patients with BCR after RP and negative bone scan [912]. The specificity of choline PET/CT is also higher than bone scan, with fewer false positive and indeterminate findings [416]. Detection of LN metastases using choline PET/CT remains limited by the relatively poor sensitivity of the technique (see Section 5.3.2.3). Choline PET/CT sensitivity is strongly dependent on the PSA level and kinetics [424, 913, 914]. In patients with BCR after RP, PET/CT detection rates are only 5–24% when the PSA level is < 1 ng/mL but rise to 67–100% when the PSA level is > 5 ng/mL. Despite its limitations, choline PET/CT may change medical management in 18–48% of patients with BCR after primary treatment [915-917].

Choline PET/CT should only be recommended in patients fit enough for curative loco-regional salvage treatment.

6.4.4.1.3 Fluoride PET/CT

^{18}F-NaF PET/CT has a higher sensitivity than bone scan in detecting bone metastases [918]. However, ^{18}F -NaF PET/CT is limited by a relative lack of specificity and by the fact that it does not assess soft-tissue metastases [919].

6.4.4.1.4 Fluciclovine PET/CT

^{18}F-Fluciclovine PET/CT has been approved in the U.S. and Europe and it is therefore one of the PCa-specific radiotracers widely commercially available [919-922].

^{18}F-Fluciclovine PET/CT has a slightly higher sensitivity than choline PET/CT in detecting the site of relapse in BCR [923]. In a multi-centre trial evaluating 596 patients with BCR in a mixed population, fluciclovine PET/CT showed an overall detection rate of 67.7%; lesions could be visualised either at local level (38.7%) or in pelvic LNs (32.6%) [924]. As for choline PET/CT, fluciclovine PET/CT sensitivity is dependent on the PSA level, with a sensitivity likely inferior to 50% at PSA level < 1 ng/mL.

In a prospective RCT evaluating the impact of ^{18}F-fluciclovine PET/CT on SRT management decisions in patients with recurrence post-prostatectomy, in 28 of 79 (35.4%) patients overall radiotherapeutic management changed following ^{18}F-fluciclovine PET/CT [925]. ^{18}F-Fluciclovine PET/CT had a significantly higher positivity rate than conventional imaging (abdominopelvic CT or MRI plus bone scan) for whole body (79.7% vs. 13.9%, p < 0.001), prostate bed (69.6% vs. 5.1%, p < 0.001), and pelvic LNs (38.0% vs. 10.1%, p < 0.001) [925]. However, as yet, no data demonstrating that these changes translate into a survival benefit are available.

6.4.4.1.5 Prostate-specific membrane antigen based PET/CT

PSMA PET/CT has shown good potential in patients with BCR, although most studies are limited by their retrospective design. Reported predictors of ^{68}Ga-PSMA PET in the recurrence setting were updated based on a high-volume series (see Table 6.4.2) [867]. High sensitivity (75%) and specificity (99%) were observed on per-lesion analysis.

Table 6.4.2: PSMA-positivity separated by PSA level category [867]

PSA (ng/mL)	^{68}Ga-PMSA PET positivity
< 0.2	33% (CI: 16–51)
02–0.49	45% (CI: 39–52)
0.5–0.99	59% (CI: 50–68)
1.0–1.99	75% (CI: 66–84)
2.0+	95% (CI: 92–97)

PSA = prostate-specific antigen; ^{68}Ga-PSMA PET = Gallium-68 prostate-specific membrane antigen positron emission tomography.

PSMA PET/CT seems substantially more sensitive than choline PET/CT, especially for PSA levels < 1 ng/mL [926, 927]. In a study of 314 patients with BCR after treatment and a median PSA level of 0.83 ng/mL, ^{68}Ga-PSMA PET/CT was positive in 197 patients (67%) [928]. In another prospective multi-centre trial including 635 patients with BCR after RP (41%), RT (27%), or both (32%), PPV for ^{68}Ga-PSMA PET/CT was 0.84 (95% CI: 0.75–0.90) by histopathologic validation (primary endpoint, n = 87) and 0.92 (95% CI: 0.75–0.90) by a composite reference standard. Detection rates significantly increased with PSA value [929].

A prospective multi-centre, multi-reader, open-label, phase II/III trial (OSPREY) evaluated the diagnostic performance of ^{18}F-DCFPyL in patients with presumptive radiologic evidence of recurrent or metastatic PCa on conventional imaging [837]. Median sensitivity and median PPV were 95.8% (95% CI: 87.8%–99.0%) and 81.9% (95% CI: 73.7%–90.2%), respectively.

Another prospective study evaluated the diagnostic performance of 18F-DCFPyL in 208 men with BCR after RP or RT. The primary endpoint, the correct localisation rate was achieved, demonstrating positive findings on 18F-DCFPyL PET/CT in the setting of negative standard conventional imaging [930]. At present there are no conclusive data about comparison of such tracers [931].

A prospective, open label, cross-over study, the PYTHON trial, has compared the per-patient detection rates (DR) of ^{18}F-DCFPyL versus 18F-fluoromethylcholine PET/CT, in biochemical recurrence (BCR) setting. A total of 201 high-risk PCa patients with first BCR after radical prostatectomy or radiation therapy have completed the study. The per-patient DR was significantly higher for ^{18}F-DCFPyL compared to ^{18}F-fluoromethylcholine PET/CT (58% (117/201 patients) vs. 40% (81/201 patients), p < 0.0001). DR increased with higher PSA values for both tracers (PSA ≤ 0.5 ng/ml: 26/74 (35%) vs. 22/74 (30%); PSA 0.5 to ≤ 1.0 ng/ml: 17/31 (55%) vs. 10/31 (32%); PSA 1.01 to < 2.0 ng/ml: 13/19 (68%) vs. 6/19 (32%);PSA > 2.0: 50/57 (88%) vs. 39/57 (68%) for ^{18}FDCFPyL- and ^{18}F-fluoromethylcholine -PET/CT, respectively) [932]. Comparable results were found in a phase III trial of ^{18}F-PSMA-1007 versus 18F-Fluorocholine PET/CT for the localisation of prostate cancer biochemical recurrence. In this prospective, randomised, crossover multi-centre study, the overall correct detection rates were significantly higher for ^{18}F-PSMA-1007 than for ^{18}F-fluorocholine when undetermined findings were considered positive for malignancy (0.82 vs. 0.65; p < 0.0001) [933].

6.4.4.1.6 Whole-body and axial MRI

Whole body MRI has not been widely evaluated in BCR because of its limited value in the detection of early metastatic involvement in normal-sized LNs [414, 427, 934]. In a prospective series of 68 patients with BCR, the diagnostic performance of DW-MRI was significantly lower than that of ^{68}Ga-PSMA PET/CT and ^{18}NaF PET/CT for diagnosing bone metastases [935].

6.4.4.2 Assessment of local recurrences

6.4.4.2.1 Local recurrence after radical prostatectomy

Because the sensitivity of anastomotic biopsies is low, especially for PSA levels < 1 ng/mL [905], SRT is usually decided on the basis of BCR without histological proof of local recurrence. The dose delivered to the prostatic fossa tends to be uniform since it has not been demonstrated that a focal dose escalation at the site of recurrence improves the outcome. Therefore, most patients undergo SRT without local imaging.

Magnetic resonance imaging can detect local recurrences in the prostatic bed. The PSA threshold for MRI positivity seems between 0.3 and 0.5 ng/mL; PSA kinetics also influence the MRI positivity, even at low PSA values [936]. Two single-centre studies found that a negative MRI was an independent predictor of failure of SRT [937, 938]. Conversely, a small (≤0.4 cc) relapse located at the vesico-urethral anastomosis is associated with excellent prognosis at salvage RT [939]. The Prostate Imaging for Recurrence Reporting (PI-RR) system has been recently launched to standardise MRI interpretation in the context of BCR after RP or RT [940]. Initial assessment suggests good reproducibility of the score [941].

Choline PET/CT is less sensitive for local relapse than MRI but detects more regional and distant metastases [942].

The detection rates of ^{68}Ga-PSMA PET/CT in patients with BCR after RP increase with the PSA level [943]. PSMA PET/CT studies showed that a substantial part of recurrences after RP were located outside the prostatic fossa, even at low PSA levels [868, 944]. Combining ^{68}Ga-PSMA PET and MRI may improve the detection of local recurrences, as compared to ^{68}Ga-PSMA PET/CT alone [945-947].

The EMPIRE-1, a single-centre, open-label, phase II/III RCT included 365 patients with detectable PSA after RP, but negative results on conventional imaging. They were randomised to RT directed by conventional imaging alone or to conventional imaging plus ^{18}F-fluciclovine-PET/CT; patients with M1 disease in the PET/CT group (n = 4) were excluded Patients with cN1 were irradiated to the pelvic nodes, but without a boost to the metastases. After a median follow-up of 3.5 years, the PET/CT group was significantly associated with longer event-free survival (HR: 2.04, 95% CI: 1.06–3.93, p = 0.0327) [948].

6.4.4.2.2 Local recurrence after radiation therapy

In patients with BCR after RT, biopsy status is a major predictor of outcome, provided the biopsies are obtained 18–24 months after initial treatment. Given the morbidity of local salvage options it is necessary to obtain histological proof of the local recurrence before treating the patient [905].

MRI has yielded excellent results in identifying local recurrence and can be used for biopsy targeting and guiding local salvage treatment [905, 949, 950], even if it slightly underestimates the volume of the local recurrence [951]. Prostate-specific membrane antigen PET/CT can also detect local recurrences after RT [867] and concordance between PSMA PET/CT and MRI is highly suggestive of cancer recurrence [952].

6.4.4.3 Summary of evidence of imaging in case of biochemical recurrence

In patients with BCR imaging can detect both local recurrences and distant metastases, however, the sensitivity of detection depends on the PSA level. After RP, PSMA PET/CT is the imaging modality with the highest sensitivity at low PSA levels (< 0.5 ng/mL) and may help distinguishing patients with recurrences confined to the prostatic fossa from those with distant metastases which may impact the design and use of post-RP SRT. After RT, MRI has shown excellent results at detecting local recurrences and guiding prostate biopsy. Given the substantial morbidity of post-RT local salvage treatments, distant metastases must be ruled out in patients with local recurrences and who are fit for these salvage therapies. Choline-,fluciclovine- or PSMA-PET/CT can be used to detect metastases in these patients but for this indication PSMA PET/CT seems the most sensitive technique.

6.4.4.4 Summary of evidence and guidelines for imaging in patients with biochemical recurrence

Recommendations	Strength rating
Prostate-specific antigen (PSA) recurrence after radical prostatectomy	
Perform prostate-specific membrane antigen (PSMA) positron emission tomography/ computed tomography (PET/CT) if the PSA level is > 0.2 ng/mL and if the results will influence subsequent treatment decisions (EAU BCR risk groups).	Weak
In case PSMA PET/CT is not available, and the PSA level is ≥ 1 ng/mL, perform fluciclovine PET/CT or choline PET/CT imaging if the results will influence subsequent treatment decisions.	Weak
PSA recurrence after radiotherapy	
Perform prostate magnetic resonance imaging to localise abnormal areas and guide biopsies in patients fit for local salvage therapy.	Weak
Perform PSMA PET/CT (if available) or fluciclovine PET/CT or choline PET/CT in patients fit for curative salvage treatment.	Strong

6.4.5 *Treatment of PSA-only recurrences*

The timing and treatment modality for PSA-only recurrences after RP or RT remain a matter of controversy based on the limited evidence.

6.4.5.1 *Treatment of PSA-only recurrences after radical prostatectomy*

6.4.5.1.1 Salvage radiotherapy for PSA-only recurrence after radical prostatectomy (cTxcN0M0, without PET/CT)

Early SRT provides the possibility of cure for patients with an increasing PSA after RP. Boorjian *et al.*, reported a 75% reduced risk of systemic progression with SRT when comparing 856 SRT patients with 1,801 non-SRT patients [953]. The RAVES and RADICAL trials assessing SRT in post-RP patients with PSA levels exceeding 0.1–0.2 ng/mL showed 5-year freedom from BCR and BCR-free survival rates of 88% [841, 954]. Tilki *et al.* demonstrated the results of a matched pair analysis of 1832 patients with BCR, 32.9% (n = 603) received SRT without ADT, 1229 (67,1%) had a observational strategy. The median follow-up was 95.9 months. Median total SRT dose was 70.2 Gy. After 1:1 propensity score matching, at fiveteen years after RP, MFS and OS rates were 84.3 versus 76.9% (p < 0.001) and 85.3 versus 74.4% (p = 0.04) for SRT and noRT, respectively [955].

The PSA level at BCR was shown to be prognostic [953]. More than 60% of patients who are treated before the PSA level rises to > 0.5 ng/mL will achieve an undetectable PSA level [956-958], corresponding to a ~80% chance of being progression-free five years later [959]. A retrospective analysis of 635 patients who were followed after RP and experienced BCR and/or local recurrence and either received no salvage treatment (n = 397) or SRT alone (n = 160) within two years of BCR showed that SRT was associated with a 3-fold increase in PCa-specific survival relative to those who received no salvage treatment (p < 0.001). Salvage RT has been shown to be effective mainly in patients with a short PSA-DT [960].

In a retrospective multi-centre study including 25,551 patients with at most one high-risk factor after RP (ISUP grade group 4-5 or pT3/4), initiating sRT above a PSA level of 0.25 ng/mL was associated with increased ACM-risk. After a median follow-up of six years, patients who received sRT at a PSA level >0.25 ng/mL had a significantly higher ACM-risk (AHR, 1.49; 95% CI, 1.11 to 2.00; P =.008) compared with men who received sRT when the PSA was ≤0.25 mg/mL [961]. For an overview of SRT see Table 6.4.3.

The EAU BCR definitions have been externally validated and may be helpful for individualised treatment decisions [898, 903]. Despite the indication for salvage RT, a 'wait and see' strategy remains an option for the EAU BCR 'Low-Risk' group [898, 903].

Although biochemical progression is now widely accepted as a surrogate marker of PCa recurrence; metastatic disease, disease-specific and OS are more meaningful endpoints to support clinical decision-making. A SR and meta-analysis on the impact of BCR after RP reports SRT to be favourable for OS and PCSM. In particular SRT should be initiated in patients with rapid PSA kinetics after RP and with a PSA cut-off of 0.4 ng/mL [898]. An international multi-institutional analysis of pooled data from RCTs has suggested that MFS is the most valid surrogate endpoint with respect to impact on OS [962, 963]. Table 6.4.4 summarises results of recent studies on clinical endpoints after SRT.

Table 6.4.3: Selected studies of post-prostatectomy salvage radiotherapy, stratified by pre-salvage radiotherapy PSA level* (cTxcN0M0, without PET/CT)

Study	n	Median FU (mo)	pre-SRT PSA (ng/mL) median	RT dose ADT	bNED/PFS (year)	5-yr. results
Bartkowiak, *et al.* 2018 [964]	464	71	0.31	66.6 Gy	54% (5.9)	73% vs. 56%; PSA < 0.2 vs. ≥ 0.2 ng/mL p < 0.0001
Stish, *et al.* 2016 [956]	1,106	107	0.6	68 Gy 16% ADT	50% (5) 36% (10)	44% vs. 58%; PSA ≤ 0.5 vs. > 0.5 ng/mL p < 0.001
Tendulkar, *et al.* 2016 [965]	2,460	60	0.5	66 Gy 16% ADT	56% (5)	Pre-SRT PSA 71% 0.01–0.2 ng/mL 63% 0.21–0.5 ng/mL 54% 0.51–1.0 ng/mL 43% 1.01–2.0 ng/mL 37% > 2.0 ng/mL p < 0.001

Tilki *et al.* 2023 [961]	25,551 SRT at: PSA <0.25 N=1,556 PSA>0.25 N=1.677 No RT: N=21,645	72	Not given	Med. 68.4 Gy SRT+ADT:1489 ART:N= 673 ADT: 208	Not given	ACM (six years): HR 1.49 of higher risk when SRT at start was >0.25 (p=0.008)

**Androgen deprivation therapy can influence the outcome 'biochemically no evidence of disease (bNED)' or 'progression-free survival'. To facilitate comparisons, 5-year bNED/PFS read-outs from Kaplan-Meier plots are included.*

ADT = androgen deprivation therapy; bNED = biochemically no evidence of disease; FU = follow up; mo = months; n = number of patients; PFS = progression-free survival; PSA = prostate-specific antigen; SRT = salvage radiotherapy; yr = year.

Table 6.4.4: Selected studies reporting clinical endpoints after SRT (cTxcN0M0, without PET/CT) (the majority of included patients did not receive ADT)

Study	n	Median FU (mo)	Regimen	Outcome
Bartkowiak, *et al.* 2018 [964]	464	71	66.6 (59.4-72) Gy no ADT	5.9 yr. OS post-SRT PSA < 0.1 ng/mL 98% post-SRT PSA ≥ 0.1 ng/mL 92% p = 0.005
Jackson, *et al.* 2014 [966]	448	64	68.4 Gy no ADT	5 yr. DM post-SRT PSA < 0.1 ng/mL 5% post-SRT PSA ≥ 0.1 ng/mL 29% p < 0.0001 5 yr. DSM post-SRT PSA < 0.1 ng/mL 2% post-SRT PSA ≥ 0.1 ng/mL 7% p < 0.0001 OS post-SRT PSA < 0.1 ng/mL 97% post-SRT PSA ≥ 0.1 ng/mL 90% p < 0.0001

ADT = androgen deprivation therapy; DM = distant metastasis; DSM = disease specific mortality; FU = follow up; mo. = month; n = number of patients; OS = overall survival; PSA = prostate specific antigen; SRT = salvage radiotherapy.

6.4.5.1.2 Salvage radiotherapy combined with androgen deprivation therapy (cTxcN0, without PET/CT)

Data from RTOG 9601 suggest both CSS and OS benefit when adding two years of bicalutamide (150 mg o.d.) to SRT [967]. According to GETUG-AFU 16 also 6-months treatment with a LHRH-analogue can significantly improve 10-year BCR, biochemical PFS and, modestly, MFS. However, SRT combined with either goserelin or placebo showed similar DSS and OS rates [968]. In addition, Pollack *et al.*, reported on the results of a randomised 3-arm phase III trial (NRG Oncology/RTOG 0534 SPPORT) adding six months treatment with a LHRH-analogue to SRT of the prostate bed (PBRT) (group 2) compared with PBRT alone (group 1) or the former combination with PBRT-RT and pelvic LN RT (PLNRT) (group 3) [969]. The primary endpoint was freedom from progression (FFP) after five years. However, using the phoenix-definition of biochemical progression (nadir + 2 ng/mL used for definitive RT), and not the criterion of nadir + 0.2, as is used commonly (but without clear evidence) will have resulted in a later diagnosis of progression in the SPPORT trial.

With a median follow-up of 8.2 years of the surviving patients FFP increased significant for group 3 (87.4%) compared with group 2 (81.3%) ($p = 0.0027$) and group 1 (70.9%) ($p < 0.0001$) The difference between group 2 and group 1 was also significant ($p < 0.0001$). Distant metastasis incidence rates were lowest in group 3 and were lower compared with group 1 (PBRT only, HR: 0.52) similar to the rate of PCa deaths (HR: 0.51). No significant difference was seen for OS. There was a significantly higher risk of both acute- and late side effects in group 3. Therefore, the role of additional PLNRT remains unclear and should be further proven in RCTs including PSMA PET-CT [970]. Table 6.4.5 provides an overview of these three RCTs.

These RCTs support adding ADT to SRT. However, when interpreting these data it has to be kept in mind that RTOG 9601 used outdated radiation dosages (< 66 Gy) and technique. The question with respect to the patient risk profile, whether to offer combination treatment or not, and the optimal combination (LHRH or bicalutamide) remains, as yet, unsolved. The EAU BCR risk classification may offer guidance in this respect [898].

One of these RCTs reports improved OS (RTOG 96-01) and the other (GETUG-AFU 16) improved MFS but due to methodological discrepancies and also related to follow-up and risk, it is, as yet, not evident which patients should receive ADT, which type of ADT, and for how long. Men at high risk of further progression (e.g., with a PSA ≥ 0.7 ng/mL and GS ≥ 8) may benefit from SRT combined with two years of ADT; for those at lower risk (e.g., PSA < 0.7 ng/mL and GS = 8) SRT combined with six months of ADT may be sufficient. Men with a low-risk profile (PSA < 0.5 ng/mL and GS < 8) may receive SRT alone. In a sub-analysis of men with a PSA of 0.61 to 1.5 (n = 253) there was an OS benefit associated with antiandrogen assignment (HR: 0.61, 95% CI: 0.39–0.94) [971]. In those receiving early SRT (PSA 0.6 ng/mL, n = 389), there was no improvement in OS (HR: 1.16, 95% CI: 0.79–1.70), with increased other-cause mortality (sub-distribution HR: 1.94, 95% CI: 1.17–3.20, p = 0.01) and increased odds of late grades 3–5 cardiac and neurologic toxic side effects (OR: 3.57, 95% CI: 1.09–15.97, p = 0.05). These results suggest that pre-SRT PSA level may be a prognostic biomarker for outcomes of anti-androgen treatment with SRT. In patients receiving late SRT (PSA > 0.6 ng/mL), HT was associated with improved outcomes. In men receiving early SRT (PSA < 0.6 ng/mL), long-term anti-androgen treatment was not associated with improved OS [971].

A SR addressing the benefit from combining HT with SRT suggested risk stratification of patients based on the pre-SRT PSA (< 0.5, 0.6–1, > 1 ng/mL), margin status and ISUP grade as a framework to individualise treatment [972].

Table 6.4.5: Randomised controlled trials comparing salvage radiotherapy combined with androgen deprivation therapy vs. salvage radiotherapy alone

ADT = androgen deprivation therapy; DM = distant metastasis; DSM = disease specific mortality; PFS = progression free survival; FFP = Freedom From Progression; FU = follow-up; LHRH = luteinising hormone-releasing hormone; MFS = metastasis-free survival; OS = overall survival; PFS = progression-free survival; mo = months; n = number of patients; RT = radiotherapy; yr = year, PBRT = prostate bed radiotherapy; PLNRT = pelvic lymph node radiotherapy.

6.4.5.1.2.1 Target volume, dose, toxicity

There have been various attempts to define common outlines for 'clinical target volumes' for pN0 PCa [973, 974] and for organs at risk of normal tissue complications [973]. However, given the variations of techniques and dose-constraints, a satisfactory consensus has not yet been achieved. A benefit in biochemical PFS but not MFS has been reported in patients receiving whole pelvis SRT (± ADT) but the advantages must be weighed against possible side effects [970]. This is supported by data from the SPPORTTrial (NRG Oncology/RTOG 0534 SPPORT) but it remains controversial [969].

The optimal SRT dose has not been well defined. It should be at least 64 Gy to the prostatic fossa (± the base of the SVs, depending on the pathological stage after RP) [846, 957, 975]. In a SR, the pre- SRT PSA level and SRT dose both correlated with BCR, showing that relapse-free survival decreased by 2.4% per 0.1 ng/mL PSA and improved by 2.6% per Gy, suggesting that the treatment dose above 70 Gy should be administered at the lowest possible PSA level [976]. The combination of pT stage, margin status and ISUP grade group and the PSA at SRT seems to define the risk of biochemical progression, metastasis and overall mortality [838, 977, 978]. In a study on 894 node-negative PCa patients, doses ranging from 64 to > 74 Gy were assigned to twelve risk groups defined by their pre-SRT PSA classes < 0.1, 0.1–0.2, 0.2–0.4, and > 0.4 ng/mL and ISUP grade group < 1 vs. 2/3 vs. > 4 [979]. The updated Stephenson nomograms incorporate the SRT and ADT doses as predictive factors for biochemical failure and distant metastasis [965].

Two RCT's were published (Table 6.4.6). Intensity-modulated radiation therapy plus IGRT was used in 57% of the patients in the SAKK-trial [980] and in all patients of a Chinese trial [981]. No patient had a PSMA PET/CT before randomisation. The primary endpoint in both trials was 'freedom from biochemical progression', which was not significantly improved with higher doses. However, in the Chinese trial a subgroup analysis showed a significant improvement of this endpoint for patients with Gleason 8-10 tumours (79.7% vs. 55%, p = 0.049) [981]. In this trial, patients were treated with ART or SRT and the number of patients was relatively small (n = 144). At this time it seems difficult to draw final conclusions about the optimal total RT-dose and longer follow-up should be awaited.

Table 6.4.6: Randomised trials investigating dose escalation for SRT without ADT and without PET-CT

Trial	n	PCa condition	Radiotherapy Dose	Follow-up (median)	Outcome	Results
SAKK 09/10 trial, 2021 [846]	350	pT2a-3b R0 – R1 pN0 or cN0 PSA post op undetectable (< 0.1 ng/mL) or persistent (> 0.1 ng/mL < 0.4 ng/mL)	64 Gy vs.70 Gy No ADT allowed VMAT+ IGRT: 57% 3-D planning: 43%	6.2 yr.	Primary endpoint: FFBP	**6 yr. FFBP:** **62% vs. 61%** **OS: no difference** **Late side effects:** **GI grade 2:** **7.3% vs. 20%** **GI grade 3:** **4.2% vs. 2.3%** p for ≥ grade 2/3: 0.009
Phase-III-Trial *Qi X, et al., 2020 [981]*	144 ART: 33% SRT: 67%	pT2-4 R0-R1 pN0 or cN0 Med. PSA pre-RT: 0.2 ng/mL	66 Gy vs. 72 Gy All patients VMAT+ IGRT No ADT allowed High risk (pT3-4, GS: 8-10, PSA>20 ng/mL): whole pelvis RT: 126 (87.5%)	49 mo.	Primary endpoint: FFBP	**4 yr. ADT = androgen deprivation therapy; ART = adjuvant radiotherapy; FFBP = freedom from biochemical failure; GI = gastro-intestinal; GU = genito-urinary; Gy = Gray; IGRT = image guided radiotherapy; mo = month; n = number of patients; PSA = prostate-specific antigen; RT = radiotherapy; SRT = y = year; vs. = versus; VMAT = volumetric arc radiation therapy.

Salvage RT is associated with toxicity. In one report on 464 SRT patients receiving median 66.6 (max. 72) Gy, acute grade 2 toxicity was recorded in 4.7% for both the GI and GU tract. Two men had late grade 3 reactions of the GI tract, but overall, severe GU tract toxicity was not observed. Late grade 2 complications occurred in 4.7% (GI tract) and 4.1% (GU tract), respectively, and 4.5% of the patients developed moderate urethral stricture [964].

In a RCT on dose escalation for SRT (n = 350), acute grade 2 and 3 GU toxicity was observed in 13.0% and 0.6%, respectively, with 64 Gy and in 16.6% and 1.7%, respectively, with 70 Gy. Gastro-intestinal tract grades 2 and 3 toxicity occurred in 16.0% and 0.6%, respectively, with 64 Gy, and in 15.4% and 2.3%, respectively, with 70 Gy [982, 983]. Late grade 2 and 3 GI toxicity was significantly increased with higher doses but without significant differences in QoL. In this study, however, the rectal wall dose constraints were rather permissive and in 44% of the patients outdated 3-D-techniques were used [980].

With dose escalation over 72 Gy and/or up to a median of 76 Gy, the rate of severe side effects, especially GU symptoms, clearly increases, even with newer planning and treatment techniques [984, 985]. In particular, when compared with 3D-CRT, IMRT was associated with a reduction in grade 2 GI toxicity from 10.2 to 1.9% (p = 0.02) but no effect on the relatively high level of GU toxicity was shown (5-year, 3D-CRT 15.8% vs. IMRT 16.8%) [984]. However, in a RCT comparing 66 Gy and 72 Gy with all patients having IMRT plus IGRT (n = 144), no significant differences for GI and GU-toxicity was demonstrated [981]. After a median salvage IMRT dose of 76 Gy however, the 5-year risk of grade 2–3 toxicity rose to 22% for GU and 8% for GI symptoms, respectively [985]. Doses of at least 64 Gy and up to 72 Gy in patients without PET/CT can be recommended [964, 982].

6.4.5.1.2.2 Salvage radiotherapy with or without ADT (cTx cN0/1) with PET/CT

In a prospective multi-centre study of 323 patients with BCR, PSMA PET/CT changed the management intent in 62% of patients as compared to conventional staging. This was due to a significant reduction in the number of men in whom the site of disease recurrence was unknown (77% vs. 19%, p < 0.001) and a significant increase in the number of men with metastatic disease (11% vs. 57%) [986].

A prospective study in a subgroup of 119 BCR patients with low PSA (< 0.5 ng/mL) reported a change in the intended treatment in 30.2% of patients [868]; however, no data exist on the impact on final outcome.

Another prospective study in 272 patients with early biochemical recurrent PCa after RP showed that ^{68}Ga-PSMA PET/CT may tailor further therapy decisions (e.g., local vs. systemic treatment) at low PSA values (0.2–1 ng/mL) [870].

A single-centre study retrospectively assessed 164 men who underwent imaging with PSMA PET/CT for a rising PSA after RP with PSA levels < 0.5 ng/mL. In men with a negative PSMA PET/CT who received SRT, 85% (23 out of 27) demonstrated a treatment response compared to a further PSA increase in 65% of those not treated (22 out of 34). In the 36/99 men with disease confined to the prostate fossa on PSMA, 83% (29 out of 36) responded to SRT [987]. Thus, PSMA PET/CT might stratify men into a group with high response (negative findings or recurrence confined to the prostate) and poor response (positive nodes or distant disease) to SRT.

A multi-centre retrospective study evaluated patients who underwent SRT for BCR after RP, without any signs of distant metastatic disease on PET/CT. After case-controle matching, two cohorts (n = 108 patients each), with and without PSMA PET/CT prior to SRT were analysed. In the cohort without PSMA PET/CT, 23 patients (21%) had BCR at one year after SRT vs. nine patients (8%) who underwent restaging with PSMA PET/C prior to SRT (p = 0.007). PSMA-PET/CT was found to be associated with an improved oncological outcome in patients with BCR after RP, receiving SRT to the prostatic fossa [988]. It is worth mentioning that in this study the median biologically effective radiation dose administered in the PSMA-cohort was significantly higher than in the historical cohort (70 Gy vs. 66 Gy, respectively, p < 0.001). However, in the SAKK 09/10 randomised phase-III-trial (all patients without PET-CT before SRT) the biochemical progression rate after SRT between patients who underwent 64 Gy or 70 Gy to the prostate bed, without HT for BCR, did not differ significantly [980]. Therefore, it is questionable whether this difference in administered radiation dose influenced the outcome in both cohorts. As there are no prospective phase III data including PET-CT before SRT (in particular not for PCa-specific survival or OS) these results have to be confirmed before a recommendation can be provided.

A single-centre open-label, phase II/III RCT (EMPIRE-1) evaluated the role of 18F-fluciclovine-PET/CT compared with conventional imaging for SRT. Three hundred and sixty five patients with detectable PSA after RP but negative results on conventional imaging, were randomised to RT directed by conventional imaging alone or to conventional imaging plus PET/CT; patients with M1 disease in the PET/CT group (n = 4) were excluded. Patients with cN1 were irradiated to the pelvic lymphatics but without a boost to the metastasis. Median follow 103 up was 3.5 years. In adjusted analyses, the study group was significantly associated with event-free survival (HR: 2.04, 95% CI: 1.06–3.93, p = 0.0327) [948].

6.4.5.1.2.3 Nodal-directed therapy for rcN1 (with PET/CT)

Radiolabelled PSMA PET/CT is increasingly used as a diagnostic tool to assess metastatic disease burden in patients with BCR following prior definitive therapy. A review including 30 studies and 4,476 patients showed overall estimates of positivity in a restaging setting of 38% in pelvic LNs and 13% in extra-pelvic LN metastases [867]. The percentage positivity of PSMA PET/CT was proven to increase with higher PSA values [867]. Results of this review demonstrated a high sensitivity and specificity of 68Ga-PSMA in advanced PCa, with a per-lesion-analysed sensitivity and specificity of 75% and 99%, respectively.

A large retrospective international study included patients with LN-recurrent PCa (cN1 and M1a) and PSA progression following multi-modality treatment (surgery and post-operative RT) [989]. The aim of the study was to compare standard of care (SOC) with nodal metastasis-directed therapy (MDT). The nodal MDT-group showed significantly better CSS than the SOC control group (5-year survival 98.6% vs. 95.7%, p < 0.01, respectively) [989].

Another retrospective study compared SBRT with elective nodal irradiation (ENRT) in nodal oligo-recurrent PCa (n = 506 patients, 365 of which with N1 pelvic recurrence). With a median follow-up of 36 months, ENRT (n = 197) was associated with a significant reduction of nodal recurrences (p < 0.001), compared with SABR (n = 309) of 2% vs. 18%, respectively. In multi-variable analysis, patients with one LN at recurrence had longer adjusted MFS after ENRT (HR: 0.50, 95% CI: 0.30–0.85, p = 0.009). The tendency to relapse was higher for pelvic- than extra-pelvic nodes (p < 0.001) [990]. For patients presenting with two or more (extra)pelvic LNs, adjusted MFS was not significantly different (HR: 0.92, 95% CI: 0.54– 1.59, p = 0.8). In these situations, SABR should be used in highly selected patients in prospective cohorts or clinical trials only, before any recommendations can be made. For MDT in M1 patients see Section 6.4.7.

6.4.5.1.3 Salvage lymph node dissection

The surgical management of recurrent nodal metastases in the pelvis has been the topic of several retrospective analyses [991-993] and a SR [994]. The reported five-year BCR-free survival rates ranged from 6% to 31%. Five-year OS was approximately 84% [994]. Biochemical recurrence rates were found to be dependent on PSA at salvage surgery and location and number of positive nodes [995]. Addition of RT to the lymphatic template after salvage LN dissection may improve the BCR rate [996]. In a multi-centre retrospective study long-term outcomes of 189 patients who underwent salvage LN dissection were reported to be worse than previously described in studies with shorter follow-up [997]. Biochemical recurrence (BCR)-free survival at ten years was 11%. Patients with a PSA response after salvage LN dissection and patients receiving ADT within six months from salvage LN dissection had a lower risk of death from PCa [997]. The majority of the patients (81%) had received a choline PET and median PSA at salvage LN dissection was 2.5 ng/mL. In a cohort study including patients treated with salvage LN dissection via PSMA–radioguided surgery (PSMA-RGS), two-year BCR-free survival rate was 32% [998]. In multi-variable analyses, higher pre-operative PSA, higher number of PSMA-avid lesions, multiple (pelvic plus retroperitoneal), and retroperitoneal localisation of lesions at pre-operative imaging were independent predictors of BCR after PSMA-RGS. High-level evidence for the oncological value of salvage LN dissection (including adjuvant RT of the LNs) is still lacking [994].

6.4.5.2 Management of PSA failures after radiation therapy

Therapeutic options in these patients are ADT or salvage local procedures, as well as a 'wait and see' approach, based on EAU BCR risk categories at relapse. A SR and meta-analysis included studies comparing the efficacy and toxicity of salvage RP, salvage HIFU, salvage cryotherapy, SBRT, salvage LDR BT, and salvage HDR BT in the management of locally recurrent PCa after primary radical EBRT [999]. The outcomes were BCR-free survival at two and five years. No significant differences with regards to recurrence-free survival (RFS) between these modalities was found. Five-year RFS ranged from 50% after cryotherapy to 60% after HDR BT and SBRT. The authors reported that severe GU toxicity exceeded 21% for HIFU and RP, whereas it ranged from 4.2% to 8.1% with re-irradiation. Differences in severe GI toxicity also appeared to favour re-irradiation, particularly HDR BT [999]. Due to the methodological limitations of this review (the majority of the included studies were uncontrolled single-arm case series and there was considerable heterogeneity in the definitions of core outcomes) the available evidence for these treatment options is of low quality and strong recommendations regarding the choice of any of these techniques cannot be made. The following is an overview of the most important findings for each of these techniques.

6.4.5.2.1 Salvage radical prostatectomy

Salvage RP after RT is associated with a higher likelihood of AEs compared to primary surgery because of the risk of fibrosis and poor wound healing due to radiation [1000].

6.4.5.2.1.1 Oncological outcomes

In a SR of the literature, Chade, *et al.*, showed that SRP provided five and ten years BCR-free survival estimates ranging from 47–82% and from 28–53%, respectively. The ten-year CSS and OS rates ranged from 70–83% and from 54–89%, respectively. The pre-SRP PSA value and prostate biopsy ISUP grade group were the strongest predictors of the presence of organ-confined disease, progression, and CSS [1001]. In a multi-centre analysis including 414 patients, five-year BCR-free survival, CSS and OS were 56.7%, 97.7% and 92.1%, respectively [1002]. Pathological T stage ≥ T3b (OR: 2.348) and GS (up to OR 7.183 for GS > 8) were independent predictors for BCR (see Table 6.4.7).

Table 6.4.7: Oncological results of selected salvage radical prostatectomy case series

Study	n	Median FU (mo)	Pathologic Organ-confined (%)	PSM (%)	Lymph-node involvement (%)	BCR-free probability (%)	CSS (%)	Time probability
Chade, *et al.* 2011 [1003]	404	55	55	25	16	37	83	10 yr.
Mandel, *et al.* 2016 [1004]	55	36	50	27	22	49	89	5 yr.
Ogaya-Pinies, *et al.* 2018 [1005]	96	14	50	17	8	85*	-	14 mo.
Marra, *et al.* 2021 [1002]	414	36	46	30	16	57	98	5 yr.

**Percentage of patients without BCR.*

BCR = biochemical recurrence; CSS = cancer-specific survival; FU = follow-up; mo = months; n = number of patients; PSM = positive surgical margin; yr. = year.

6.4.5.2.1.2 Morbidity

Compared to primary open RP, SRP is associated with a higher risk of later anastomotic stricture (47 vs. 5.8%), urinary retention (25.3% vs. 3.5%), urinary fistula (4.1% vs. 0.06%), abscess (3.2% vs. 0.7%) and rectal injury (9.2 vs. 0.6%) [1006]. A series, these complications appear to be less common [1000, 1001, 1004].

Functional outcomes are also worse compared to primary surgery, with urinary incontinence ranging from 21% to 90% and ED in nearly all patients [1001, 1004].

6.4.5.2.1.3 Summary of salvage radical prostatectomy

In general, SRP should be considered only in patients with low co-morbidity, a life expectancy of at least ten years, a pre-SRP PSA < 10 ng/mL and initial biopsy ISUP grade group ≤ 2/3, no LN involvement or evidence of distant metastatic disease pre-SRP, and those whose initial clinical staging was T1 or T2 [1001].

6.4.5.2.2 Salvage cryoablation of the prostate

6.4.5.2.2.1 Oncological outcomes

Salvage cryoablation of the prostate (SCAP) has been proposed as an alternative to salvage RP, as it has a potentially lower risk of morbidity and equal efficacy.

In a SR a total of 32 studies assessed SCAP, recruiting a total of 5,513 patients. The overwhelming majority of patients (93%) received whole-gland SCAP. The adjusted pooled analysis for two-year BCR-free survival for SCAP was 67.49% (95% CI: 61.68–72.81%), and for five-year BCR-free survival was 50.25% (95% CI: 44.10–56.40%). However, the certainty of the evidence was low. Table 6.3.8 summarises the results of a selection of the largest series on SCAP to date in relation to oncological outcomes (BCR only) [999] (Table 6.4.8).

Table 6.4.8: Oncological results of selected salvage cryoablation of the prostate case series, including at least 250 patients

Study	n	Median FU (mo)	Time point of outcome measurement (yr)	BCR-free probability	Definition of failure
Ginsburg, *et al.* 2017 [1007]	898	19.0	5	71.3%	Phoenix criteria
Spiess, *et al.* 2010 [1008]	450	40.8	3.4	39.6%	PSA > 0.5 ng/mL
Li, *et al.* 2015 [1009]	486	18.2	5	63.8%	Phoenix criteria
Kovac, *et al.* 2016 [1010]	486	18.2	5	75.5% (nadir PSA < 0.4 ng/mL); 22.1% (nadir PSA ≥ 0.4 ng/mL)	Phoenix criteria
Ahmad, *et al.* 2013 [1011]	283	23.9	3	67.0% (nadir PSA ≤ 1 ng/mL); 14.0% (nadir PSA > 1 ng/mL)	Phoenix criteria
Pisters, *et al.* 2008 [1012]	279	21.6	5	58.9% (ASTRO) 54.5% (Phoenix)	ASTRO and Phoenix criteria

ASTRO = American Society for Therapeutic Radiology and Oncology; BCR = biochemical recurrence; FU = follow-up; mo. = months; n = number of patients; PSA = prostate-specific antigen; yr. = year.

6.4.5.2.3 Salvage re-irradiation

6.4.5.2.3.1 Salvage brachytherapy for radiotherapy failure

Carefully selected patients with a good PS, primary localised PCa, good urinary function and histologically proven local recurrence are candidates for salvage BT using either HDR or LDR.

In a SR a total of sixteen studies (four prospective) and 32 studies (two prospective) assessed salvage HDR and LDR BT, respectively, with the majority (> 85%) receiving whole-gland BT rather than focal treatment [999]. The adjusted pooled analysis for two-year BCR-free survival for HDR was 77% (95% CI: 70–83%) and for LDR was 81% (95% CI:74–86%). The five-year BCR-free survival for HDR was 60% (95% CI: 52–67%) and for LDR was 56% (95% CI: 48–63%). As noted above, BT techniques are associated with lower rates of severe GU toxicity when compared to RP or HIFU, at 8% for HDR (95% CI: 5.1–11%) and 8.1% for LDR (95% CI: 4.3–13%). Rates of severe GI toxicity are reported to be very low at 0% for HDR (95% CI: 0–0.2%) and 1.5% for LDR (95% CI: 0.2–3.4%). High-dose-rate or LDR BT are effective treatment options with an acceptable toxicity profile. However, the published series are small and likely under-report toxicity. Consequently, this treatment should be offered in experienced centres ideally within randomised clinical trials or prospective registry studies (see Table 6.4.9).

Table 6.4.9: Treatment-related toxicity and BCR-free probability in selected salvage brachytherapy studies including at least 100 patients.

Study	Study design	n and BT type	Median FU (mo)	Treatment toxicity	BCR-free probability
Lopez, *et al.* 2019 [1013]	multi-centre retrospective	75 HDR 44 LDR	52	23.5% late G3+ GU	5 yr 71% (95% CI: 65.9-75.9%)
Crook, *et al.* 2019 [1014]	multi-centre prospective	100 LDR	54	14% late G3 combined GI/GU	n.r.
Smith, *et al.* 2020 [1015]	single-centre retrospective	108 LDR	76	15.7%/2.8% late G3 GU/GI	5 yr. 63.1% 10 yr. 52%
Lyczek, *et al.* 2009 [1016]	single-centre retrospective	115 HDR	n.r.	12.2%/0.9% late G3+ GU/GI	60% at 40 mo.

BT = brachytherapy; CI = confidence interval; G = grade; GI = gastro-intestinal; GU = genito-urinary; HDR = high-dose rate; LDR = low-dose rate; mo = months; n = number of patients; n.r. = not reported; yr = year.

6.4.5.2.3.2 Salvage stereotactic ablative body radiotherapy for radiotherapy failure

6.4.5.2.3.2.1 Oncological outcomes and morbidity

Stereotactic ablative body radiotherapy (CyberKnife® or linac-based treatment) is a potentially viable new option to treat local recurrence after RT. Carefully selected patients with good IPSS-score, without obstruction, good PS and histologically proven localised local recurrence are potential candidates for SABR. In a metaanalysis and SR five mostly retrospective studies including 206 patients were treated with CyberKnife® or linac-based treatment showing two-year RFS estimates (61.6%, 95% CI: 52.6–69.9%) [999]. In a retrospective multi-centre study (n = 100) the median pre-salvage PSA was 4.3 ng/mL with 34% of patients having received ADT for twelve months (median). All recurrences were biopsy proven. Patients were treated with the CyberKnife® with a single dose of 6 Gy in six daily fractions (total dose 36 Gy). With a median followup of 30 months the estimated three-year second BCR-free survival was 55% [1017].

In a smaller retrospective series including 50 men with histologically proven local recurrence with a median pre-salvage PSA of 3.9 ng/mL only 15% had received additional ADT. The estimated five-year second BCR-free survival was 60% (median follow-up of 44 months) which is an outcome comparable to series treating patients with RP, HIFU or BT [1018]. Table 6.4.10 summarises the results of the two larger SABR series addressing oncological outcomes and morbidity.

Table 6.4.10: Treatment-related toxicity and BCR-free survival in selected SABR studies

Study	Study design	n and RT-type	Median FU (mo)	Fractionation (SD/TD)	ADT	Treatment toxicity	BCR-free survival
Bergamin, *et al.* 2020 [1019]	single-centre prospective	25 LINAC based	25	SD 6-6.2 TD 36-38 Gy	0/25	2 yr. late G1 GI 8% G2 GU 4%	2 yr. 80%
Fuller, *et al.* 2020 [1018]	single-centre retrospective	50 Cyber Knife	44	SD 6.8 Gy TD 34 Gy	7/50	5 yr: 8% late G3+ GU	5 yr. 60%
Pasquier, *et al.* 2020 [1017]	multi-centre retrospective	100 Cyber Knife	30	SD 6 Gy TD 36 Gy	34/100 median 12 mo.	3 yr. grade 2+ GU 20.8% GI 1%	3 yr. 55%

BCR = biochemical recurrence; FU = follow-up; mo = months; n = number of patients; RT-type = type of radio-therapy; SD = single dose; TD = total dose; yr = year.

6.4.5.2.3.2.2 Morbidity

In a retrospective single-centre study with 50 consecutive patients chronic significant toxicity was only seen for the GU domain with five-year grade 2+ and grade 3+ GU rates of 17% and 8%, respectively. No GI toxicity > grade 1 was seen. Of note, of the fifteen patients who were sexually potent pre-salvage SBRT, twelve subsequently lost potency [1018]. In a retrospective French (GETUG) multi-centre series (n = 100) the three-year late grade 2+ GU and GI toxicity was 20.8% (95% CI: 13–29%) and 1% (95% CI: 0.1–5.1%), respectively [1017].

6.4.5.2.3.2.3 Summary of salvage stereotactic ablative body radiotherapy

Despite the encouraging results so far the number of patients treated with SABR is relatively limited. In view of the rates of higher grade 2+ GU side effects, SABR should only be offered to selected patients, in experienced centres as part of a clinical trial or well-designed prospective study.

6.4.5.2.4 Salvage high-intensity focused ultrasound

6.4.5.2.4.1 Oncological outcomes

Salvage HIFU has emerged as an alternative thermal ablation option for radiation-recurrent PCa. Being relatively newer than SCAP the data for salvage HIFU are even more limited. A SR and metaanalysis included 20 studies (n = 1,783) assessing salvage HIFU [999]. The overwhelming majority of patients (86%) received whole-gland salvage HIFU. The adjusted pooled analysis for two-year BCR-free survival for salvage HIFU was 54.14% (95% CI: 47.77–60.38%) and for five-year BCR-free survival 52.72% (95% CI: 42.66– 62.56%). However, the certainty of the evidence was low. Table 6.4.11 summarises the results of a selection of the largest series on salvage HIFU to date in relation to oncological outcomes (BCR only).

Table 6.4.11: Oncological results of selected salvage cryoablation of the prostate case series, including at least 250 patients

Study	n	Median FU (mo)	Time point of outcome measurement (yr)	BCR-free probability	Definition of failure
Crouzet, *et al.* 2017 [1020]	418	39.6	5	49.0%	Phoenix criteria
Murat, *et al.* 2009 [1021]	167	Mean 18.1	3	25.0% (high-risk) 53.0% (low-risk)*	Phoenix criteria or positive biopsy or initiation of post-HIFU salvage therapy
Kanthabalan, *et al.* 2017 [1022]	150	35.0	3	48.0%	Phoenix criteria
Jones, *et al.* 2018 [1023]	100	12.0	1	50.0%	Nadir PSA > 0.5 ng/mL or positive biopsy

**Results stratified by pre-EBRT D'Amico risk groups.*

BCR = biochemical recurrence; FU = follow-up; mo = months; n = number of patients; yr = year.

6.4.5.2.4.2 Morbidity

The main adverse effects and complications relating to salvage HIFU include urinary incontinence, urinary retention due to bladder outflow obstruction, rectourethral fistula and ED. The SR and meta-analysis showed an adjusted pooled analysis for severe GU toxicity for salvage HIFU of 22.66% (95% CI: 16.98–28.85%) [999]. The certainty of the evidence was low. Table 6.4.12 summarises the results of a selection of the largest series on salvage HIFU to date in relation to GU outcomes.

Table 6.4.12: Peri-operative morbidity, erectile function and urinary incontinence in selected salvage HIFU case series, including at least 100 patients

Study	n	Time point of outcome measurement (yr)	Incontinence* (%)	Obstruction/ retention (%)	Rectourethral fistula (%)	ED (%)
Crouzet, *et al.* 2017 [1020]	418	Median 39.6	42.3	18.0	2.3	n.r.
Murat, *et al.* 2009 [1021]	167	Median 18.1	49.5	7.8	3.0	n.r.
Kanthabalan, *et al.* 2017 [1022]	150	24	12.5	8.0	2.0	41.7
Jones, *et al.* 2018 [1023]	100	12	42.0	49.0	5.0	74.0

**Incontinence was heterogeneously defined; figures represent at least 1 pad usage.*

ED = erectile dysfunction; n.r. = not reported; n = number of patients.

6.4.5.2.4.3 Summary of salvage high-intensity focused ultrasound

There is a lack of high-certainty data which prohibits any recommendations regarding the indications for salvage HIFU in routine clinical practice. There is also a risk of significant morbidity associated with its use in the salvage setting. Consequently, salvage HIFU should only be performed in selected patients in experienced centres as part of a clinical trial or well-designed prospective cohort study.

*6.4.6 **Hormonal therapy for relapsing patients***

The Panel conducted a SR including studies published from 2000 onwards [1024]. Conflicting results were found on the clinical effectiveness of HT after previous curative therapy of the primary tumour. Some studies reported a favourable effect of HT, including the only RCT addressing the research question of this review (86% vs. 79% advantage in OS in the early HT group) [1025]. Other studies did not find any differences between early vs. delayed, or no, HT. One study found an unfavourable effect of HT [1026]. This may be the result of selecting clinically unfavourable cases for (early) HT and more intensive diagnostic workup and follow-up in these patients.

The studied population is highly heterogeneous regarding their tumour biology and therefore clinical course. Predictive factors for poor outcomes were short PSA-DT, high ISUP grade group, high PSA, increased age and comorbidities. In some studies, such as the Boorjian, *et al.*, study [1027], high-risk patients, mainly defined by a high ISUP grade group and a short PSA-DT (most often less than six months) seem to benefit most from (early) HT, especially men with a long life expectancy.

Non-steroidal anti-androgens have been claimed to be inferior compared to castration, but this difference was not seen in M0 patients [960]. One of the included RCTs suggested that intermittent HT is not inferior to continuous HT in terms of OS and CSS [1028]. A small advantage was found in some QoL domains but not overall QoL outcomes. An important limitation of this RCT is the lack of any stratifying criteria such as PSA-DT or initial risk factors. Based on the lack of definitive efficacy and the undoubtedly associated significant side effects, patients with recurrence after primary curative therapy should not receive standard HT since only a minority of them will progress to metastases or PCa-related death. The objective of HT should be to improve OS, postpone distant metastases, and improve QoL. Biochemical response to only HT holds no clinical benefit for a patient. For older patients and those with comorbidities the side effects of HT may even decrease life expectancy; in particular cardiovascular risk factors need to be considered [1029, 1030]. Early HT should be reserved for those at the highest risk of disease progression defined mainly by a short PSA-DT at relapse (< 6–12 months) or a high initial ISUP grade group (> 2/3) and a long life expectancy.

A three-arm randomised phase III trial (EMBARK) looked at patients with prostate cancer who had high-risk biochemical recurrence defined as a PSA-DT of ≤9 months and a PSA level of ≥2 ng/ml above the nadir after radiation therapy or ≥1 ng/ml after radical prostatectomy with or without postoperative radiation therapy [1031]. Patients were randomly assigned 1:1:1 to receive enzalutamide daily plus leuprolide every 12 weeks (combination group), placebo plus leuprolide (leuprolide-alone group), or enzalutamide monotherapy (monotherapy group). The primary end point was MFS, in the combination group as compared with the leuprolide- alone group. The MFS in the monotherapy group as compared with the leuprolide-alone group was a key secondary endpoint. A total of 1068 patients were randomised. After a median follow-up of 60.7 months, the five year - MFS was 87.3% (95% CI, 83.0 - 90.6) in the combination group, 71.4% (95% CI, 65.7 - 76.3) in the leuprolide-alone group, and 80.0% (95% CI, 75.0 - 84.1) in the monotherapy group. The combination of enzalutamide plus leuprolide was superior to leuprolide alone with regards to the MFS (HR 0.42; 95% CI, 0.30 - 0.61; P<0.001). Enzalutamide monotherapy also showed a superior MFS compared to leuprolide alone (HR 0.63; 95% CI, 0.46 - 0.87; P = 0.005). These results led to the FDA approval for enzalutamide alone or in combination with ADT for patients with high-risk biochemical recurrence in November 2023 [1032].

At the time of the MFS analysis, OS data were immature with 12% deaths in the overall population. Also, an intermittent treatment approach can be considered. Enzalutamide treatment can be suspended if PSA is undetectable (< 0.2 ng/mL) after 36 weeks of therapy. Treatment may be reinitiated when PSA has increased to ≥ 2.0 ng/mL for patients who had prior radical prostatectomy or ≥ 5.0 ng/mL for patients who had prior primary radiation therapy. There were no new safety signals. Of note, at a median follow-up of five years, the overall percentage of patients who had fractures was 14% [1033].

6.4.7 *Observation*

In unselected relapsing patients the median actuarial time to the development of metastasis will be 8 years and the median time from metastasis to death will be a further five years [825]. For patients with EAU Low-Risk BCR features (see Section 6.3.3), unfit patients with a life expectancy of less than ten years or patients unwilling to undergo salvage treatment, active follow-up may represent a viable option.

6.4.8 *Guidelines for second-line therapy after treatment with curative intent*

Local salvage treatment	Strength rating
Recommendations for biochemical recurrence (BCR) after radical prostatectomy	
Offer early salvage intensity-modulated radiotherapy/volumetric arc radiation therapy plus image-guided radiotherapy to men with two consecutive PSA rises.	Strong
A negative positron emission tomography/computed tomography (PET/CT) scan should not delay salvage radiotherapy (SRT), if otherwise indicated.	Strong
Offer monitoring, including prostate-specific antigen (PSA), to EAU Low-Risk BCR patients.	Weak
Do not wait for a PSA threshold before starting treatment. Once the decision for SRT has been made, SRT (at least 64 Gy) should be given as soon as possible.	Strong
Offer hormonal therapy in addition to SRT to men with BCR.	Weak
Recommendations for BCR after radiotherapy	
Offer monitoring, including PSA to EAU Low-Risk BCR patients.	Weak
Only offer salvage radical prostatectomy (RP), brachytherapy, stereotactic body radiotherapy, high-intensity focused ultrasound, or cryosurgical ablation to highly selected patients with biopsy-proven local recurrence within a clinical trial setting or well-designed prospective cohort study undertaken in experienced centres.	Strong
Recommendations for systemic salvage treatment	
Do not offer androgen deprivation therapy to M0 patients with a PSA-doubling time > twelve months.	Strong
Offer enzalutamide with or without androgen deprivation therapy to M0 patients with high-risk BCR, defined as a PSA doubling time of ≤9 months and a PSA level of ≥2ng/ml above nadir after radiation therapy or ≥1 ng/ml after radical prostatectomy with or without postoperative radiation therapy.	Strong
Recommendations for follow-up after radical prostatectomy or radiotherapy	
Routinely follow-up asymptomatic patients by obtaining at least a disease-specific history and serum prostate-specific antigen (PSA) measurement.	Strong
At recurrence, only perform imaging if the result will affect treatment planning.	Strong

6.5 Systemic treatments for prostate cancer

6.5.1 *Hormonal therapy*

6.5.1.1 *Different types of hormonal therapy*

Androgen deprivation can be achieved by suppressing the secretion of testicular androgens in different ways. This can be combined with inhibiting the action of circulating androgens at the level of their receptor which has been known as complete (or maximal or total) androgen blockade (CAB) using the old-fashioned antiandrogens [1034].

6.5.1.2 *Castration level*

The castration level of testosterone is < 50 ng/dL (1.7 nmol/L), which was defined more than 40 years ago when testosterone testing was less sensitive. Current methods have shown that the mean value after surgical castration is 15 ng/dL [1035]. Therefore, a more appropriate level should be defined as < 20 ng/dL (< 0.7 nmol/L). This definition is important as better results are repeatedly observed with lower testosterone levels compared to 50 ng/dL [1036-1038]. However, the castrate level considered by the regulatory authorities and in clinical trials addressing castration in PCa is still the historical < 50 ng/dL (1.7 nmol/L).

6.5.1.3 *Bilateral orchiectomy*

Bilateral orchiectomy or subcapsular pulpectomy is still considered the primary treatment modality for ADT. It is a simple, cheap and virtually complication-free surgical procedure. It is easily performed under local anaesthesia, and it is the quickest way to achieve a castration level which is usually reached within less than twelve hours. It is irreversible and therefore does not allow for intermittent treatment [1039].

6.5.1.4 Oestrogens

Treatment with oestrogens results in testosterone suppression and is not associated with bone loss [1040]. Early studies tested oral diethylstilboestrol (DES) at several doses. Due to severe side effects, especially thromboembolic complications, even at lower doses these drugs are not considered as standard first-line treatment [1041, 1042]. Oestrogen patches are under investigation [1043].

6.5.1.5 Luteinising-hormone-releasing hormone agonists

Long-acting LHRH agonists are currently the main forms of ADT. These synthetic analogues of LHRH are delivered as depot injections on a 1-, 2-, 3-, 6-monthly, or yearly basis. The first injection induces a transient rise in luteinising hormone (LH) and follicle-stimulating hormone (FSH) leading to the 'testosterone surge' or 'flare-up' phenomenon which starts two to three days after administration and lasts for about one week. This may lead to detrimental clinical effects (the clinical flare) such as increased bone pain, acute bladder outlet obstruction, obstructive renal failure, spinal cord compression, and cardiovascular death due to hypercoagulation status [1044]. Patients at risk are usually those with high-volume symptomatic bony disease. Concomitant therapy with an anti-androgen decreases the incidence of clinical flare but does not completely remove the risk. Anti-androgen therapy is usually continued for four weeks but neither the timing nor the duration of anti-androgen therapy are based on strong evidence. In addition, the long-term impact of preventing 'flare up' is unknown [1045].

Chronic exposure to LHRH agonists results in the down-regulation of LHRH-receptors, suppressing LH and FSH secretion and therefore testosterone production. A castration level is usually obtained within two to four weeks [1046]. Although there is no formal direct comparison between the various compounds, they are considered to be equally effective [1047]. So far, no survival difference between LHRH agonists and orchiectomy has been reported due to the lack of high-quality trials [1048].The different products have practical differences that need to be considered in everyday practice, including the storage temperature, whether a drug is ready for immediate use or requires reconstitution, and whether a drug is given by subcutaneous or intramuscular injection.

6.5.1.6 Luteinising-hormone-releasing hormone antagonists

Luteinising-hormone-releasing hormone antagonists immediately bind to LHRH receptors, leading to a rapid decrease in LH, FSH and testosterone levels without any flare. The practical shortcoming of these compounds is the lack of a long-acting depot formulation with, so far, only monthly formulations being available. Degarelix is a LHRH antagonist. The standard dosage is 240 mg in the first month followed by monthly injections of 80 mg. Most patients achieve a castrate level at day three [1046]. A phase III RCT compared degarelix to monthly leuprorelin following up patients for twelve months, suggesting a better PSA PFS for degarelix 240/80 mg compared to monthly leuprorelin [1049]. A SR did not show a major difference between agonists and degarelix and highlighted the paucity of on-treatment data beyond twelve months as well as the lack of survival data [1050]. Its definitive superiority over the LHRH analogues remains to be proven. Short-term follow-up data from a meta-analysis indicate that the use of LHRH antagonist is associated with significantly lower overall mortality and cardiovascular events as compared with agonists. On the other hand, other adverse effects such as decreased libido, hot flushes, ED, weight gain, and injection site reactions are seen less often with the agonists [1051, 1052].

Relugolix is an oral LHRH antagonist. It was compared to the LHRH agonist leuprolide in a randomised phase III trial [1053]. The primary endpoint was sustained testosterone suppression to castrate levels through 48 weeks. There was a significant difference of 7.9 percentage points (95% CI: 4.1–11.8) showing non-inferiority and superiority of relugolix. The incidence of major adverse cardiovascular events was significantly lower with relugolix (prespecified safety analysis). Relugolix has been approved by the FDA [1054] and EMA [1055] for hormone sensitive PCa.

6.5.1.7 Anti-androgens

These oral compounds are classified according to their chemical structure as:

- steroidal, e.g., cyproterone acetate (CPA), megestrol acetate and medroxyprogesterone
- acetate;
- non-steroidal or pure, e.g., nilutamide, flutamide and bicalutamide.

Both classes compete with androgens at the receptor level. This leads to an unchanged or slightly elevated testosterone level. Conversely, steroidal anti-androgens have progestational properties leading to central inhibition by crossing the blood-brain barrier.

6.5.1.7.1 Steroidal anti-androgens

These compounds are synthetic derivatives of hydroxyprogesterone. Their main pharmacological side effects are secondary to castration (gynaecomastia is quite rare) whilst the non-pharmacological side effects are cardiovascular toxicity (4–40% for CPA) and hepatotoxicity.

Cyproterone acetate was the first licensed anti-androgen but the least studied. Its most effective dose as monotherapy is still unknown. Although CPA has a relatively long half-life (31–41 hours), it is usually administered in two or three fractionated doses of 100 mg each. In one RCT CPA showed a poorer OS when compared with LHRH analogues [1056]. An underpowered RCT comparing CPA monotherapy with flutamide in M1b PCa did not show any difference in DSS and OS at a median follow-up of 8.6 years [1057]. Other CPA monotherapy studies suffer from methodological limitations preventing firm conclusions.

6.5.1.7.2 Non-steroidal anti-androgens

Non-steroidal anti-androgen monotherapy with e.g. nilutamide, flutamide or bicalutamide does not suppress testosterone secretion and it is claimed that libido, overall physical performance and bone mineral density (BMD) are frequently preserved [1058]. Non-androgen-related pharmacological side effects differ between agents. Bicalutamide shows a more favourable safety and tolerability profile than flutamide and nilutamide [1059]. The dosage licensed for use in CAB is 50 mg/day, and 150 mg/day for monotherapy. The androgen pharmacological side effects are mainly gynaecomastia (70%) and breast pain (68%). However, non-steroidal anti-androgen monotherapy offers clear bone protection compared with LHRH analogues and probably LHRH antagonists [1058, 1060]. All three agents share the potential for liver toxicity (occasionally fatal), requiring regular monitoring of patients' liver enzymes.

6.5.1.7.3 New androgen receptor pathway inhibitors (ARPis)

Once on ADT the development of castration-resistance (CRPC) is only a matter of time. It is considered to be mediated through two main overlapping mechanisms: androgen-receptor (AR)-independent and AR-dependent mechanisms (see Section 6.5 - Castrate-resistant PCa). In CRPC, the intracellular androgen level is increased compared to androgen sensitive cells and an over-expression of the AR has been observed, suggesting an adaptive mechanism [1061]. This has led to the development of several new compounds targeting the androgen axis. In mCRPC, abiraterone acetate and enzalutamide have been approved. In addition to ADT (sustained castration), abiraterone acetate, apalutamide and enzalutamide have been approved for the treatment of metastatic hormone sensitive PCa (mHSPC) by the FDA and the EMA. For the updated approval status see EMA and FDA websites [1032, 1062-1065]. Finally, apalutamide, darolutamide and enzalutamide have been approved for non-metastatic CRPC (nmCRPC) at high risk of further metastases [1066-1070].

6.5.1.7.3.1 Abiraterone acetate

Abiraterone acetate is a CYP17 inhibitor (a combination of 17α-hydrolase and 17,20-lyase inhibition). By blocking CYP17, abiraterone acetate significantly decreases the intracellular testosterone level by suppressing its synthesis at the adrenal level and inside the cancer cells (intracrine mechanism). This compound must be used together with prednisone/prednisolone to prevent drug-induced hyperaldosteronism [1062, 1064].

6.5.1.7.3.2 Apalutamide, darolutamide, enzalutamide (alphabetical order)

These agents are novel non-steroidal anti-androgens with a higher affinity for the AR receptor than traditional non-steroidal anti-androgens. In addition, while previous non-steroidal anti-androgens still allow transfer of ARs to the nucleus and would act as partial agonists, all three agents also block AR transfer and therefore suppress any possible agonist-like activity [1065-1067]. Darolutamide has structurally unique properties In particular, in preclinical studies, it was shown not to cross the blood-brain barrier [1071, 1072].

*6.5.2 **Cytotoxic drug treatment***

6.5.2.1 Taxanes

Paclitaxel derivatives promote the assembly of microtubules and inhibit the subsequent depolymeization, impairing the tubulin dynamics that foster the mitotic spindle assembly during interphase in mitosis [1073]. Docetaxel binds ß-tubulin dimers in a 1:1 stoichiometric ratio, exhibiting a stronger dynamic instability using its inhibitory effect in tubulin depolymerization [1074]. It also activates NF-kB causing apoptosis via a mitochondria-dependent pathway [1075]. Docetaxel shows significant activity against prostatetumours. Cabazitaxel also works by binding to the microtubules. This prevents cellular mitosis and stabilises the tumour cells. As a result, the cells do not divide. In addition, it inhibits androgen receptors by binding to the microtubules and microtubule-associated motor protein dynein. As a consequence, androgen receptor nuclear translocation is prevented [1073]. Common side-effects include peripheral neuropathy, myalgias, neutropenia and arthralgia.

*6.5.3 **Non-hormonal non-cytotoxic drug treatments***

6.5.3.1 Poly (ADP-ribose) polymerase inhibitirs (PARPi)

Poly (ADP-ribose) polymerase inhibitors (PARPi) block the enzyme poly ADP-ribose polymerase (PARP) and were developed aiming to selectively target cancer cells harbouring BRCA mutations and other mutations inducing homologous recombination deficiency and high level of replication pressure with a sensitivity to PARPi treatment. Due to the oncogenic loss of some DNA repair effectors and incomplete DNA repair repertoire, some cancer cells are addicted to certain DNA repair pathways such as Poly (ADP-ribose) polymerase (PARP)-related single-strand break repair pathway. The interaction between BRCA and PARP is a form of synthetic lethal effect which means the simultaneously functional loss of two genes leads to cell death, while a defect in any single gene only has a limited effect on cell viability [1076]. The therapeutic indications for PCa are discussed in Sections 6.5.8.1.

6.5.3.2 AKT inhibitors

AKT inhibitors are small molecules which are designed to target and bind to all three isoforms of AKT, which is a key component of the PI3K/AKT pathway. In clinical trials, ipatasertib, an oral, highly specific, AKT inhibitor was used and showed significant activity when combined with abiraterone acetate in patients with loss of the tumour suppressor protein PTEN on immunohistochemistry within the tumour [1077, 1078]. Available data can be found in table 6.5.2. Currently, there are no approved AKT inhibitors.

6.5.3.3 Immune checkpoint inhibitors

Checkpoint inhibitors target the molecules CTLA4, programmed cell death protein 1 (PD-1), and programmed death-ligand 1 (PD-L1). For advanced PCa patients that are microsatellite instability-high/deficient mismatch repair (MSI-H/*dMMR*), the PD-1 inhibitor pembrolizumab has been approved by the FDA but not by the EMA. The label is tumour agnostic [1079, 1080]. See also Section 6.6.2.1

6.5.3.4 Radiopharmaceutical therapy

Radiopharmaceutical therapy (RPT) is based on the delivery of radioactive isotopes to tumour-associated targets. The mechanism of action for RPT is radiation-induced killing of cells. Radionuclides with different emission properties are used to deliver radiation. The most commonly used radionuclides are represented by β-particles (e.g., ^{177}Lu) or α-particles (e.g., ^{223}Ra, ^{225}Ac). ^{177}Lu is increasingly used because of its optimal imaging range (100–200 keV), favourable half time (6.6 days) and appropriate β-particle energy for therapy. The short path of the β-particles (0.05–0.08 mm) results in minimal toxic effects in adjacent healthy tissue. These properties enable such radionuclides to be used as theranostics (i.e., the same radionuclide may be used for both diagnostic and therapeutic purposes). However, an essential requirement prior to any RPT is to assess the targeting of the agent, mainly using PET techniques which show the tumour expression and the extent of cancer [1081]. ^{177}Lu has been approved by the FDA for the treatment of adult patients with PSMA-positive mCRPC who have been treated with ARPI and taxane-based chemotherapy [1082, 1083]. Clinical details are discussed in Section 6.6.8.

6.6 Management of Metastatic prostate cancer

*6.6.1 **Introduction***

All prospective data available rely on the definition of M1 disease based on CT scan or MRI and bone scintigraphy. The influence on treatment and outcome of newer, more accurate, imaging has not been assessed yet.

*6.6.2 **Prognostic factors***

Median survival of patients with newly diagnosed metastases (synchronous mHSPC) is approximately 50 months with ADT alone, however, it is highly variable since the M1 population is heterogeneous [1084]. Several prognostic factors for survival have been suggested including the number and location of bone metastases, presence of visceral metastases, ISUP grade group, PS status and initial PSA and alkaline phosphatase level, but only few have been validated [1085-1088].

'Volume' of disease as a potential predictor was introduced by CHAARTED (Chemo-hormonal Therapy versus Androgen Ablation Randomised Trial for Extensive Disease in Prostate Cancer) [1088-1090] (see table 6.4.1) and subsequently, in STAMPEDE, was shown to be predictive in an adequately powered subgroup analysis for benefit of addition of prostate RT to ADT in the subgroup of patients with low volume/burden disease [1091] (See table 6.4.1).

'Metachronous' metastatic disease (after radical local treament of the primary tumour) vs. synchronous (or *de novo*) metastatic disease has also been shown to have generally a better prognosis [1092].

Based on a large SWOG 9346 cohort, the PSA level after seven months of ADT was used to create three prognostic groups (see Table 6.4.2) [1093]. A PSA ≤ 0.2 ng/mL at seven months has been confirmed as

a prognostic marker for men receiving ADT for metastatic disease in the CHAARTED study independent of the addition of docetaxel [1094]. Similarly reaching PSA levels of ≤ 0.1ng/ml after six months were shown to be correlated with long-term outcomes in the LATITUDE study [1095]. Also for patients treated with ADT and apalutamide a deep PSA decline defined by ≥ 90% from baseline or to PSA≤ 0.2 ng/ml at a landmark of three months was associated with longer OS [1096] for patients.

Table 6.6.2.1 Definition of high- and low-volume in CHAARTED [1088-1090] and high- and low-risk in LATITUDE [1070]

	High	Low
CHAARTED (volume)	≥ 4 Bone metastases including ≥ 1 outside vertebral column or pelvis **AND/OR** Visceral metastasis*	Not high
LATITUDE (risk)	≥ 2 high-risk features of: • ≥ 3 Bone metastasis • Visceral metastasis • ≥ ISUP grade 4	Not high

**Lymph nodes are not considered as visceral metastases.*

Table 6.6.2.2: Prognostic factors based on the SWOG 9346 study [1093]

PSA after 7 months after start of ADT	Median survival on ADT monotherapy
< 0.2 ng/mL	75 months
0.2 ≤ 4 ng/mL	44 months
> 4 ng/mL	13 months

6.6.3 First-line hormonal treatment

Primary ADT has been the SOC for over 50 years [1034]. There is no high-level evidence in favour of a specific type of ADT for oncological outcomes, neither for orchiectomy nor for a LHRH agonist or antagonist. The level of testosterone is reduced much faster with orchiectomy and LHRH antagonist, therefore patients with impending spinal cord compression or other potential impending complications from the cancer should be treated with either a bilateral orchidectomy or LHRH antagonists as the preferred options.

There is a suggestion in some studies and a SR and meta-analysis that cardiovascular side effects are less frequent in patients treated with LHRH antagonists than patients treated with LHRH agonists [1053, 1097-1099]; therefore, patients with pre-existing cardiovascular disease or other cardiovascular risk factors might be considered to be treated with antagonists if a chemical castration is chosen.

6.6.3.1 Non-steroidal anti-androgen monotherapy

Based on a Cochrane review comparing older generation non-steroidal anti-androgen (NSAA) monotherapy to ADT (either medical or surgical), NSAA was considered to be less effective in terms of OS, clinical progression, treatment failure and treatment discontinuation due to AEs [1100] and is generally not recommended also because ADT-based combination treatments have become SOC.

6.6.3.2 Intermittent versus continuous androgen deprivation therapy

Three independent reviews [1101-1103] and two meta-analyses [1104, 1105] looked at the clinical efficacy of intermittent androgen deprivation (IAD) therapy. All of these reviews included eight RCTs of which only three were conducted in patients with exclusively M1 disease.

So far, the SWOG 9346 is the largest trial addressing IAD in M1b patients [1106]. Of 3,040 screened patients, only 1,535 patients met the inclusion criteria. This highlights that only about 50% of M1b patients can be expected to be candidates for IAD, i.e. the best PSA responders. This was a non-inferiority trial leading to inconclusive results: the actual upper limit was above the pre-specified 90% upper limit of 1.2 (HR: 1.1, CI: 0.99–1.23), the pre-specified non-inferiority limit was not achieved, and the results did not show a significant inferiority for any treatment arm. However, based on this study inferior survival with IAD cannot be completely ruled out even in this highly selected subgroup. The use of intermittent ADT has been superseeded as continuous ADT based combination therapy has become SOC.

6.6.3.3 Early versus deferred androgen deprivation therapy

Early treatment before the onset of symptoms is recommended in the majority of patients with metastatic hormone-sensitive disease despite lack of randomised phase III data in this specific setting and specifically not with the combination therapies that are standard nowadays.

A Cochrane analysis from 2019 about the topic concluded that early ADT probably extends time to death of any cause and time to death from PCa [1107]. Since the analysis included only a very limited number of metastatic patients, the benefit of early ADT in this setting remains unproven. All of the trials testing the combination therapies in the metastatic hormone-sensitive setting also included asymptomatic patients.

The only candidates with metastatic disease who may possibly be considered for deferred treatment are asymptomatic patients with a strong wish to avoid treatment-related side effects. The risk of developing symptoms, and even dying from PCa, without receiving the benefit from ADT with deferred treatment has been highlighted [1108, 1109], but in the era before next generation imaging was used.

Patients with deferred treatment for advanced PCa must be amenable to close follow-up. Another potential exception are patients with recurrent oligometastatic disease who have a strong wish to postpone the start of ADT (see Section 6.4.7).

6.6.4 ***Combination therapies***

All of the following combination therapies have been studied with continuous ADT, not intermittent ADT.

6.6.4.1 'Combined' androgen blockade with older generation NSAA (bicalutamide, flutamide, nilutamide)

Systematic reviews have shown that CAB using a NSAA appears to provide a small survival advantage (< 5%) vs. monotherapy (surgical castration or LHRH agonists) [1110, 1111] but this minimal survival advantage must be balanced against the increased side effects. In addition, the newer combination therapies (see Tables 6.4.3, 6.4.4, 6.4.5) are more effective as shown specifically for enzalutamide which was tested against NSAA in a phase III trial [1112]. More recently another trial has demonstrated a significant OS benefit for the addition of rezvilutamide vs. addition of bicalutamide to ADT in patients with high-volume mHSPC [1113]. Therefore combination with NSAAs should only be considered if other combination therapies are not available.

6.6.4.2 Androgen deprivation combined with other agents

6.6.4.2.1 Androgen deprivation therapy combined with chemotherapy

Three large RCTs were conducted [775, 1088, 1114]. All trials compared ADT alone as the SOC with ADT combined with immediate docetaxel (75 mg/sqm, every three weeks within three months of ADT initiation). The primary objective in all three studies was to assess OS. The key findings are summarised in Table 6.4.3.

Table 6.6.3: Key findings - Hormonal treatment combined with chemotherapy

	STAMPEDE [775, 1115]		**GETUG-AFU 15** [1114]		**CHAARTED** [1088, 1089]

HR (95% CI)	0.78 (0.66-0.93)	1.01 (0.75-1.36)	0.72 (0.59-0.89)
M1 only			
N	1,086	-	-
HR (95% CI)	0.81 (0.69-0.95)	-	-

ADT = androgen deprivation therapy; CI = confidence interval; ECOG = Eastern Cooperative Oncology Group; HR = hazard ratio; ISUP = International Society for Urological Pathology; mo = month; n = number of patients; OS = overall survival; P = prednisone; PSA-DT = prostate-specific antigen-doubling time.

In the GETUG 15 trial, all patients had M1 PCa, either *de novo* or after a primary treatment [1114]. They were stratified based on previous treatment and Glass risk factors [1085]. In the CHAARTED trial the same inclusion criteria applied, and patients were stratified according to disease volume (see Table 6.4.1) [1088].

STAMPEDE is a multi-arm multi-stage trial in which the reference arm (ADT monotherapy) included 1,184 patients. One of the experimental arms was docetaxel combined with ADT (n = 593), another was docetaxel combined with zoledronic acid (n = 593). Patients were included with either M1 or N1 or having two of the following three criteria: T3/4, PSA ≥ 40 ng/mL or ISUP grade group 4–5. Also relapsed patients after local treatment were included if they met one of the following criteria: PSA ≥ 4 ng/mL with a PSA-DT < six months or a PSA ≥ 20 ng/mL, N1 or M1. No stratification was used regarding metastatic disease volume (high/low volume) [775]. In all three trials toxicity was mainly haematological with around 12–15% grade 3–4 neutropenia, and 6–12% grade 3–4 febrile neutropenia. The use of granulocyte colony-stimulating factor receptor (GCSF) was shown to be beneficial in reducing febrile neutropenia. Primary or secondary prophylaxis with GCSF should be based on available guidelines [1116, 1117].

Docetaxel in all three trials was used at the standard dose of 75 mg/sqm every three weeks, six cycles in CHAARTED and STAMPEDE and up to nine cycles in GETUG-AFU-15. In subgroup analyses from GETUG-AFU 15 and CHAARTED the beneficial effect of the addition of docetaxel to ADT was most evident in men with *de novo* metastatic high-volume disease [1089, 1090], while it was in the same range whatever the volume in the *post-hoc* analysis from STAMPEDE [1115]. The effect of adding docetaxel was less apparent in men who had prior local radical treatment although the numbers were small and the event rates lower. A SR and meta-analysis which included these three trials showed that the addition of docetaxel to SOC improved survival [1117]. The HR of 0.77 (95% CI: 0.68–0.87, p < 0.0001) translates into an absolute improvement in 4-year survival of 9% (95% CI: 5–14). In a SR and meta-analysis of individual participant data from the the three trials it has been shown that there is no meaningful beneficial effect of addition of docetaxel to ADT for patients with metachronous low volume disease. Interestingly the largest absolute improvement at five years was observed for the patients with high volume and clinical stage four disease [1118].

Based on these data, upfront docetaxel combined with ADT was considered as a standard in men presenting with metastases at first presentation, provided they are fit enough to receive docetaxel [1117]. More recently two large Phase III studies have now shown an OS benefit by adding an ARPI to ADT and docetaxel. Therefore adding docetaxel alone to ADT should only be considered if no ARPI is available or all available ones are contraindicated (see Section 6.4.4.2.3).

6.6.4.2.2 Combination with an ARPI alone (abiraterone, apalutamide, enzalutamide)

In two large RCTs (STAMPEDE, LATITUDE) the addition of abiraterone acetate (1000 mg daily) plus prednisone (5 mg daily) to ADT in men with mHSPC was studied [814, 1070, 1119] (see table 6.4.4). The primary objective of both trials was an improvement in OS. Both trials showed a significant OS benefit. In LATITUDE with only *de novo* high-risk metastatic patients included, the HR reached 0.62 (0.51–0.76) [1070]. The HR in STAMPEDE was very similar with 0.63 (0.52–0.76) in the total patient population (metastatic and non-metastatic) and a HR of 0.61 in the subgroup of metastatic patients [814]. While only high-risk patients were included in the LATITUDE trial a *post-hoc* analysis from STAMPEDE showed the same benefit whatever the risk or the volume category was [1120].

All secondary objectives such as PFS, time to radiographic progression, time to pain, or time to chemotherapy were in favour of the combination. No difference in treatment-related deaths was observed with the combination of ADT plus AAP compared to ADT monotherapy (HR: 1.37 [0.82–2.29]). However, twice as many patients

discontinued treatment due to toxicity in the combination arms in STAMPEDE (20%) compared to LATITUDE (12%) [1119]. Based on these data upfront AAP combined with ADT should be considered as a standard in men presenting with metastases at first presentation, provided they are fit enough to receive the drug.

In three large RCTs (TITAN, ARCHES and ENZAMET) the addition of AR antagonists to ADT in men with mHSPC was tested [1068, 1069, 1112]. In ARCHES the primary endpoint was radiographic PFS (rPFS). In the primary analysis rPFS was significantly improved for the combination of enzalutamide and ADT with a HR of 0.39 (0.3–0.5). Approximately 36% of the patients had low-volume disease; around 25% had prior local therapy and 18% of the patients had received prior docetaxel. In the final prespecified analysis the key secondary enpoint OS was significantly improved with a HR of 0.66 (0.53-0.81) and a significant benefit for rPFS was maintained with a HR of 0.63 (0,52–0.76) [1121]. In ENZAMET the primary endpoint was OS. The addition of enzalutamide to ADT in the first analysis improved OS with a HR of 0.67 (0.52–0.86) compared to ADT plus a non-steroidal antiandrogen. Approximately half of the patients had concomitant docetaxel; about 40% had prior local therapy and about half of the patients had low-volume disease [1069]. In a planned later analysis with a median follow-up of 68 months the OS benefit of adding enzalutamide was maintained with a HR of 0.7 (0.58-0.84) [1122] In the TITAN trial, ADT plus apalutamide was used and rPFS and OS were co-primary endpoints. In the primary analysis rPFS was significantly improved by the addition of apalutamide with a HR of 0.48 (0.39–0.6); OS at 24 months was improved for the combination with a HR of 0.67 (0.51–0.89). In the final analysis the HR for OS was 0.65 (0.53–0.79) without adjustment for cross-over. In this trial 16% of patients had prior local therapy, 37% had low-volume disease and 11% received prior docetaxel [1068, 1123]. In the more recently published CHART trial, ADT plus rezvilutamide was tested vs. ADT plus bicalutamide in patients with high-volume *de novo* metastatic disease. Ninety percent of the patients were recruited in China. Overall survival and rPFS were co-primary endpoints. At the pre-planned interim analysis rezvilutamide significantly improved rPFS compared with bicalutamide with a HR of 0.44 (0.33–0.58) and OS with a HR of 0.58 (0.44–0.77) [1113].

In summary, the addition of the new AR antagonists significantly improves clinical outcomes with no convincing evidence of differences between subgroups. The majority of patients had *de novo* metastatic disease and the evidence is most compelling in this situation. In the trials with the new AR antagonists, a proportion of patients had metachronous disease (see Table 6.4.5); in the subgroup analyses the effect seemed to be consistent and therefore, a combination should also be offered for men progressing after radical local therapy [1122, 1124, 1125].

Table 6.6.4: Results from the STAMPEDE arm G and LATITUDE studies

	STAMPEDE [814]		**LATITUDE** [1070]

HR = hazard ratio; mo = month; n = number of patients; OS = overall survival; rPFS = radiographic progression-free survival; yr = year.

6.6.4.2.3 Combination with docetaxel and an ARPI

The addition of abiraterone to ADT and docetaxel has been reported to have a benefit in rPFS and in OS in the PEACE-1 trial [1126, 1127]. The trial has a 2x2 factorial design and participants with *de novo* (synchronous) metastatic PCa were randomised to SOC; at the beginning of the trial ADT, later ADT plus docetaxel for 6 cycles if chemotherapy-fit) vs. SOC plus radiotherapy vs. SOC plus abiraterone vs. SOC plus radiotherapy plus abiraterone. Co-primary endpoints were rPFS and OS, both were statistically significantly improved in the total population. Also in the group of patients who received ADT plus docetaxel as SOC (n = 710) both rPFS and OS were increased with a HR: 0.5 (0.34–0.71) and 0.75 (0.59–0.95), respectively. Of note; in this population about 35% had low-volume disease. Toxicity was modestly increased, mostly hypertension.

In the ARASENS Phase III trial all patients received ADT and docetaxel for 6 cycles as SOC plus darolutamide or placebo [1128]. 1,306 metastatic patients were included, 14 % of them with relapsed disease after radical local treatment (metachronous). Primary endpoint was OS and this was statistically significanty increased by the addition of darolutamide with a HR of 0.68 (0.57–0.8).

Interestingly, in this trial the occurrence of AEs was similar in both arms. In both trials docetaxel and the ARPI have been given concomitantly. Of the included patients 77% had high volume and 70% high-risk disease. In an unplanned subgroup analysis the beneficial effect of adding darolutamide versus placebo for OS was seen in the patients with high-volume (HR 0.69; 0.57-0.82), with high-risk (HR 0.71; 0.58-0.86) and in low-risk disease (HR 0.62; 0.42-0.9), for the small subgroup of patients with low-volume disease the results were suggestive of an OS benefit (HR 0.68; 0.41-1.13) [1129]

Also in ENZAMET, TITAN and ARCHES there were patients who received docetaxel as a part of SOC, thus not all concomitantly, but the percentage of patients receiving docetaxel in these trials was much lower [1068, 1069, 1112].

There are also SRs and network meta-analysis for systemic triplet therapies and they confirm that the triplets are more effective than ADT and docetaxel alone [1130], in one analysis looking into subgroups statistically significant for patients with high volume disease and *de novo* disease [1131].

*6.6.5 **Treatment selection and patient selection***

There have been several network meta-analyses of the published data concluding that combination therapy is more efficient than ADT alone, but none of the doublet combination therapies has been convincingly proven to be superior over another [1132-1137]. In a SR and meta-analysis looking at association between age and efficacy of combination therapy patients seemed to profit from combination therapy irrespective of age [1138]. As a consequence, patients should be offered combination treatment unless there are clear contra-indications or they present with asymptomatic disease and a very short life expectancy (based on non-cancer comorbidities).

Since the data of the above mentioned Phase III trials of the triplet therapies have been reported, docetaxel as sole addition to ADT is not longer a valid option in the majority of patients if an androgen receptor pathway inhibitor (ARPI) is available and there are no contra-indications to use one. From subgroup analysis of all the above-mentioned RCTs we know that probably all subgroups (high vs. low volume/risk and synchronous vs. metachronous) can profit from the addition of an ARPI to ADT. Therefore, in view of the current data the recommendation is using ADT plus ARPI as the sole additional therapy or the triplet with an ARPI plus docetaxel. Formally the question what the added value of adding docetaxel to ADT plus an ARPI has not been evaluated, but since triplet therapy seems not to add a lot of unexpected overlapping toxicities, the data should be discussed with patients who are fit for chemotherapy and an ARPI, realising that most of the toxicity is caused by adding the chemotherapy. There is more evidence for using the triplet in synchronous disease and the OS benefit in PEACE-1 seemed to be driven mostly by the high volume patients at the time point of the analysis for the publication, in ARASENS only few patients had low volume disease.

Of interest in some SRs and meta-analysis the authors found no significant difference for OS and/or PFS using the systemic triplet therapy compared to adding an ARPI alone to ADT [1135, 1139-1141]. In contrast one meta-analysis suggested a benefit of systemic triplet therapy versus ADT and ARPI and another meta-analysis showed a benefit in patients with high volume disease [1136, 1142]. In summary, the choice will most likely be driven by fitness for docetaxel, the nature of the disease (low/high volume; synchronous/metachronous), patient preference, the specific side effects, availability, logistics and cost.

*6.6.6 **Treatment of the primary tumour in newly diagnosed metastatic disease***

The first reported trial evaluating prostate RT in men with metastatic castration-sensitive disease was the HORRAD trial. Four hundred and thirty-two patients were randomised to ADT alone or ADT plus IMRT with IGRT to the prostate. Overall survival was not significantly different (HR: 0.9 [0.7–1.14]), median time to PSA progression was significantly improved in the RT arm (HR: 0.78 [0.63–0.97]) [1143]. The STAMPEDE trial evaluated 2,061 men with metastatic castration-sensitive PCa (mCSPC) who were randomised to ADT alone vs.

ADT plus RT to the prostate. This trial confirmed that RT to the primary tumour did not improve OS in unselected patients [1091]. However, following the results from CHAARTED and prior to analysing the data, the original screening investigations were retrieved, and patients categorised as low- or high volume. In the low-volume subgroup (n = 819) there was a significant OS benefit by the addition of prostate RT. This was confirmed by the latest analysis of long-term follow-up (median follow-up of 61 months [HR: 0.64 for OS benefit in the low-volume group]) [1144].

A secondary, not pre-planned analysis of the STAMPEDE trial confirmed the benefit of prostate RT in patients with ≤ 3 bone metastases, but also showed a benefit in patients with M1a disease [1145]. No evidence of difference in time to symptomatic local events was found with median follow-up of over five years [1144].The dose used in these indications should be equivalent of up to 72 Gy in 2 Gy fractions.

Therefore, RT of the prostate only in patients with low-volume metastatic disease should be considered. Of note, only 18% of these patients had additional docetaxel and no patients had additional AAP, so no clear recommendation can be made about triple combinations. In addition, it is not clear if these data can be extrapolated to RP as local treatment as results of ongoing trials are awaited.

In a SR and meta-analysis including the above two RCTs, the authors found that, overall, there was no evidence that the addition of prostate RT to ADT improved survival in unselected patients (HR: 0.92, 95% CI: 0.81–1.04, p = 0.195) [1146]. However, there was a clear difference in the effect of metastatic burden on survival with an absolute improvement of 7% in three-year survival in men who had four or fewer bone metastases.

*6.6.7 **Metastasis-directed therapy in M1-patients***

In patients relapsing after a local treatment, a metastases-targeting therapy has been proposed, with the aim to delay systemic treatment. In a retrospective analysis on 211 patients treated with MDT, Milenkovic *et al.* aimed at defining prognostic factors for MFS, palliative ADT-free (pADT) survival and cause-specific survival (CSS). With a median follow-up of 42 months after MDT, patients with cN1 only had significantly superior 5-years MFS, pADT and CSS when compared to patients with M1 disease (p<0.02). Of interest, 23% of patients were free of biochemical recurrence at five years [1147]. There are two randomised phase II trials testing metastasis-directed therapy (MDT) using surgery ± SABR vs. surveillance [1148] or SABR vs. surveillance in men with oligo-recurrent PCa [1149]. Oligo-recurrence was defined as < 3 lesions on choline-PET/CT only [1148] or conventional imaging with MRI/CT and/or bone scan [1149]. The sample size was small with 62 and 54 patients, respectively, and a substantial proportion of them had nodal disease only [1148]. Androgen deprivation therapy-free survival was the primary endpoint in one study which was longer with MDT than with surveillance [1148]. The primary endpoint in the ORIOLE trial was progression after six months which was significantly lower with SBRT than with surveillance (19% vs. 61%, p = 0.005) [1149].

Recently the combined results of STOMP and ORIOLE confirmed the significant improvement in PFS in favour of MDT (HR: 0.44, p < 0.001) [1150].

A phase II trial assessed the biochemical response after ^{18}F-DCFPyL PET/MRI and subsequent MDT. Overall biochemical response rate, defined as ≥ 50% PSA decline, was 60%, including 22% of patients with complete biochemical response [1151].

Currently there are no data to suggest an improvement in OS. Two comprehensive reviews highlighted MDT (SABR) as a promising therapeutic approach that must still be considered as investigational until the results of the ongoing RCT are available [1152, 1153]. Thus far, the toxicity of MDT appears to be low, but this also needs to be confirmed [1154, 1155].

*6.6.8 **Guidelines for the first-line treatment of hormone-sensitive metastatic disease****

Recommendations	Strength rating
Offer immediate systemic treatment with androgen deprivation therapy (ADT) to palliate symptoms and reduce the risk for potentially serious sequelae of advanced disease (spinal cord compression, pathological fractures, ureteral obstruction) to M1 symptomatic patients.	Strong
Offer short-term administration of an older generation androgen receptor (AR) antagonist to M1 patients starting LHRH agonist to reduce the risk of the 'flare-up' phenomenon.	Weak
At the start of ADT offer luteinising hormone-releasing hormone (LHRH) antagonists or orchiectomy to patients with impending clinical complications such as spinal cord compression or bladder outlet obstruction.	Strong
Do not offer AR antagonist monotherapy to patients with M1 disease.	Strong

Do not offer ADT monotherapy to patients whose first presentation is M1 disease if they have no contra-indications for combination therapy and have a sufficient life expectancy to benefit from combination therapy (≥ 1 year) and are willing to accept the increased risk of side effects.	Strong
Offer ADT combined with abiraterone acetate plus prednisone or apalutamide or enzalutamide to patients with M1 disease who are fit for the regimen.	Strong
Offer docetaxel only in combination with ADT plus abiraterone or darolutamide to patients with M1 disease who are fit for docetaxel.	Strong
Offer ADT combined with prostate radiotherapy (using doses up to the equivalent of 72 Gy in 2 Gy fractions) to patients whose first presentation is M1 disease and who have low volume of disease by CHAARTED criteria.	Strong
Do not offer ADT combined with surgery to M1 patients outside of clinical trials.	Strong
Only offer metastasis-directed therapy to M1 patients within a clinical trial setting or a well-designed prospective cohort study.	Strong

**All the following statements are based on metastatic disease defined by bone scintigraphy and CT scan/MRI.*

6.7 Treatment: Castration-resistant PCa (CRPC)

*6.7.1 **Definition of CRPC***

Castrate serum testosterone < 50 ng/dL or 1.7 nmol/L plus either:

a. Biochemical progression: Three consecutive rises in PSA at least one week apart resulting in two 50% increases over the nadir, and a PSA > 2 ng/mL or

b. Radiological progression: The appearance of new lesions: either two or more new bone lesions on bone scan or a soft tissue lesion using RECIST (Response Evaluation Criteria in Solid Tumours) [1156]. Symptomatic progression alone must be questioned and subject to further investigation. It is not sufficient to diagnose CRPC.

*6.7.2 **Management of mCRPC - general aspects***

Selection of treatment for mCRPC is multifactorial and in general dependent on:

- previous treatment for mHSPC and for non-mHSPC;
- previous treatment for nmCRPC and mCRPC;
- quality of response and pace of progression on previous treatment;
- known cross resistance between androgen receptor pathway inhibitor (ARPI);
- co-medication and known drug interactions (see approved summary of product characteristics);
- known genetic alterations and microsatellite instability–high (MSI-H)/mismatch repair–deficient (dMMR) status;
- known histological variants and DNA repair deficiency (to consider platinum or targeted therapy like PARPi);
- local approval status of drugs and reimbursement situation;
- available clinical trials;
- The patient and his comorbidities.

6.7.2.1 Molecular diagnostics

All metastatic patients should be offered somatic genomic testing for homologous repair and MMR defects early on, preferably before firstline mCRPC treatment is established. Testing should preferably be performed on metastatic carcinoma tissue but testing on primary tumour may also be performed. Alternatively, but still less common, genetic testing on circulating tumour DNA (ctDNA) is an option and has been used in some trials. One test, the FoundationOne® Liquid CDx, has been FDA approved [1157]. Defective *MMR* assessment can be performed by IHC for MMR proteins (MSH2, MSH6, MLH1 and PMS2) and/or by next generation sequencing (NGS) assays [1158]. Germline testing for *BRCA1/2*, *ATM* and *MMR* is recommended for high-risk- and particularly for metastatic PCa if clinically indicated.

Molecular diagnostics should be performed by a certified (accredited) institution using a standard NGS multiplication procedure (minimum depth of coverage of 200 X). The genes and respective exons should be listed; not only DNA for mutations but RNA needs to be examined for fusions and protein expression to obtain all clinically relevant information. A critical asset is the decision support helping to rate the mutations according to their clinical relevance [1159, 1160].

Level 1 evidence for the use of PARP-inhibitors has been reported [248, 1161, 1162]. Microsatellite instability (MSI)-high (or *MMR* deficiency) is rare in PCa, but for those patients, pembrolizumab has been approved by the FDA and could be a valuable additional treatment option [1080, 1163]. Germline molecular testing is discussed in Section 5.1.6 - Genetic testing for inherited PCa. Recommendations for germline testing are provided in Section 5.1.7.

6.7.3 Treatment decisions and sequence of available options

Approved agents for the treatment of mCRPC in Europe are docetaxel, abiraterone/prednisolone (AAP), enzalutamide, cabazitaxel, olaparib, niraparib/AAP, talazoparib/enzalutamide, radium-223 and lutetium (^{177}Lu) vipivotide tetraxetan. Regarding CRPC, darolutamide and apalutamide have been approved only for nmCRPC. In general, sequencing of ARPIs like abiraterone and enzalutamide is not recommended particularly if the time of response to ADT and to the first ARPI was short (≤ six to twelve months) and high-risk features of rapid progression are present (see detailed discussion in Section 6.7.7) [1164, 1165].

The use of chemotherapy with docetaxel and subsequent cabazitaxel in the treatment sequence is recommended and should be applied early enough when the patient is still fit for chemotherapy. This is supported by high-level evidence [1164].

6.7.4 Non-metastatic CRPC

Frequent PSA testing in men treated with ADT has resulted in earlier detection of biochemical progression. Of these men approximately one-third will develop bone metastases within two years, detected by conventional imaging [893].

In men with CRPC and no detectable clinical metastases using bone scan and CT-scan, baseline PSA level, PSA velocity and PSA-DT have been associated with time to first bone metastasis, bone MFS and OS [893, 1166]. These factors may be used when deciding which patients should be evaluated for metastatic disease. A consensus statement by the PCa Radiographic Assessments for Detection of Advanced Recurrence (RADAR) group suggested a bone scan and a CT scan when the PSA reached 2 ng/mL and if this was negative, it should be repeated when the PSA reached 5 ng/mL, and again after every doubling of the PSA based on PSA testing every three months in asymptomatic men [1167]. Symptomatic patients should undergo relevant investigations regardless of PSA level. With more sensitive imaging techniques like PSMA PET/CT or whole-body MRI, more patients are diagnosed with early mCRPC [1168]. It remains unclear if the use of PSMA PET/CT in this setting improves outcome.

Three large phase III RCTs, PROSPER [1169] , SPARTAN [1170] and ARAMIS [1171] , evaluated MFS as the primary endpoint in patients with nmCRPC (M0 CRPC) treated with enzalutamide (PROSPER) vs. placebo or apalutamide (SPARTAN) vs. placebo or darolutamide (ARAMIS) vs. placebo ,respectively (see Table 6.7.1). The M0 status was established by CT and bone scans. Only patients at high risk for the development of metastasis with a short PSA-DT of ≤ ten months were included. Patient characteristics in the trials revealed that about two-thirds of participants had a PSA-DT of < six months. All trials showed a significant MFS benefit. All three trials showed a survival benefit after a follow-up of more than 30 months. In view of the long-term treatment with these AR targeting agents in asymptomatic patients, potential AEs need to be taken into consideration and the patient informed accordingly.

Table 6.7.1: Randomised phase III controlled trials – nmCRPC

Study	Intervention	Comparison	Selection criteria	Main outcomes
ARAMIS 2019, 2020 [1171, 1172]	ADT + darolutamide	ADT + placebo	nmCRPC; baseline PSA ≥ 2 ng/mL PSA-DT ≤ 10 mo.	**59% reduction of distant progression or death** **Median MFS: darolutamide 40.4 vs placebo 18.4 mo;** **31% reduction in risk of death** HR = 0.69 (95% CI: 0.53–0.88) p = 0.003
PROSPER 2018, 2020 [1169, 1173]	ADT + enzalutamide	ADT + placebo	nmCRPC; baseline PSA ≥ 2 ng/mL PSA-DT ≤ 10 mo.	**71% reduction of distant progression or death** **Median MFS: enzalutamide 36.6 vs placebo 14.7 months;** **27% reduction in risk of death** HR = 0.73 (95% CI: 0.61–0.89) p = 0.001

SPARTAN 2018, 2021 [1170, 1174]	ADT + apalutamide	ADT + placebo	nmCRPC; baseline PSA ≥ 2 ng/mL PSA-DT ≤ 10 mo.	**72% reduction of distant progression or death** **Median MFS: apalutamide 40.5 vs placebo 16.2 months;** **22% reduction in risk of death** HR = 0.78 (95% CI: 0.64–0.96) p = 0.0161

ADT = androgen-deprivation therapy; CI = confidence interval; HR = hazard ratio; MFS = metastasis-free survival; nmCRPC = non-metastatic castrate-resistent prostate cancer; PSA-DT = prostate-specific antigen doubling time.

*6.7.5 **Metastatic CRPC***

The remainder of this section focuses on the management of men with proven mCRPC on conventional imaging.

6.7.5.1 Conventional androgen deprivation in CRPC

Eventually men with PCa will show evidence of disease progression despite castration. Two trials have shown only a marginal survival benefit for patients remaining on LHRH analogues during second- and thirdline therapies [1175, 1176]. However, in the absence of prospective data, the modest potential benefits of continuing castration outweigh the minimal risk of treatment. In addition, all subsequent treatments have been studied in men with ongoing androgen suppression, therefore, it should be continued in these patients.

*6.7.6 **First-line treatment of metastatic CRPC***

6.7.6.1 Abiraterone

Abiraterone was evaluated in 1,088 chemo-naive, asymptomatic or mildly symptomatic mCRPC patients in the phase III COU-AA-302 trial. Patients were randomised to abiraterone acetate or placebo, both combined with prednisone [1177]. Patients with visceral metastases were excluded. The main stratification factors were ECOG PS 0 or 1 and asymptomatic or mildly symptomatic disease. Overall survival and rPFS were the co-primary endpoints. After a median follow-up of 22.2 months there was significant improvement of rPFS (median 16.5 vs. 8.2 months, HR: 0.52, p < 0.001) and the trial was unblinded. At the final analysis with a median follow-up of 49.2 months, the OS endpoint was significantly positive (34.7 vs. 30.3 months, HR: 0.81, 95% CI: 0.70–0.93, p = 0.0033) [1178]. Adverse events related to mineralocorticoid excess and liver function abnormalities were more frequent with abiraterone, but mostly grade 1–2. Subset analysis of this trial showed the drug to be equally effective in an elderly population (> 75 years) [1179].

6.7.6.2 Enzalutamide

A randomised phase III trial (PREVAIL) included a similar patient population and compared enzalutamide and placebo [1180]. Men with visceral metastases were eligible but the numbers included were small. Corticosteroids were allowed but not mandatory. PREVAIL was conducted in a chemo-naive mCRPC population of 1,717 men and showed a significant improvement in both co-primary endpoints, rPFS (HR: 0.186, CI: 0.15–0.23, p < 0.0001), and OS (HR: 0.706, CI: 0.6–0.84, p < 0.001). A ≥ 50% decrease in PSA was seen in 78% of patients. The most common clinically relevant AEs were fatigue and hypertension. Enzalutamide was equally effective and well tolerated in men > 75 years [1181] as well as in those with or without visceral metastases [1182]. However, for men with liver metastases, there seemed to be no discernible benefit [1182, 1183].

Enzalutamide has also been compared with bicalutamide 50 mg/day in a randomised double-blind phase II study (TERRAIN) showing a significant improvement in PFS (15.7 months vs. 5.8 months, HR: 0.44, p < 0.0001) in favour of enzalutamide [1183]. With extended follow-up and final analysis the benefit in OS and rPFS were confirmed [1184].

6.7.6.3 Docetaxel

A statistically significant improvement in median survival of 2.0–2.9 months has been shown with docetaxel based chemotherapy compared to mitoxantrone plus prednisone [1185, 1186]. The standard first-line chemotherapy is docetaxel 75 mg/m^2, three-weekly doses combined with prednisone 5 mg twice a day (BID), up to ten cycles. Prednisone can be omitted if there are contra-indications or no major symptoms. The following independent prognostic factors: visceral metastases, pain, anaemia (Hb < 13 g/dL), bone scan progression, and prior estramustine may help stratify the response to docetaxel. Patients can be categorised into three risk groups: low risk (0 or 1 factor), intermediate (2 factors) and high risk (3 or 4 factors), and show three significantly different median OS estimates of 25.7, 18.7 and 12.8 months, respectively [1187].

Age by itself is not a contra-indication to docetaxel [1188] but attention must be paid to careful monitoring and comorbidities as discussed in Section 5.4 - Estimating life expectancy and health status [1189].

In men with mCRPC who are thought to be unable to tolerate the standard dose and schedule, docetaxel 50 mg/m^2 every two weeks seems to be well tolerated with less grade 3–4 AEs and a prolonged time to treatment failure [1190].

6.7.6.4 Sipuleucel-T

In 2010 a phase III trial of sipuleucel-T showed a survival benefit in 512 asymptomatic or minimally symptomatic mCRPC patients [1191]. After a median follow-up of 34 months, the median survival was 25.8 months in the sipuleucel-T group compared to 21.7 months in the placebo group, with a HR of 0.78 (p = 0.03). No PSA decline was observed and PFS was similar in both arms. The overall tolerance was very good, with more cytokine-related AEs grade 1–2 in the sipuleucel-T group, but the same grade 3–4 AEs in both arms. Sipuleucel-T is not available in Europe.

6.7.6.5 Ipatasertib

The AKT inhibitor ipatasertib in combination with AAP was studied in asymptomatic or mildly symptomatic patients with and without PTEN loss by IHC and previously untreated for mCRPC. The randomised phase III trial (IPAtential) showed a significant benefit for the first endpoint rPFS in the PTEN loss (IHC) 18.5 vs. 16.5 mo; p = 0.0335, HR: 0.77, 95% CI: 0.61–0,98) but not in the intention to treat (ITT) population. The OS results are still pending. Side effects of the AKT inhibitor ipatasertib include rash and diarrhoea [1077]. Grade 3 or higher AEs occurred nearly double as often in the combination group and the discontinuation rate due to AEs was four times higher. This combination is still investigational [1192].

6.7.6.6 Combinations with PARP inhibitors

Based on the suggestion that there is a synergistic antitumour effect when combining an ARPI with a PARP inhibitor, several such combination trials were conducted in first-line mCRPC patients with different trial designs, different patient selection and conflicting results.

Abiraterone/prednisone plus olaparib

A randomised double-blind, phase III trial (PROpel) of AAP plus olaparib (300 mg twice daily) or placebo in patients with mCRPC in the first-line setting was conducted [1193, 1194]. Patients (n=796) were randomly assigned 1:1 to study treatment regardless of homologous recombination repair gene mutation (HRRm) status which was retrospectively evaluated and determined by tumour tissue and circulating tumour DNA tests. The primary end point was imaging-based PFS (ibPFS) by investigator assessment. The result was significantly positive in favour of the combination with ibPFS of 24.8 vs. 16.6 mo (HR 0.66; 95% CI: 0.54 to 0.81; p = 0.001). In the prespecified final analyses the key secondary endpoint OS had only 47.9% maturity and did not meet the prespecified 2-sided boundary for significance (HR 0.95% CI: 0.81, 0.67-1.0, p= 0,054).The subgroup of patients with positive HRRm status showed a rPFS HR of 0.50 (CI: 0.34 to 0.73). The BRCA mutated patients (11% of the ITT population) had an even larger benefit for rPFS (HR 0.24; 95% CI: 0.12, 0.45) and the OS HR in these patients was 0.30 (95% CI: 0.15, 0.59), suggesting that the improvement in rPFS observed in the ITT population was primarily driven by patients with a BRCA mutation [1195].

The most common AEs in patients receiving olaparib plus AAP were anaemia (48%; ≥G3 15%; at least one blood transfusion in 18%; multiple transfusions 12% [1195]. The most common adverse reactions with olaparib plus abiraterone were anaemia (48%), fatigue (38%), nausea (30%), diarrhoea (19%), decreased appetite (16%), lymphopenia (14%), dizziness (14%), and abdominal pain (13%); 18% of patients required at least one blood transfusion and 12% required multiple transfusions. The combination of olaparib plus AAP was approved by the EMA for the treatment of adult patients with mCRPC in whom chemotherapy is not clinically indicated [1240]. In the US, the FDA has approved olaparib with AAP for mCRPC patients with deleterious or suspected deleterious BRCA-mutations as determined by an FDA-approved companion diagnostic test [1197].

Abiraterone/prednisone plus niraparib

In a randomised, double-blind, phase III trial (MAGNITUDE) AAP plus niraparib 200 mg once/daily or placebo, was evaluated [1198]. The study prospectively included 2 cohorts, an HRR-negative and an HRR-positive cohort. The HRR-negative cohort was closed early for futility after enrolling 200 patients. In the overall HRR-positive cohort, the addition of Niraparib to AAP resulted in a significant improvement in the first endpoint rPFS compared to AAP plus placebo (HR = 0.73; 95% CI 0.56-0.96; p = 0.0217) and the median rPFS was 16.5 vs. 13.7 months in favour of the combination. In particular, the 113 patients with BRCA 1/ 2 mutations [1199] who received AAP plus niraparib [1199] derived a major rPFS benefit (19.5 versus 10.9 months; HR = 0.55 [95% CI 0.39-0.78]; nominal p = 0.0007). The OS data is still immature. The most common side effects with Niraparib plus AAP in the ITT population were anemia (46.2%), fatigue (26.4%), hypertension (31.6%) and constipation (30.7%). The combination of niraparib plus AAP in a dual-action tablet has been approved by the EMA and the FDA for patients with mCRPC and BRCA 1/2 mutations in whom chemotherapy is not clinically indicated [1200].

Enzalutamide plus Talazoparib

A randomised double-blind, phase III trial (TALAPRO-2) of the PARP inhibitor talazoparib (0.5mg daily) plus enzalutamide versus enzalutamide/placebo showed a significantly better median rPFS (first endpoint) in favour of the combintion regardless of homologous recombination repair pathway status [1202].

The median was not yet reached for the combination as compared to 21.9 mo in the control arm (95% CI 16.6-25.1). The HR for rPFS was 0.63 (0.51-0.78) with p<0.0001. For the subgroups of patients with HRR mutations the benefit of the combination was much more pronounced. The HRR gene-mutated population showed a median rPFS of 27.9 (16.6–not reached) for the talazoparib combination versus 16.4 (10.9–24.6) for the placebo group (0.46; 95% CI: 0.30–0.70; p=0.0003) and 0.70 (0.54–0.89; p=0.0039) in patients with a status of non-deficient or unknown. In an exploratory analysis, the HR for rPFS in patients with BRCA-mutated mCRPC was 0.23 (0.10–0.53; p=0.0002) and, in patients with non-BRCAm HRR gene-mutated mCRPC, it was 0.66 (0.39–1.12; p=0.12) in favour of the talazoparib combination.[1202] The OS data are still immature. The expected clinical benefit in the subgroups needs to be weighed against the potential burden of side effects.

The most common treatment-emergent adverse events with the addition of talazoparib were anaemia, neutropenia, and fatigue; the most common grade 3–4 event was anaemia (46%), which improved after dose reduction, however, 39% required a blood transfusion, including 22% who required multiple transfusions, 8% discontinued treatment due to anemia and 2 patients on the combination were diagnosed with myelodysplastic syndrome/acute myeloid leukemia [1202]. In TALAPRO-2 also an HRR-deficient-only cohort (cohort 2; N = 230) was recruited. The primary analysis for the combined HRR-deficient population (N = 399) met the rPFS endpoint with a HR 0.45 (95% CI, 0.33 to 0.61; P < 0.0001; median not reached at the time of the analysis for the talazoparib group versus 13.8 months for the placebo group). Also for this cohort data for OS are immature but favor talazoparib (HR 0.69; 95% confidence interval, 0.46 to 1.03; P = 0.07) [1203].

The FDA approved talazoparib with enzalutamide only for HRR gene-mutated mCRPC [1201]. The European commission approved talazoparib with enzalutamide for the treatment of patients with mCRPC (with or without gene mutations) in whom chemotherapy is not clinically indicated.

Table 6.7.2: Randomised phase III controlled trials - first-line treatment of mCRPC

Study	Intervention	Comparison	Selection criteria	Main outcomes
DOCETAXEL				
SWOG 99-16 2004 [1204]	docetaxel/EMP, every 3 weeks, 60 mg/m^2, EMP 3 x 280 mg/day	mitoxantrone, every 3 weeks, 12 mg/m^2 prednisone 5 mg BID		**OS: 17.52 vs. 15.6 mo.** (p = 0.02, HR: 0.80; 95% CI: 0.67-0.97) **PFS: 6.3 vs. 3.2 mo.** (p < 0.001)
TAX 327 2004, 2008 [1185, 1186]	docetaxel, every 3 weeks, 75 mg/m^2 prednisone 5 mg BID or docetaxel, weekly, 30 mg/m^2 prednisone 5 mg BID	mitoxantrone, every 3 weeks, 12 mg/m^2, Prednisone 5 mg BID		**OS: 19.2 for 3 weekly vs. 17.8 mo. 4-weekly and 16.3 in the control group.** (p = 0.004, HR: 0.79, 95% CI: 0.67-0.93)
ABIRATERONE				
COU-AA-302 2013, 2014, 2015 [1177, 1178, 1205]	abiraterone + prednisone	placebo + prednisone	- No previous docetaxel. - ECOG 0-1. - PSA or radiographic progression. - No or mild symptoms. - No visceral metastases.	**OS: 34.7 vs. 30.3 mo.** (HR: 0.81, p = 0.0033). **FU: 49.2 mo. rPFS: 16.5 vs. 8.3 mo.** (p < 0.0001)
ENZALUTAMIDE				
PREVAIL 2014 [1180]	enzalutamide	placebo	- No previous docetaxel. - ECOG 0-1. - PSA or radiographic progression. - No or mild symptoms. - 10% had visceral mets.	**OS: 32.4 vs. 30.2 mo.** (p < 0.001). FU: 22 mo. (p < 0.001 HR: 0.71, 95% CI: 0.60-0.84) **rPFS: 20.0 mo. vs. 5.4 mo.** HR: 0.186 (95% CI: 0.15-0.23) p < 0.0001)

*6.7.7 **Second-line treatment for mCRPC***

All patients who receive treatment for mCRPC will eventually progress. All treatment options in this setting are presented in Table 6.7.3. High-level evidence exists for second-line treatments after first-line treatment for mCRPC with docetaxel or with ARPI. There is a paucity of high-level data with regards to the sequence of treatments in case of pretreatment with ARPI and/or docetaxel for mHSPC.

6.7.7.1 Cabazitaxel

Cabazitaxel is a taxane with activity in docetaxel-resistant cancers. It was studied in a large prospective, randomised, phase III trial (TROPIC) comparing cabazitaxel plus prednisone vs. mitoxantrone plus prednisone in 755 patients with mCRPC, who had progressed after or during docetaxel-based chemotherapy [1208]. Patients received a maximum of ten cycles of cabazitaxel (25 mg/m^2) or mitoxantrone (12 mg/m^2) plus prednisone (10 mg/day). Overall survival was the primary endpoint which was significantly longer with cabazitaxel (median: 15.1 vs. 12.7 months, $p < 0.0001$). There was also a significant improvement in PFS (median: 2.8 vs. 1.4 months, $p < 0.0001$), objective RECIST response (14.4% vs. 4.4%, $p < 0.005$), and PSA response rate (39.2% vs. 17.8%, $p < 0.0002$). Treatment-associated WHO grade 3–4 AEs developed significantly more often in the cabazitaxel arm, particularly haematological (68.2% vs. 47.3%, $p < 0.0002$) but also non-haematological (57.4 vs. 39.8%, $p < 0.0002$) toxicity. In two post-marketing randomised phase III trials, cabazitaxel was shown not to be superior to docetaxel in the first-line setting; in the second-line setting in terms of OS, 20 mg/m^2 cabazitaxel was not inferior to 25 mg/m^2, but less toxic. Therefore, the lower dose should be preferred [1209, 1210]. Cabazitaxel should preferably be given with prophylactic granulocyte colonystimulating factor (G-CSF) and should be administered by physicians with expertise in handling neutropenia and sepsis [1211].

6.7.7.2 Abiraterone acetate after docetaxel

Positive results of the large phase III trial (COU-AA-301) were reported after a median follow-up of 12.8 months [1212] and confirmed by the final analysis [1213]. A total of 1,195 patients with mCRPC were randomised 2:1 to AAP or placebo plus prednisone. All patients had progressive disease based on the Prostate Cancer Clinical Trials Working Group 2 (PCWG2) criteria after docetaxel therapy (with a maximum of two previous chemotherapeutic regimens). The primary endpoint was OS, with a planned HR of 0.8 in favour of AAP. After a median follow-up of 20.2 months, the median survival in the AAP group was 15.8 months compared to 11.2 months in the placebo arm (HR: 0.74, $p < 0.0001$). The benefit was observed in all subgroups and all the secondary objectives were in favour of AAP (PSA, radiologic tissue response, time to PSA or objective progression). The incidence of the most common grade 3–4 AEs did not differ significantly between arms, but mineralocorticoid-related side effects were more frequent in the AAP group, mainly grade 1–2 (fluid retention, oedema and hypokalaemia).

6.7.7.3 Enzalutamide after docetaxel

The planned interim analysis of the AFFIRM study was published in 2012 [1214]. This trial randomised 1,199 patients with mCRPC in a 2:1 fashion to enzalutamide or placebo. The patients had progressed after docetaxel treatment, according to the PCWG2 criteria. Corticosteroids were not mandatory, but could be prescribed, and were received by about 30% of the patients. The primary endpoint was OS, with an expected HR benefit of 0.76 in favour of enzalutamide. After a median follow-up of 14.4 months, the median survival in the enzalutamide group was 18.4 months compared to 13.6 months in the placebo arm (HR: 0.63, $p < 0.001$). This led to the recommendation to halt and unblind the study. The benefit was observed irrespective of age, baseline pain intensity, and type of progression. In the final analysis with longer follow-up the OS results were confirmed despite crossover and extensive post-progression therapies [1160]. Enzalutamide was active also in patients with visceral metastases.

All the secondary objectives were in favour of enzalutamide (PSA, soft tissue response, QoL, time to PSA, or objective progression). No difference in terms of side effects was observed in the two groups, with a lower incidence of grade 3–4 AEs in the enzalutamide arm. There was a 0.6% incidence of seizures in the enzalutamide group compared to none in the placebo arm.

6.7.7.4 Radium-223 after ARPI or both ARPI and docetaxel

The only bone-specific drug that is associated with a survival benefit is the α-emitter radium-223. In a large phase III trial (ALSYMPCA) 921 patients with symptomatic mCRPC, who failed or were unfit for docetaxel, were randomised to six injections of 50 kBq/kg radium-223 or placebo plus SOC. The primary endpoint was OS. Radium-223 significantly improved median OS by 3.6 months (HR: 0.70, $p < 0.001$) and was also associated with prolonged time to first skeletal event, improvement in pain scores and improvement in QoL [1215]. The associated toxicity was mild and, apart from slightly more haematologic toxicity and diarrhoea with radium-223, which did not differ significantly from that in the placebo arm [1215]. Radium-223 was effective and safe whether or not patients were docetaxel pre-treated [1216]. Due to safety concerns, use of radium-223 was

restricted to after docetaxel and at least one AR targeted agent [1217]. In particular, the use of radium-223 in combination with AAP showed significant safety risks related to fractures and more deaths. This was most striking in patients without the concurrent use of bone health agents [1218] so that radium-223 should always be used together with bone health agents (see chapter 6.7.11.2)

6.7.7.5 Rucaparib after ARPI [1219]

In a 2:1 randomised, controlled, phase III trial (TRITON-3) 405 mCRPC patients were included. Patients were selected for a *BRCA1*, *BRCA2*, or ATM alteration and disease progression after treatment with an ARPI for mCRPC. Treatment was as follows: rucaparib 600 mg twice daily or a physician's choice control, either second line docetaxel or the ARPI which had not been given previously. The first endpoint rPFS in the intention-to-treat group was significantly better with rucaparib (median, 10.2 months and 6.4 months, respectively; HR 0.61; 95% CI, 0.47 to 0.80; p<0.001). The small ATM subgroup did not derive abenefit. An interim analysis revealed OS to be immature. The study designed allowed for cross-over and 60% of patients received a PARP inhibitor at progression (47% rucaparib). With regards to the control arms, the median rPFS was longer with rucaparib than with docetaxel (11.2 months vs. 8.3 months; hazard ratio, 0.53; 95% CI, 0.37 to 0.77) and it was also longer than with an ARPI (11.2 months vs. 4.5 months; hazard ratio, 0.38; 95% CI, 0.25 to 0.58). The most frequent adverse events with rucaparib were fatigue, nausea and anemia, including 24% Grade ≥3 anemia and 29% of patients on rucaparib required at least one blood transfusion [1220]. Rucaparib has been approved by the FDA.

6.7.7.6 Olaparib after ARPI (see chapter 6.7.8.3 PARP inhibitors for mCRPC)

*6.7.8 **Treatment after docetaxel and one line of hormonal treatment for mCRPC***

6.7.8.1 General considerations

For men progressing quickly on AR targeted therapy (< twelve months) it is now clear that cabazitaxel is the treatment supported by the best data. The CARD trial, an open label randomised phase III trial, evaluated cabazitaxel after docetaxel and one line of ARPI (either AAP or enzalutamide) [1164]. It included patients progressing in less than twelve months on previous abiraterone or enzalutamide for mCRPC. Cabazitaxel more than doubled rPFS vs. another ARPI and reduced the risk of death by 36% vs. ARPI. The rPFS with cabazitaxel remained superior regardless of the ARPI sequence and if docetaxel was given before, or after, the first ARPI.

The choice of further treatment after docetaxel and one line of HT for mCRPC is open for patients who have a > twelve months response to first-line abiraterone or enzalutamide for mCRPC [1184]. Either second-line chemotherapy (cabazitaxel), radium-223 (if bone-only metastases), 177Lu–PSMA-617 radioligand therapy [1221, 1222] and PARP inhibitors (if BRCA mutation) are valuable options.

Men previously treated with at least one ARPI or both an ARPI and docetaxel and whose tumours demonstrated homozygous deletions or deleterious mutations in DNA-repair genes showed an 88% response rate to olaparib [1223] and in another confirmatory trial a composite response of 54.3% (95% CI: 39.0–69.1) in the 400 mg cohort and in 18 of 46 (39.1%; 25.1–54.6) evaluable patients in the 300 mg cohort [1224]. See also section 'Second-line management'). In general, subsequent treatments in unselected patients are expected to have less benefit than with earlier use [1225, 1226] and there is evidence of cross-resistance between enzalutamide and abiraterone [1227, 1228].

6.7.8.2 Radiopharmaceuticals

6.7.8.2.1 Introduction

Historically, several radiopharmaceuticals including phosphorous-32, strontium-89, yttrium-90, samarium-153, and rhenium-186 were developed for the treatment of bone pain secondary to metastases from PCa [1229]. They proved effective in a palliation setting, by relieving pain and improving QoL, especially in the setting of diffuse bone metastases. However, they never gained widespread adoption. The first radioisotope to demonstrate a survival benefit was radium-223 (see Section 6.7.7.4).

6.7.8.2.2 PSMA-based therapy

The increasing use of PSMA PET as a diagnostic tracer and the realisation that this allowed identification of a greater number of metastatic deposits led to attempts to treat cancer by replacing the imaging isotope with a therapeutic isotope which accumulates where the tumour is demonstrated (theranostics) [1230]. Therefore, after identification of the target, usually with diagnostic 68Gallium-labelled PSMA, therapeutic radiopharmaceuticals labelled with β(lutetium-177 or yttrium-90) or α(actinium-225)-emitting isotopes could be used to treat metastatic PCa.

The PSMA therapeutic radiopharmaceutical supported by the most robust data is ^{177}Lu-PSMA-617. The first patient was treated in 2014 and early clinical studies evaluating the safety and efficacy of ^{177}Lu-PSMA therapy have demonstrated promising results, despite the fact that a significant proportion of men had already

progressed on multiple therapies [1231]. The early data were based on single-centre experience [1232]. Data from uncontrolled prospective phase II trials reported high response rates with low toxic effects [1233, 1234]. Positive signals are also coming from a randomised pase II trial (TheraP) [1235].

In TheraPpatients for whom cabazitaxel was considered the next appropriate standard treatment after docetaxel and who were highly selected by ^{68}Ga-PSMA-11 and ^{18}FDG PET-CT scans, were randomised to receive ^{177}Lu-PSMA-617 (6.0–8.5 GBq intravenously, every six weeks, for up to six cycles) or cabazitaxel (20 mg/m^2 for up to ten cycles). The primary endpoint was a reduction of at least 50% in PSA. The first endpoint was met (66% vs. 37% for ^{177}Lu–PSMA-617 vs. cabazitaxel, respectively, by intention to treat; difference 29% (95% CI: 16–42; p < 0.0001; and 66% vs. 44% by treatment received; difference 23% [9–37]; p = 0.0016) [1235]. At 36 months follow-up, the secondary endpoint OS was similar in those patients randomly assigned to 177Lu-PSMA versus cabazitaxel (19.1 vs. 19.6 months, difference -0.5, 95% CI -3.7 to + 2.7; ^{177}Lu-PSMA vs. cabazitaxel, respectively), HR: 0.97, 95% CI: 0.7-1.4, p=0.99) [1236].

An open-label phase III trial (VISION) compared ^{177}Lutetium Vipivotid tetraxetan (^{177}Lu-PSMA-617 radioligand therapy) with protocol-permitted SOC (i.e., excluded chemotherapy, immunotherapy, radium-223 and investigational drugs) in mCRPC patients, with PSMA expressing metastases on PET/CT, previously treated with at least one ARPI and one (around 53%) or two taxanes. Imaging-based PFS and OS were the alternate primary endpoints. More than 800 patients were randomised. 177Lu-PSMA-617 plus SOC significantly prolonged both imaging-based PFS and OS, as compared with SOC alone (see Table 6.6.3). Grade 3 or above AEs were higher with ^{177}Lu-PSMA-617 than without (52.7% vs. 38.0%), but QoL was not adversely affected. ^{177}Lu–PSMA-617 has shown to be an additional treatment option in this mCRPC population [1237].

A SR and updated meta-analysis, investigated the proportion of patients with any or more than 50% PSA decrease, and OS. The review, including 69 articles and a total of 4,157 patients, showed that patients treated with ^{177}Lu–PSMA 617 had a significantly higher response to therapy compared to controls, based on ≥ 50% PSA decrease (OR = 5.33, 95% CI: 1.24–22.90, p < 0.05). Meta-analysis revealed an OS of 0.26 according to pooled HRs for any PSA decline, which was significant after 177Lu–PSMA-617 therapy (95% CI: 0.18–0.37, p < 0.00001) and an OS of 0.52 for ≥ 50% PSA decrease, also significant after radioligand (RLT) (95% CI: 0.40–0.67, p < 0.00001) [1238].

There is an increasing interest for PSMA-targeted alpha therapy (^{225}Ac-PSMA) due to the ability to deliver potent higher local radiation more selectively to cancer cells than PSMA-targeted beta therapy, while minimising unwanted damage to the surrounding normal tissues. Additionally, the intensive radiation to cancer cells results in more effective DNA strand breakage and reduces the development of treatment resistance. A meta-analysis, including nine studies with 263 patients, investigated the therapeutic effects of ^{225}Ac-PSMA RLT in patients with metastatic CRPC, pre-treated with chemotherapy, ^{177}Lu-PSMA and/or radium-223. The pooled proportions of patients with more than 50% PSA decline and any PSA decline were 60.99% (95% CI: 54.92%– 66.83%) and 83.57% (95% CI: 78.62%–87.77%), respectively. The estimated mean PFS and mean OS were 9.15 months (95% CI: 6.69–11.03 months) and 11.77 months (95% CI: 9.51–13.49 months), respectively. These findings suggests that ^{225}Ac-PSMA RLT may be an effective treatment option for patients with mCRPC [1239]. Despite the encouraging therapeutic response and survival of patients who received ^{225}Ac-PSMA RLT, major AEs like xerostomia and severe haematotoxicity have to be considered as possible reasons for dose reduction or discontinuation of the therapy.

6.7.8.3 PARP inhibitors for mCRPC

So far, two PARP inhibitors as monotherapy, olaparib and rucaparib, are licenced by the FDA (EMA only approved olaparib) and several other PARP inhibitors are under investigation or were approved only in combination with an ARPI (see chapter 6.7.6.6; e.g., talazoparib, niraparib).

A randomised phase III trial (PROfound) compared the PARP inhibitor olaparib to an alternative ARPI in mCRPC with alterations in ≥ 1 of any qualifying gene with a role in HRR and progression on an ARPI. Most patients were heavily pre-treated with 1–2 chemotherapies and up to 2 ARPIs [248, 1162]. Radiographic PFS by blinded independent central review in the *BRCA1/2* or ATM mutated population (Cohort A) was the first endpoint and significantly favoured olaparib (HR: 0.49, 95% CI: 0.38–0.63). The final results for OS demonstrated a significant improvement among men with *BRCA1/2* or ATM mutations (Cohort A) (p = 0.0175; HR: 0.69, 95% CI: 0.50– 0.97). This was not significant in men with any (other) HRR alteration (Cohort B) (HR: 0.96, 95% CI: 0.63–1.49). Of note, patients in the physician's choice of enzalutamide/abiraterone-arm who progressed, 66% (n = 86/131) crossed over to olaparib.

The most common AEs were anaemia (46.1% vs. 15.4%), nausea (41.4% vs. 19.2%), decreased appetite (30.1% vs. 17.7%) and fatigue (26.2% vs. 20.8%) for olaparib vs. enzalutamide/abiraterone. Among patients receiving olaparib 16.4% discontinued treatment secondary to an AEs, compared to 8.5% of patients receiving enzalutamide/abiraterone. Interestingly, 4.3% of patients receiving olaparib had a pulmonary embolism, compared to 0.8% among those receiving enzalutamide/abiraterone, none of which were fatal. There were no reports of myelodysplastic syndrome or acute myeloid leukaemia. This is the first trial to show a benefit for genetic testing and precision medicine in mCRPC.

The olaparib approval by the FDA is for patients with deleterious or suspected deleterious germline- or somatic HRR gene-mutated mCRPC, who have progressed following prior treatment with enzalutamide or abiraterone. The EMA approved olaparib for patients with *BRCA1* and *BRCA2* alterations [1240]. The recommended olaparib dose is 600 mg daily (300 mg taken orally twice daily), with or without food.

Rucaparib has been approved by the FDA for patients with deleterious BRCA mutations (germline and/or somatic) who have been treated with ARPI and a taxane-based chemotherapy [1241]. Approval was based on the results of the single-arm TRITON2 trial (NCT02952534). The confirmed ORR per independent radiology review in 62 patients with deleterious BRCA mutations was 43.5% (95% CI: 31–57) [1242]. Rucaparib second line after ARPI was studied in the TRITON 3 trial and is discussed in chapter 6.7.7.5

The combination of ARPI plus a PARP inhibitor in first-line mCRPC was studied in several RCTs including AAP plus Olaparib [1193], AAP plus Niraparib [1198] and Enzalutamide plus Talazoparib [1202]. See Table 6.7.2.

6.7.8.4 Sequencing treatment

6.7.8.4.1 ARPI -> ARPI (chemotherapy-naïve mCRPC patients)

The use of sequential ARPIs in mCRPC showed limited benefit in retrospective series as well as in one prospective trial [1245-1252]. In particular in patients who had a short response to the first ARPI for mCRPC (< twelve months), this sequence should be avoided because of known cross resistance and the availability of chemotherapy and PARP inhibitors (if a relevant mutation is present).

In highly selected patients treated for more than 24 weeks with AAP, the sequence with enzalutamide showed some activity with a median rPFS of 8.1 months (95% CI: 6.1–8.3) and an unconfirmed PSA response rate of 27% [1253]. In case the patient is unfit for chemotherapy and a PARP inhibitor, best supportive care should be considered in case no other appropriate treatment option is available (clinical trial or immunotherapy if MSI-high). An ARPI-ARPI sequence should never be the preferred option but might be considered in such patients if the PS still allows for active treatment and the potential side effects seem manageable.

First prospective cross-over data on an ARPI-ARPI sequence [1245] and a SR and meta-analysis suggest that for the endpoints PFS and PSA PFS, but not for OS, abiraterone followed by enzalutamide is the preferred choice [1254].

6.7.8.4.2 ARPI -> PARP inhibitor

This sequence in patients with deleterious or suspected deleterious germline or somatic HRR gene-mutated mCRPC is supported by data from the randomised phase III PROfound trial studying olaparib [1162] and TRITON 3 studying rucaparib [1219]. A subgroup of patients in pROfound was pre-treated with one or two ARPIs and no chemotherapy (35%).

The ARPI-PARP inhibitor sequence versus ARPI-ARPI or ARPI-docetaxel in patients with BRCA 1/ 2 (and ATM) altered tumours was studied in TRITON-3 and showed a significant rPFS benefit in favour of the PARP inhibitor following the first ARPI. These data underscore the importance of early genomic testing in mCRPC patients. (see also chapter 6.7.7.5)

6.7.8.4.3 Docetaxel for mHSPC -> docetaxel rechallenge

There is limited evidence for second- or third-line use of docetaxel after treatment with docetaxel for mHSPC. Docetaxel seems to be less active than ARPI at progression to mCRPC following docetaxel for mHSPC [1255].

6.7.8.4.4 ARPI -> docetaxel or docetaxel -> ARPI followed by PARP inhibitor

Both olaparib and rucaparib are active in biomarker-selected mCRPC patients after ARPI and docetaxel in either sequence [1162, 1241].

6.7.8.4.5 ARPI before or after docetaxel

There is level 1 evidence for both sequences (see Table 6.7.3).

6.7.8.4.6 ARPI –> docetaxel -> cabazitaxel or docetaxel –> ARPI -> cabazitaxel

Both third-line treatment sequences are supported by level 1 evidence. Of note, there is high-level evidence favouring cabazitaxel vs. a second ARPI after docetaxel and one ARPI in particular in patients progressing ≤ twelve months on a prior ARPI. CARD is the first prospective randomised phase III trial addressing this question (see Table 6.7.3) [1164].

Table 6.7.3: Randomised controlled phase II/III - second-line/third-line trials in mCRPC

Study	Intervention	Comparison	Selection criteria	Main outcomes
ABIRATERONE				
COU-AA-301 2012 [1213]	abiraterone + prednisone HR	placebo + prednisone	- Previous docetaxel. - ECOG 0–2. - PSA or radiographic progression.	**OS: 15.8 vs. 11.2 mo.** (p < 0.0001, HR: 0.74, 95% CI: 0.64–0.86; p < 0.0001). FU: 20.2 mo. **rPFS: no change**
COU-AA-301 2011 [1212]				**OS: 14.8 vs. 10.9 mo.** (p < 0.001 HR: 0.65; 95% CI: 0.54–0.77). FU: 12.8 mo. **rPFS: 5.6 vs. 3.6 mo.**
Radium-223				
ALSYMPCA 2013 [1256]	radium-223	placebo	- Previous or no previous docetaxel. - ECOG 0–2. - Two or more symptomatic bone metastases. - No visceral metastases.	**OS: 14.9 vs. 11.3 mo.** (p = 0.002, HR: 0.61; 95% CI: 0.46–0.81). All secondary endpoints show a benefit over best SOC.
CABAZITAXEL				
TROPIC 2013 [1208]	cabazitaxel + prednisone	mitoxantrone + prednisone	- Previous docetaxel. - ECOG 0–2.	**OS: 318/378 vs. 346/377 events** (OR: 2.11; 95% CI: 1.33–3.33). FU: 25.5 months OS ≥ 2 yr 27% vs. 16% PFS: -
TROPIC 2010 [1204]				**OS: 15.1 vs. 12.7 mo.** (p < 0.0001, HR: 0.70; 95% CI: 0.59–0.83). FU: 12.8 mo. PFS: 2.8 vs. 1.4 mo. (p < 0.0001, HR: 0.74, 95% CI: 0.64-0.86)

TheraP 2021 [1235, 1236]	^{177}Lu-PSMA-617 (8.5 GBq i.v.q 6-weekly, decreasing 0.5 GBq/cycle; up to 6 cycles)	cabazitaxel (20 mg/m^2 i.v.q 3-weekly, up to 10 cycles)	- Post docetaxel, - Suitable for cabaziaxel	**First endpoint PSA reduction of > 50%:** 66 vs. 37 PSA responses; 66% vs. 37% by ITT; difference 29% (95% CI: 16–42; p < 0.0001; and 66% vs. 44% by treatment received; difference 23% [9–37]; p = 0.0016). **Secondary endpoint OS:** 19.1 vs. 19.6 mo (^{177}Lu-PSMA vs. cabazitaxel). HR: 0.97, 95% CI: 0.7-1.4 (p=0.99)

**Only studies reporting survival outcomes as primary endpoints have been included.*
ARPI = androgen receptor pathway inhibitor; CI = confidence interval; ECOG = Eastern Cooperative Oncology Group; FU = follow-up; GBq = gigabecquerel; HR = hazard ratio; Lu = lutetium; mo = months OS = overall survival; OR = odds ratio; ORR = objective response rate; PSA = prostate-specific antigen; PSMA = prostatespecific membrane antigen; (r)PFS = (radiographic) progression-free survival; SOC = standard of care; yr = year; HRR= homologous recombination repair.

6.7.8.5 Platinum chemotherapy

Cisplatin or carboplatin as monotherapy or combinations have shown limited activity in unselected patients in the pre-docetaxel era [1257]. The combination of cabazitaxel and carboplatin was evaluated in pre-treated mCRPC patients in a randomised phase I/II trial. The combination improved the median PFS from 4.5 months (95% CI: 3.5–5.7) to 7.3 months (95% CI: 5.5–8.2; HR: 0.69, 95% CI: 0.50–0.95, p = 0.018) and the combination was well tolerated [1258]. On a histopathological and molecular level, there is preliminary evidence that platinum adds efficacy in patients with aggressive variant PCa molecular signatures including TP53, RB1, and PTEN [1259].

Patients with mCRPC and alterations in DDR genes are more sensitive to platinum chemotherapy than unselected patients [1260], also after progression on PARP inhibitors. Interestingly, in contemporary retrospective series, unselected patients as well as patients without DDR gene alterations also showed a 50% PSA decline when treated with platinum in up to 36% of patients. In view of the excellent tolerability of e.g., carboplatin monotherapy, platinum could be offered to patients with far advanced mCRPC harbouring DDR gene aberrations after having progressed on standard treatment options. Prospective controlled trials are ongoing.

6.7.9 ***Monitoring of treatment***

Baseline examinations should include a medical history, clinical examination as well as baseline blood tests (PSA, total testosterone level, full blood count, renal function, baseline liver function tests, alkaline phosphatase), bone scan and CT of chest, abdomen and pelvis [1261, 1262]. The use of choline or PSMA PET/CT scans for progressing CRPC is unclear and most likely not as beneficial as for patients with BCR or hormone-naive disease. Flares, PSMA upregulation and discordant results compared with PSA response or progression on ARPI have been described [1263]. Prostate-specific antigen alone is not reliable enough [1264] for monitoring disease activity in advanced CRPC since visceral metastases may develop in men without rising PSA [1265]. Instead, the PCWG2 recommends a combination of bone scintigraphy and CT scans, PSA measurements and clinical benefit in assessing men with CRPC [1266]. A majority of experts at the 2015 Advanced Prostate Cancer Consensus Conference (APCCC) suggested regular review and repeating blood profile every two to three months with bone scintigraphy and CT scans at least every six months, even in the absence of a clinical indication [1261]. This reflects that the agents with a proven OS benefit all have potential toxicity and considerable cost and patients with no objective benefit should have their treatment modified. The APCCC participants stressed that such treatments should not be stopped for PSA progression alone. Instead, at least two of the three criteria (PSA progression, radiographic progression and clinical deterioration) should be fulfilled to stop treatment. For trial purposes, the updated PCWG3 put more weight on the importance of documenting progression in existing lesions and introduced the concept of no longer 'clinically benefiting' to underscore the distinction between first evidence of progression and the clinical need to terminate or change treatment [1267]. These recommendations also seem valid for clinical practice outside trials.

6.7.10 ***When to change treatment***

The timing of mCRPC treatment change remains a matter of debate in mCRPC although it is clearly advisable to start or change treatment immediately in men with symptomatic progressing metastatic disease. Preferably, any treatment change should precede development of *de novo* symptoms or worsening of existing symptoms. Although, the number of effective treatments is increasing, head-to-head comparisons are still rare, as are prospective data assessing the sequencing of available agents. Therefore it is not clear how to select the most appropriate 'second-line' treatment, in particular in patients without HRR alterations or other biomarkers. A positive example, however, is the CARD trial which clearly established cabazitaxel as the better third-line treatment in docetaxel pre-treated patients after one ARPI compared to the use of a second ARPI [1164].

The ECOG PS has been used to stratify patients. Generally men with a PS of 0–1 are likely to tolerate treatments and those with a PS of > 2 are less likely to benefit. However, it is important that treatment decisions are individualised, in particular when symptoms related to disease progression are impacting on PS. In such cases, a trial of active life-prolonging agents to establish if a given treatment will improve the PS may be appropriate. Sequencing of treatment is discussed in the summary papers published following the 2019 and 2022 APCCC Conferences [1268, 1269].

6.7.11 ***Symptomatic management in metastatic castration-resistant prostate cancer***

Castration-resistant PCa is usually a debilitating disease often affecting the elderly male. A multidisciplinary approach is required with input from urologists, medical oncologists, radiation oncologists, nurses, psychologists and social workers [1268, 1270]. Critical issues of palliation must be addressed when considering additional systemic treatment, including management of pain, constipation, anorexia, nausea, fatigue and depression.

6.7.11.1 Common complications due to bone metastases

Most patients with CRPC have painful bone metastases. External beam RT is highly effective, even as a single fraction [1271, 1272]. A single infusion of a third generation bisphosphonate could be considered when RT is not available [1273]. Common complications due to bone metastases include vertebral collapse or deformity, pathological fractures and spinal cord compression. Cementation can be an effective treatment for painful spinal fracture whatever its origin, clearly improving both pain and QoL [1274]. It is important to offer standard palliative surgery, which can be effective for managing osteoblastic metastases [1275, 1276]. Impending spinal cord compression is an emergency. It must be recognised early and patients should be educated to recognise the warning signs. Once suspected, high-dose corticosteroids must be given and MRI performed as soon as possible. A systematic neurosurgery or orthopaedic surgeon consultation should be planned to discuss a possible decompression, followed by EBRT [1277]. Otherwise, EBRT with, or without, systemic therapy, is the treatment of choice.

6.7.11.2 Preventing skeletal-related events

6.7.11.2.1 Bisphosphonates

Zoledronic acid has been evaluated in mCRPC to reduce skeletal-related events (SRE). This study was conducted when no active anti-cancer treatments, but for docetaxel, were available. Six hundred and forty three patients who had CRPC with bone metastases were randomised to receive zoledronic acid, 4 or 8 mg every three weeks for fiveteen consecutive months, or placebo [1278]. The 8 mg dose was poorly tolerated and reduced to 4 mg but did not show a significant benefit. However, at fiveteen and 24 months of follow-up, patients treated with 4 mg zoledronic acid had fewer SREs compared to the placebo group (44 vs. 33%, p = 0.021) and in particular fewer pathological fractures (13.1 vs. 22.1%, p = 0.015). Furthermore, the time to first SRE was longer in the zoledronic acid group. No survival benefit has been seen in any prospective trial with bisphosphonates.

6.7.11.2.2 RANK ligand inhibitors

Denosumab is a fully human monoclonal antibody directed against RANKL (receptor activator of nuclear factor κ-B ligand), a key mediator of osteoclast formation, function, and survival. In M0 CRPC, denosumab has been associated with increased bone-MFS compared to placebo (median benefit: 4.2 months, HR: 0.85, p = 0.028) [1271]. This benefit did not translate into a survival difference (43.9 compared to 44.8 months, respectively) and neither the FDA or the EMA have approved denosumab for this indication [1279].

The efficacy and safety of denosumab (n = 950) compared with zoledronic acid (n = 951) in patients with mCRPC was assessed in a phase III trial. Denosumab was superior to zoledronic acid in delaying or preventing SREs as shown by time to first on-study SRE (pathological fracture, radiation or surgery to bone, or spinal cord compression) of 20.7 vs. 17.1 months, respectively (HR: 0.82, p = 0.008). Both urinary N-telopeptide and bone-specific alkaline phosphatase were significantly suppressed in the denosumab arm compared with the zoledronic acid arm (p < 0.0001 for both). However, these findings were not associated with any survival benefit and in a *post-hoc* re-evaluation of endpoints, denosumab showed identical results when comparing SREs and symptomatic skeletal events [1280].

The potential toxicity (e.g., osteonecrosis of the jaw, hypocalcaemia) of these drugs must always be kept in mind (5–8.2% in M0 CRPC and mCRPC, respectively) [1281, 1282]. Patients should have a dental examination before starting therapy as the risk of jaw necrosis is increased by several risk factors including a history of trauma, dental surgery or dental infection [1283]. Also, the risk for osteonecrosis of the jaw increased numerically with the duration of use in a pivotal trial [1284] (one year vs. two years with denosumab), but this was not statistically significant when compared to zoledronic acid [1279]. According to the EMA, hypocalcaemia is a concern in patients treated with denosumab and zoledronic acid. Hypocalcaemia must be avoided by adequate intake of calcium and vitamin D before initiating therapy [1285]. Hypocalcaemia should be identified and prevented during treatment with bone protective agents (risk of severe hypocalcaemia is 8% and 5% for denosumab and zoledronic acid, respectively) [1282]. Serum calcium should be measured in patients starting therapy and monitored during treatment, especially during the first weeks and in patients with risk factors for hypocalcaemia or on other medication affecting serum calcium. Daily calcium (> 500 mg) and vitamin D (> 400 IU equivalent) are recommended in all patients, unless in case of hypercalcaemia [1282, 1286, 1287].

*6.7.12 **Summary of evidence and guidelines for life-prolonging treatments of castrate-resistant***

Summary of evidence	**LE**
Treatment for mCRPC will be influenced by which treatments patients have already been exposed to.	4

Recommendations	**Strength rating**
Ensure that testosterone levels are confirmed to be < 50 ng/dL before diagnosing castrate-resistant PCa (CRPC).	Strong
Counsel, manage and treat patients with metastatic CRPC (mCRPC) in a multidisciplinary team.	Strong
Treat patients with mCRPC with life-prolonging agents.	Strong
Offer mCRPC patients somatic and/or germline molecular testing as well as testing for mismatch repair deficiencies or microsatellite instability.	Strong

6.7.13 *Guidelines for systematic treatments of castrate-resistant disease*

Summary statement for mCRPC first line combination therapy:
The combination of ARPI plus PARP inhibitors showed a significant rPFS benefit in RCTs for unselected patients. However, this benefit is mainly driven by HRR- and even more pronounced by BRCA 1/2- altered patients. So far, no clear OS benefit was seen, and the side effects of PARP inhibitors add substantial toxicity to ARPI monotherapy. Therefore, no recommendation is given for patients without HRR or BRCA 1/2 -mutations and the data will be re-evaluated after longer follow-up.

Recommendations	Strength rating
Base the choice of treatment on the performance status (PS), symptoms, comorbidities, location and extent of disease, genomic profile, patient preference, and on previous treatment for hormone-sensitive metastatic PCa (mHSPC) (alphabetical order: abiraterone, cabazitaxel, docetaxel, enzalutamide, ^{177}lutetium-PSMA-617-radioligand therapy, radium-223, sipuleucel-T, and for patients with DNA homologous recombination repair (HRR) alterations olaparib, olaparib/abiraterone, niraparib/abiraterone, rucaparib, talazoparib/enzalutamide).	Strong
Avoid sequencing of androgen receptor targeted agents.	Weak
Offer chemotherapy to patients previously treated with abiraterone or enzalutamide.	Strong
Offer patients with metastatic castrate-resistant PCa (mCRPC) who are candidates for cytotoxic therapy and are chemotherapy naiive docetaxel with 75 mg/m^2 every three weeks.	Strong
Offer patients previously untreated for mCRPC and harbouring an HRR or BRCA mutation abiraterone in combination with olaparib if the patient is fit for both agents.	Strong
Offer patients previously untreated for mCRPC and harbouring a BRCA mutation abiraterone in combination with niraparib if the patient is fit for both agents.	Strong
Offer patients previously untreated for mCRPC and harbouring an HRR-mutation enzalutamide in combination with talazoparib if the patient is fit for both agents.	Strong
Offer poly(ADP-ribose) polymerase (PARP) inhibitors to pre-treated mCRPC patients with relevant DNA repair gene mutations.	Strong
Offer patients with mCRPC and progression following docetaxel chemotherapy further life-prolonging treatment options, which include abiraterone, cabazitaxel, enzalutamide, radium-223 and olaparib in case of DNA homologous recombination repair (HRR) alterations.	Strong
Base further treatment decisions of mCRPC on PS, previous treatments, symptoms, comorbidities, genomic profile, extent of disease and patient preference.	Strong
Offer abiraterone or enzalutamide to patients previously treated with one or two lines of chemotherapy.	Strong
Offer cabazitaxel to patients previously treated with docetaxel.	Strong
Offer cabazitaxel to patients previously treated with docetaxel and progressing within twelve months of treatment with abiraterone or enzalutamide.	Strong
Offer ^{177}Lu-PSMA-617 to pre-treated mCRPC patients with one or more metastatic lesions, highly expressing PSMA (exceeding the uptake in the liver) on the diagnostic radiolabelled PSMA PET/CT scan.	Strong

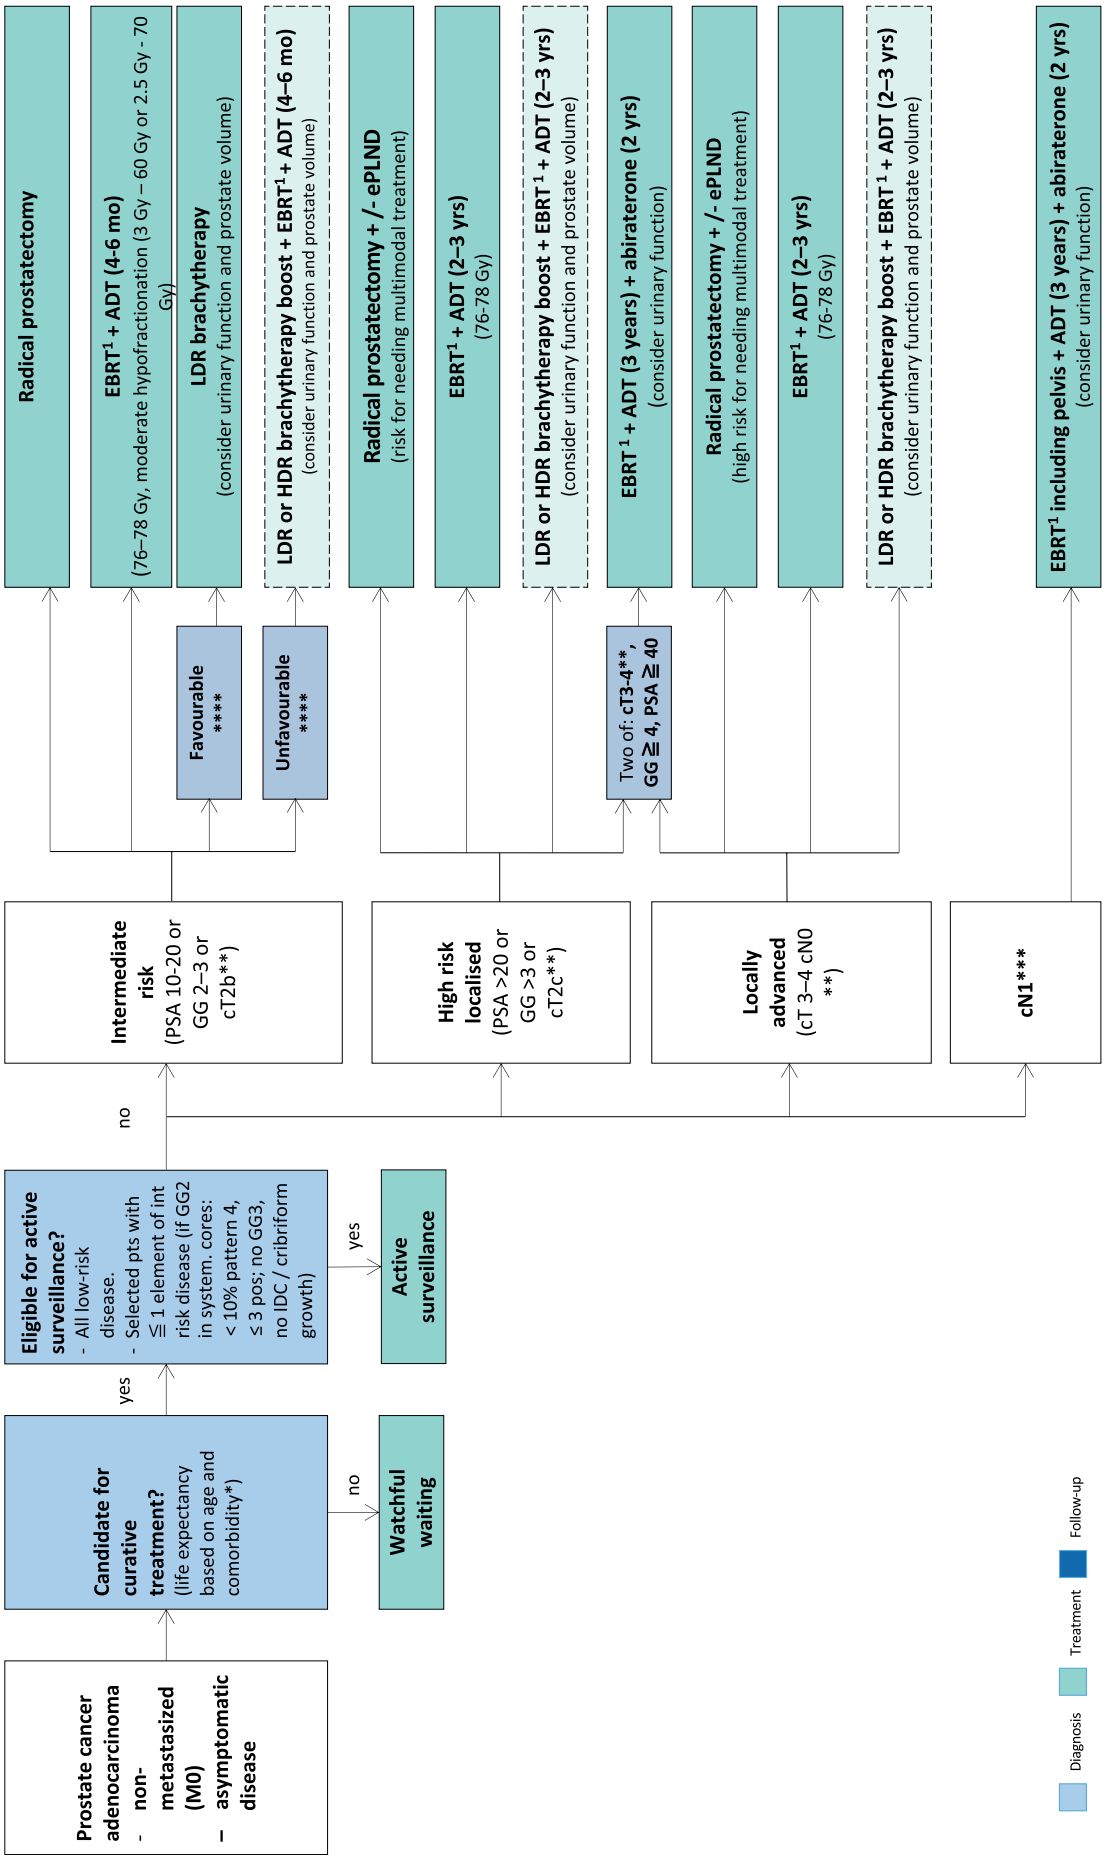
6.7.14 *Guideline for non-metastatic castrate-resistant disease*

Recommendation	Strength rating
Offer apalutamide, darolutamide or enzalutamide to patients with M0 CRPC and a high risk of developing metastasis (PSA-DT < ten months) to prolong time to metastases and overall survival.	Strong

6.7.15 *Guidelines for supportive care of castrate-resistant disease*
These recommendations are in addition to appropriate systemic therapy.

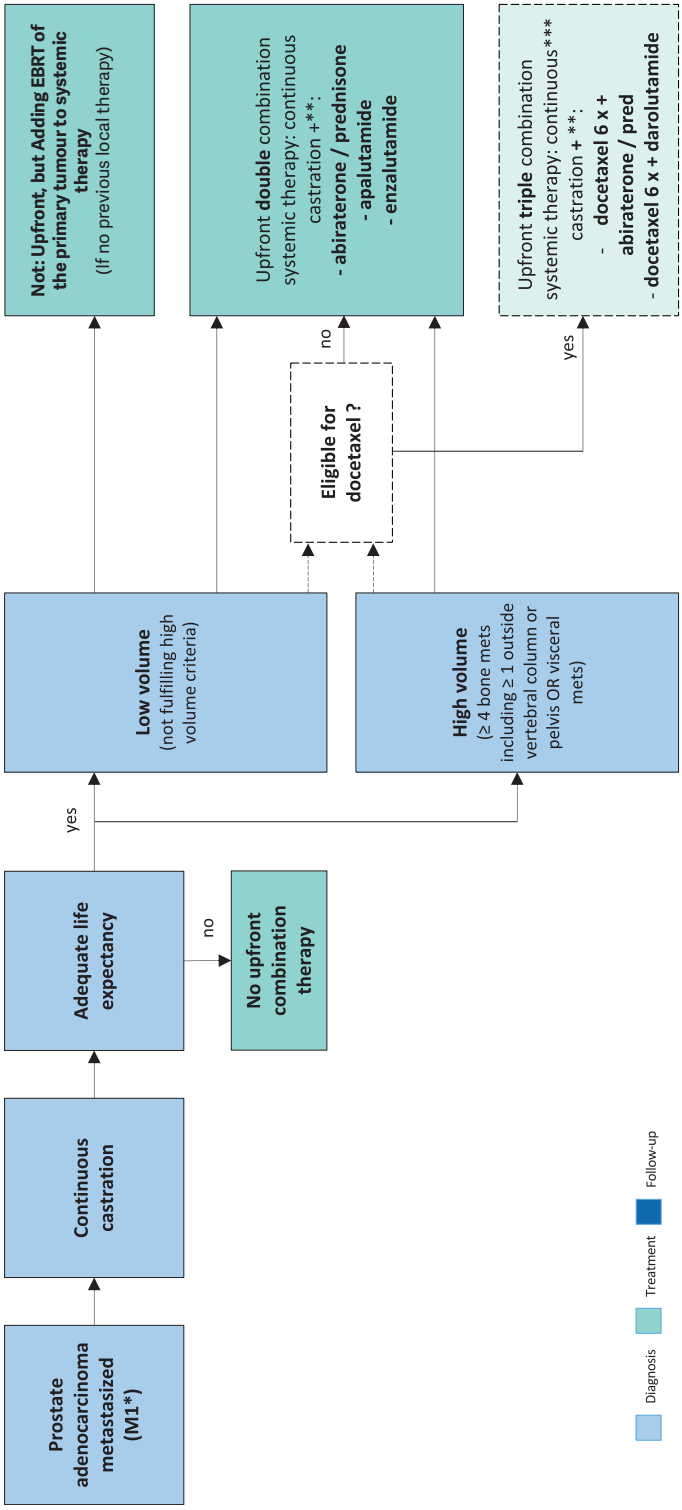
Recommendations	Strength rating
Offer bone protective agents to patients with metastatic prostate cancer and skeletal metastases to prevent osseous complications.	Strong
Monitor serum calcium and offer calcium and vitamin D supplementation when prescribing either denosumab or bisphosphonates.	Strong
Treat painful bone metastases early on with palliative measures such as intensity-modulated radiation therapy/volumetric arc radiation therapy plus image-guided radiation therapy and adequate use of analgesics.	Strong
In patients with spinal cord compression start immediate high-dose corticosteroids and assess for spinal surgery followed by irradiation. Offer radiation therapy alone if surgery is not appropriate.	Strong

Figure 6.4: Treatment non-metastasized (M0) – asymptomatic disease



** Rule of thumb: Life expectancy ten years.*
*** Recommendation based on clinical staging using digital rectal examination, not imaging.*
**** Recommendation based on staging using combination of bone scan and CT.*
***** See text, dependent on GG and (biopsy) volume.*
1EBRT: IMRT/VMAT + IGRT of the prostate.
= weak recommendation.
ADT = androgen deprivation therapy; EBRT =external beam radiotherapy; ECE = extracapsular extension; ePLND = extended pelvic lymph node dissection; GG = grade group; HDR = high-dose rate; IDC = intraducal carcinoma; IGRT = image-guided radiotherapy; IMRT = intensity-modulated radiotherapy; LDR = low-dose rate; VMAT = volumetric modulated arc therapy.

Figure 6.5: Treatment of metastasized (M1*) – disease, M+HSPC



* Based on staging using combination of bone scan and CT.
** Alphabetical order.
***not for low volume, metachronous disease.
1EBRT: IMRT/VMAT + IGRT of the prostate (equivalent of up to 72 Gy in 2 Gy fractions).
= weak recommendation.
EBRT = external beam radiotherapy; IGRT = image-guided radiotherapy; IMRT = intensity-modulated radiotherapy.
#Note: Please be aware that the various options in the following flowcharts present a generalised approach only, and cannot take the management of individual patients into account, nor the availability of resources.

7. FOLLOW-UP

The rationale for following up patients is to assess immediate- and long-term oncological results, ensure treatment compliance and allow initiation of further therapy, when appropriate. In addition, follow-up allows monitoring of side effects or complications of therapy, functional outcomes and an opportunity to provide psychological support to PCa survivors, all of which is covered in Chapter 8.

For patients the most critical aspect of PCa is the diagnosis, the ensuing treatment and follow-up. These must be discussed between the patient and the clinician for shared-decision on the treatment and the planned follow-up, including modalities, periodicity and how this will be communicated to the patient. The patient must be prepared for different potential outcomes of the follow-up, e.g., PSA levels, and what to expect from these. Otherwise, even a very small increase in PSA levels can cause unnecessary fear, even panic.

7.1 Watchful waiting

Watchful waiting refers to conservative management for patients deemed unsuitable for curative treatment from the outset, and patients are clinically 'watched' for the development of local or systemic progression with (imminent) disease-related complaints, at which stage they are then treated palliatively according to their symptoms in order to maintain QoL. (see 6.2.1.)

7.2 Active surveillance strategy

Patients included in an AS programme should be monitored according to the recommendations presented in Section 6.3.1

7.3 Follow-up: After local treatment with curative intent

*7.3.1 **Definition***

Local treatment is defined as RP or RT, either by IMRT plus IGRT or LDR- or HDR-BT, or any combination of these, including neoadjuvant and adjuvant hormonal therapy. Unestablished alternative treatments such as HIFU, cryosurgery and focal therapy options do follow the general principles as presented in this section. In general, a confirmed rising PSA is considered a sign of disease recurrence.

*7.3.2 **Why follow-up?***

The first post-treatment clinic visit focuses on detecting treatment-related complications and assist patients in coping with their new situation apart from providing information on the pathological analysis. Men with PCa are at increased risk of depression and attention for mental health status is required [1288, 1289]. Tumour or patient characteristics may prompt changing the follow-up schedule. Follow-up also allows the introduction of additional / salvage treatments should that be considered necessary in light of the expected life-expectancy, patients symptoms and EAU risk categories for biochemical recurrence (See 6.1 And Table 4.3)

*7.3.3 **How to follow-up?***

The procedures indicated at follow-up visits vary according to the clinical situation. A disease-specific history is mandatory at every follow-up visit and includes psychological aspects, signs of disease progression, and treatment-related complications. Evaluation of treatment-related complications in the post-treatment period is highlighted in Sections 8.2. The examinations used for cancer-related follow-up after curative surgery or RT are discussed below.

7.3.3.1 Prostate-specific antigen monitoring

Measurement of PSA is the cornerstone of follow-up after local treatment. While PSA thresholds depend on the local treatment used, PSA recurrence almost always precedes clinical recurrence [896, 1290]. The key question is to establish when a PSA rise is clinically significant since not all PSA increases have the same clinical value

(see Section 6.4.2) [898]. No prospective studies are available on the optimal timing for PSA testing and the impact on oncological outcomes.

7.3.3.1.1 Prostate-specific antigen monitoring after radical prostatectomy

Following RP, the PSA level is expected to be undetectable. Biochemical recurrence is any rising PSA after prostatectomy as defined in Section 6.3. Prostate-specific antigen level is expected to be undetectable two months after a RP [1291]. Prostate-specific antigen is generally determined every six months until three years and yearly thereafter but the evidence for a specific interval is low [489] and mainly based on the observation that early recurrences are more likely to be associated with more rapid progression [898, 1292, 1293]. A rising PSA may occur after longer intervals up to 20 years after treatment and depends on the initial risk group [820]. A yearly PSA after three years is considered adequate considering the fact that a longer interval to BCR is correlated with a lower EAU-BCR risk score but around 50% of recurrence should be expected beyond three years, follow-up should be terminated if life expectancy drops < 10 years. As mentioned in Section 6.4.2 no definitive threshold can be given for relapse after RP. Persistently measurable PSA in patients treated with RP is discussed in Section 6.3.6.

Ultrasensitive PSA assays remain controversial for routine follow-up after RP. Men with a PSA nadir < 0.01 ng/mL have a high (96%) likelihood of remaining relapse-free within two years [1294]. In addition, post-RP PSA levels > 0.01 ng/mL in combination with clinical characteristics such as ISUP grade group and surgical margin status may predict PSA progression and can be useful to establish follow-up intervals [1293]. However, up to 86% of men were reported to have PSA values below 0.2 ng/mL at five years after an initial PSA nadir below 0.1 ng/mL within six months after surgery [1295].

7.3.3.1.2 Prostate-specific antigen monitoring after radiotherapy

Following RT, PSA drops more slowly as compared to post RP. A PSA nadir < 0.5 ng/mL is associated with a favourable outcome after RT although the optimal cut-off value remains controversial [1296]. The interval before reaching the PSA nadir can be up to three years, or more. At the 2006 RTOG-ASTRO Consensus Conference the Phoenix definition of radiation failure was proposed to establish a better correlation between definition and clinical outcome (mainly metastases), namely, an increase of 2 ng/mL above the post-treatment PSA nadir [897]. This definition also applies to patients who received ADT [897].

7.3.3.2 Digital rectal examination

Local recurrence after curative treatment is possible without a concomitant rise in PSA level although very rarely [1297]. This has only been proven in patients with unfavourable undifferentiated tumours. Prostate specific antigen and DRE comprise the most useful combination for first-line examination in follow-up after RT but the role of DRE was questioned since it failed to detect any local recurrence in the absence of a rising PSA in a series of 899 patients [1298]. In a series of 1,118 prostatectomy patients, no local histologically proven recurrence was found by DRE alone and PSA measurement may be the most efficient test needed after RP [1299, 1300].

7.3.3.3 Transrectal ultrasound, bone scintigraphy, CT, MRI and PET/CT

Imaging techniques have no place in routine follow-up of localised PCa as long as the PSA is not rising. Imaging is only justified in patients for whom the findings will affect treatment decisions, either in case of BCR or in patients with symptoms (see Section 6.4.4.3 for a more detailed discussion).

7.3.3.4 Functional follow-up

All local treatments for PCa may cause short- and long-term side effect of various degree that will affect the patients' QoL. For quality control, and in order to help the patient in choosing the optimal treatment for him, it is essential that the functional outcomes of any treatment given is measured and registered by validated and reproducable methods. In order to adress side effects and their impact of QoL specific tools or 'patient-reported outcome measures' (PROMs) have been developed and validated for men with PCa. These questionnaires assess common issues after PCa diagnosis and treatment and generate scores which reflect the impact on perceptions of HRQoL. For further discussion on this see Section 8.3.

7.3.4 ***How long to follow-up?***

Most patients who fail treatment for PCa do so within seven years after local therapy [1243]. Patients should be followed more closely during the initial post-treatment period when risk of failure is highest. PSA measurement, disease-specific history and DRE (if considered) are recommended every six months until three years and then annually. Whether follow-up should be stopped if PSA remains undetectable (after RP) or stable (after RT) remains an unanswered question, but it seems fair that follow-up is only done to the point that if a recurrence is found the patient is fit enough for salvage therapy.

Risk assessment to predict metastases-free and PCa-specific survival after recurrence after primary treatment may guide individual decisions on a need for longer follow-up [825, 898, 1244]. Even in men with a PSA-DT less than ten months after RP who choose to defer treatment, a median MFS of 192 months and OS of 204 months from RP was observed, indicating the relatively long disease-free intervals observed in men with a rising PSA after local treatment [1301].

Symptomatic recurrence without a PSA rise is extremely rare, however, the symptoms typical for recurrent disease may vary and are poorly defined by published data. In case of the following symptoms PSA testing should be performed to exclude a possible cancer recurrence in particular in men not followed up by regular testing of their PSA levels: pelvic/skeletal pain, haematuria, progressive LUTS, progressive lower body oedema, progressive bowel complaints or complaints of fatigue, sarcopenia or unexplained weight loss [1302].

7.3.5 Summary of evidence and guidelines for follow-up after treatment with curative intent

Summary of evidence	LE
A detectable PSA, indicating a relaps of the disease, must be differentiated from a clinically meaningful relapse. The PSA threshold that best predicts further metastases after RP is > 0.4 ng/mL and > NADIR + 2 ng/mL after IMRT/VMAT plus IGRT (± ADT).	3

Recommendations	Strength rating
Routinely follow-up asymptomatic patients by obtaining at least a disease-specific history and a prostate-specific antigen measurement.	Strong
At recurrence, only perform imaging if the result will affect treatment planning.	Strong

7.4 Follow-up: During first line hormonal treatment (androgen sensitive period)

7.4.1 Introduction

Androgen deprivation therapy is used in various situations: combined with RT for localised or locally-advanced disease, as monotherapy for a relapse after a local treatment, or in the presence of metastatic disease often in combination with other treatments. All these situations are based on the benefits of testosterone blockage or suppression either by drugs (LHRH agonists or antagonists) or orchidectomy. Inevitably, the disease will become castrateresistant, although ADT will be maintained.

This section addresses the general principles of follow-up of patients on ADT alone. Section 6.5.3 includes further information on other drug treatments. Furthermore the specific follow-up needed for every single drug is outside the scope of this text, as is follow-up after chemotherapy.

To detect disease- and treatment-related complaints, regular clinical follow-up is mandatory and cannot be replaced by imaging or laboratory tests alone.

7.4.2 Purpose of follow-up

The main objectives of follow-up in patients receiving ADT are to ensure treatment compliance, to monitor treatment response, to detect side effects early, and to guide treatment at the time point of clinical progression. After the initiation of ADT, it is recommended that patients are evaluated every three to six months. This must be individualised and each patient should be advised to contact his physician in the event of troublesome symptoms. This is even more important for patients who receive a combination of ADT and other potent medication, e.g., ARPI where the frequency of follow-up is monthly for the first three months, for their disease.

7.4.3 General follow-up of men on ADT

Patients under ADT require regular follow-up, including monitoring of serum testosterone, creatinine, liver function and metabolic parameters at three to six month intervals. Men on ADT can experience toxicity independent of their disease stage. Androgen deprivation therapy reduces bone density gradually, increasing the risk of fractures [1303]. It is therefore essential to asses bone density before and during treatment with ADT with or without a combination with other drugs.

As the consequenses of ADT are so varying, a structured follow-up including lab results, radiology and QoL, may be of value both for the patient and for the treating physician [1304].

7.4.3.1 Testosterone monitoring

Testosterone monitoring should be considered standard clinical practice in men on ADT. Many men receiving medical castration will achieve a castrate testosterone level (< 20 ng/dL), and most a testosterone level < 50 ng/dL. However, approximately 13–38% of patients fail to achieve these levels and up to 24% of men may experience temporary testosterone surges (testosterone > 50 ng/dL) during long-term treatment [1291] referred

to as 'acute on-chronic effect' or 'breakthrough response' [1305]. Breakthrough rates for the < 20 ng/dL threshold were found to be more frequent (41.3%) and an association with worse clinical outcomes was suggested [1305].

The timing of measurements is not clearly defined. A three to six month testosterone level assessment has been suggested to ensure castration is achieved (especially during medical castration) and maintained. In case a castrate testosterone level is not reached, switching to another agonist or antagonist or to an orchiectomy should be considered. In patients with a confirmed rising PSA and/or clinical progression, serum testosterone must be evaluated in all cases to confirm a castration-resistant state. Ideally, suboptimal testosterone castrate levels should be confirmed with an appropriate assay [1306, 1307]. After ADT cessation (intermittent treatment or temporary ADT use as with EBRT) testosterone recovery is dependent on patients age and the duration of ADT [1308, 1309].

7.4.3.2 Liver function monitoring

Liver function tests will detect treatment toxicity (especially applicable for NSAA), but rarely indicate disease progression. Men on combined ADT should have their transaminase levels checked at least yearly but in particular in the first six months of treatment initiation since liver function disorders were observed relatively early in the majority of patients in larger trials [1310]. In view of potential liver toxicity a more frequent check is needed with some drugs (including abiraterone acetate) [1311]. Alkaline phosphatase may increase secondary to bone metastases and androgen-induced osteoporosis, therefore it may be helpful to determine bone-specific isoenzymes as none are directly influenced by ADT [1312].

7.4.3.3 Serum creatinine and haematological parameters

Estimated glomerular filtration rate monitoring is good clinical practice as an increase may be linked to ureteral obstruction or bladder retention. A decline in haemoglobin is a known side effect of ADT. A significant decline after three months of ADT is independently associated with shorter progression-free and OS rates and might explain significant fatigue although other causes should be considered [1313]. Anaemia is often multi-factorial and other possible aetiologies should be excluded. An early decrease in haemoglobin three months after ADT initiation predicted better survival whereas a decrease beyond six months was associated with poor outcome in the SPCG-5 population [1314]. Radiotherapy to more extensive bone metastases locations may result in myelosuppression and haematological toxicity [1315, 1316].

7.4.3.4 Monitoring of metabolic complications

The most severe complications of androgen suppression are metabolic syndrome, cardiovascular morbidity, mental health problems, and bone resorption (see Section 8.2.5).

All patients should be screened for diabetes by checking fasting glucose and HbA1c (at baseline and routinely) in addition to checking blood lipid levels. Men with impaired glucose tolerance and/or diabetes should be referred for an endocrine consultation. Prior to starting ADT a cardiology consultation should be considered in men with a history of cardiovascular disease and in men older than 65 years. Men on ADT are at increased risk of cardiovascular problems and hypertension and regular checks are required [1317]. More profound androgen ablation resulted in a higher cardiovascular toxicity [1318] and cardio-respiratory fitness decreased even after six months of ADT [1319]. The prematurely closed PRONOUNCE study found no difference at twelve months in major adverse cardiovascular events between men receiving degarelix or leuprolide [1320].

7.4.3.5 Monitoring bone problems

Androgen deprivation therapy increases the risk of osteoporosis. A combination of ADT with apalutamide, darolutamide, enzalutamide, abiraterone plus prednisone or docetaxel increases the fracture risk even more [1123, 1321, 1322]. Administration of ADT for more than a year, as compared to less than one year, showed a higher risk of osteoporosis (HR: 1.77 and 1.38, respectively) [1323]. Several scores (e.g., Fracture Risk Assessment Tool [FRAX score], Osteoporosis Self-Assessment Tool [OST], Osteoporosis Risk Assessment Instrument [ORAI], Osteoporosis Index of Risk [OSIRIS], Osteoporosis Risk Estimation [SCORE]) can help identify men at risk of osteoporotic complications but validation of these scores in the ADT setting is required (see Section 8.3.2.2) [1221, 1324, 1325].

Routine bone monitoring for osteoporosis should be performed at the start of ADT using dual emission X-ray absorptiometry (DEXA) scan [1222, 1326, 1327]. Presence of osteoporosis should prompt the use of bone protective agents. The criteria for initiation of bone protective agents are mentioned in Section 8.3.2.2. If no bone protective agents are given, a DEXA scan should be done regularly, at least every two years [1328].

A review summarising the incidence of bone fractures showed an almost doubling of the risk of fractures when using ADT depending on patients' age and duration and type of ADT with the highest incidence in older men and men on additional novel ARPI medication across the entire spectrum of disease [1329]. In case of an osteoporotic fracture a bone protective agent is mandatory. Vitamin D and calcium levels should be regularly monitored when patients receive ADT and patients should be supplemented if needed (see Section 8.3.2.2).

7.4.3.6 Monitoring lifestyle, cognition, fatigue and sexual function

Lifestyle (e.g., diet, exercise, smoking status, etc.) affects QoL and potentially outcome [1312]. During follow-up men should be counselled on the beneficial effects of exercise to avoid ADT-related toxicity [1330]. Androgen deprivation therapy may affect mental and cognitive health and men on ADT are three times more likely to report depression [1331]. Attention to mental health should therefore be an integral part of the follow-up scheme. Men on ADT may experience complaints of fatigue possibly related to systemic inflammation [1332]. Reduced cognitive performance and fatigue may arise within six months after initiation of ADT but can improve over time [1333]. Another apect of starting ADT is that it leads to sexual dysfunction, causing > 80% of couples to cease sexual activity completely. This aspect affects patients as well as their partners and couple counselling should be considered [1334].

*7.4.4 **Methods of follow-up in men on ADT without metastases***

7.4.4.1 Prostate-specific antigen monitoring

Prostate-specific antigen is a key marker for following the course of androgen-sensitive non-metastasised PCa. Imaging should be considered when PSA is rising > 2 ng/mL or in case of symptoms suggestive of metastasis.

7.4.4.2 Imaging

In general, asymptomatic patients with a stable PSA level do not require further imaging, although care needs to be taken in patients with aggressive variants when PSA levels may not reflect tumour progression [1335]. New bone pain requires at least targeted imaging and potentially a bone scan. When PSA progression suggests CRPC status and treatment modification is considered, imaging, by means of a bone and CT scan, is recommended for restaging. Detection of metastases greatly depends on imaging (see Section 5.8).

*7.4.5 **Methods of follow-up in men under ADT for hormone-sensitive metastatic PCa***

In metastatic patients it is of the utmost importance to counsel about early signs of spinal cord compression, urinary tract complications (ureteral obstruction, bladder outlet obstruction) or bone lesions that are at an increased fracture risk. The intervals for follow-up in M1 patients should be guided by patients' complaints and can vary. Since most men will receive another anti-cancer therapy combined with ADT such as ARPI, chemotherapy ,local RT, or combinations, follow-up frequency should also be dependent on the treatment modality. The specific points related to follow-up during the castrate-resistant situation are detailed in Section 6.7.9.

7.4.5.1 PSA monitoring

In men on ADT alone, a PSA decline to < 4 ng/mL suggests a likely prolonged response and follow-up visits may be scheduled every three to six months provided the patient is asymptomatic or clinically improving. This applied to men on ADT monotherapy as well as after ADT plus docetaxel [1094]. Depending on symptoms and risk assessment, more frequent visits may be indicated. Treatment response may be evaluated based on a change in serum PSA level [1093, 1094] and bone- and CT scan although there is no consensus about how frequently these should be performed [1268]. A rise in PSA level usually precedes the onset of clinical symptoms by several months. A rising PSA should prompt assessment of testosterone level, which is mandatory to define CRPC status, as well as restaging using imaging. However, it is now recognised that a stable PSA during ADT is not enough to characterise a non-progressive situation [1336].

7.4.5.2 Imaging as a marker of response in metastatic PCa

Treatment response in soft-tissue metastases can be assessed by morphological imaging methods using the Response Evaluation Criteria in Solid Tumours (RECIST) criteria. However, these criteria cannot be used in bone where response assessment is difficult [1337, 1338].

When bone scan is used to follow bone metastases, a quantitative estimation of tracer uptake at bone scan can be obtained through automated methods such as the Bone Scan Index [1339]. Nonetheless, bone scan is limited by the so-called 'flare' phenomenon which is defined by the development of new images induced by treatment on a first follow-up scan which, after longer observation, actually represent a favourable response. Flare is observed within eight to twelve weeks of treatment initiation and can lead to a false-positive diagnosis of disease progression. Computed tomography cannot be used to monitor sclerotic bone lesions because bone sclerosis can occur under effective treatment and reflects bone healing. Magnetic resonance imaging

can directly assess the bone marrow and demonstrate progression based on morphologic criteria or changes in apparent diffusion coefficient. A standardisation for reporting is available [1340]. The ability of PET/CT to assess response has been evaluated in a few studies. Until further data are available, MRI and PET/CT should not be used outside trials for treatment monitoring in metastatic patients [1341].
Men with metastasised PCa on ADT should also in the absence of a PSA rise be followed up with regular imaging since twenty-five percent of men with, or without, docetaxel in the CHAARTED trial developed clinical progression without a PSA rise [1336]. One in eight men with a PSA < 2 ng/mL showed clinical progression [1336]. The addition of docetaxel to ADT in the CHAARTED trial population did not reduce the incidence of clinical progression at low PSA values and this rate was similar for both low- and high-volume disease as per CHAARTED criteria [1336]. However, the optimal timing and image modality to be used remain unclear, as is the real clinical value of any findings.

*7.4.6 **Guidelines for follow-up during hormonal treatment***

Recommendations	**Strength rating**
The follow-up strategy must be individualised based on stage of disease, prior symptoms, prognostic factors and the treatment given.	Strong
In patients with stage M0 disease, schedule follow-up at least every six months. As a minimum requirement, include a disease-specific history, serum prostate-specific antigen (PSA) determination, as well as liver and renal function in the diagnostic work-up.	Strong
In M1 patients, schedule follow-up at least every three to six months.	Strong
In patients on long-term androgen deprivation therapy (ADT), measure initial bone mineral density to assess fracture risk.	Strong
In patients receiving combination treatment for offer bone protection to avoid fractures	Strong
During follow-up of patients receiving ADT, check PSA and testosterone levels and monitor patients for symptoms associated with metabolic syndrome as a side effect of ADT.	Strong
In patients on long-term ADT, as a minimum requirement, include a disease-specific history, haemoglobin, serum creatinine, alkaline phosphatase, lipid profiles and HbA1c level measurements.	Strong
Counsel patients (especially with M1b status) about the clinical signs suggestive of spinal cord compression.	Strong
When disease progression is suspected, restaging is needed and the subsequent follow-up adapted/individualised.	Strong
In patients with suspected progression, assess the testosterone level. By definition, castration-resistant PCa requires a testosterone level < 50 ng/dL (< 1.7 nmol/L).	Strong

8. QUALITY OF LIFE OUTCOMES IN PROSTATE CANCER

This chapter is presented in two parts. The first (Section 8.2) will summarise long-term consequences (≥ twelve months) of therapies for PCa. Based on two SRs, the second (Section 8.3) provides evidence-based recommendations for supporting patients when selecting primary treatment options for localised disease and also supportive interventions aimed at improving disease-specific QoL across all stages of disease.

8.1 Introduction

Quality of life and personalised care go hand in hand. Treating PCa can affect an individual both physically and mentally, as well as close relations and work or vocation. These multifaceted issues all have a bearing on an individual's perception of QoL [1342, 1343]. Approaching care from a holistic point of view requires the intervention of a multi-disciplinary team including urologists, medical oncologists, radiation oncologists, oncology nurses, behavioural practitioners and many others including fellow patients. Attention to the psychosocial concerns of people with PCa is integral to quality clinical care, and this can include the needs of carers and partners [1344]. Prostate cancer care should not be reduced to focusing on the organ in isolation: side effects or late adverse effects of treatment can manifest systemically and have a major influence on the patient's QoL. Psychological distress can be caused by the cancer diagnosis itself, cancer symptoms and/or treatment side effects [1345]. Taking QoL into consideration relies on understanding the patient's values and preferences so that optimal treatment proposals can be formulated and discussed. Cross-sectional patient reported outcomes studies in general PCa populations show the impact of treatment on global and disease specific QoL is greater than that described in clinical trial populations who often have less co-morbidity and belong to higher socio-economic groups. Individuals undergoing two or more treatments have more symptoms and greater impact on QoL [1346, 1347]. Subgroups of people including those with poor general health, being unmarried, older age and/or pre-existing depressive symptoms are more at risk of long-term mental health issues following treatment for PCa [1348].

8.2 Adverse effects of PCa therapies

*8.2.1 **Active surveillance***

In a SR [1349] on the long-term (> five year) health-related QoL in patients on active surveillance, it was observed that there were differences in specific functional outcomes between patients on AS and surgery or radiotherapy, ≥ five year after treatment. In patients on AS, the overall HRQoL and psychological well-being outcomes were good. All studies comparing AS with active treatment found no substantial or consistent difference in general HRQoL PROMs between groups. In preservation of continence there is a clear advantage for AS over, active treatment, particularly to RP. Results suggest that even after extended periods, continence is still considerably superior in AS to that in RP. Obstructive voiding symptoms were more common in patients on AS than in post-operative patients. In the domain of sexual function, it is seen that AS group has better than or comparable sexual function to that in the active treatment group. Studies comparing AS with that of PCa-free patients had mixed results with papers observing no statistically significant difference and others reporting that sexual function was, at least numerically, worse in patients on AS than in PCa-free patients. All patients on AS report good quality of life, similar to that in individuals without prostate cancer [1350]. Regarding anxiety it was seen in a registry on active surveillance in the USA that men undergoing active surveillance, had a moderate risk of cancer-specific anxiety that significantly decreases over time. Patients considering active surveillance can be informed that, although it is common experience some anxiety initially, most men rapidly adjust and report low levels of anxiety within two years [1350].

*8.2.2 **Surgery***

A lack of clear consensus in reporting surgical complications following RP, specifically urinary incontinence and stricture rates, and the introduction of different techniques has resulted in a wide variation in the types of complications reported, as well as variation in the overall incidence of complications [1351-1354]. The most common post-operative complication is ED but other related issues to consider include dry ejaculation, which occurs with removal of the prostate, change in the quality of orgasm and occasional pain on orgasm. Men also complain of loss of penile length (3.73%, 19/510 men) [1355]. The second most commonly occurring complication is long-term incontinence [1351-1354] but voiding difficulties may also occur associated with bladder neck contracture (e.g., 1.1% after RALP) [1356].

A key consideration is whether long-term consequences of surgery are reduced by using newer techniques such as RALP. Systematic reviews have documented complication rates after RALP [612-616], and can be compared with contemporaneous reports after RRP [617]. From these reports, the mean continence rates at twelve months were 89–100% for patients treated with RALP and 80–97% for patients treated with

RRP. A prospective controlled non-randomised trial of patients undergoing RP in fourteen centres using RALP or RRP demonstrated that at twelve months after RALP, 21.3% were incontinent, as were 20.2% after RRP. The unadjusted OR was 1.08 (95% CI: 0.87–1.34). Erectile dysfunction was observed in 70.4% after RALP and 74.7% after RRP. The unadjusted OR was 0.81 (95% CI: 0.66–0.98) [618, 1357]. Further follow-up demonstrates similar functional outcomes with both techniques at 24 months [1357, 1358]. A single-centre randomised phase III study comparing RALP and RRP (n = 326) also demonstrates similar functional outcomes with both techniques at 24 months [1359]. Prostatectomy was found to increase the risk of complaints from an inguinal hernia, in particular after an open procedure when compared to minimally-invasive approaches [1360, 1361]. For those undergoing minimally-invasive procedures port site hernia has been reported in 0.66% after inserting 12 mm bladeless trocar and can occur more rarely with 8 mm and 5 mm trocars [1362]. Another complication after primary treatment is lower limb and genital lymphedema. A SR found a prevalence of (0-14%) lower limb and (0-1%) genital lymphedema after radical prostatectomy with PLND [1363] and between 0-9% and 0-8% in patients after irradiation on the LNs. In the subgroup that underwent pelvic irradiation after staging pelvic LNs dissections the prevalence of lower limb (18-29%) and genital (2-22%) is substantially elevated.

*8.2.3 **Radiotherapy***

8.2.3.1 Side effects of external beam radiotherapy

Analysis of the toxicity outcomes of the ProtecT trial shows that patients treated with EBRT and six months of ADT report bowel toxicity including persistent diarrhoea, bowel urgency and/or incontinence and rectal bleeding (described in detail in Section 8.3.1.1 below) [1364]. Participants in the ProtecT study were treated with 3D-CRT and studies using IMRT demonstrate less bowel toxicity than noted previously with 3D-CRT [1365].

A SR and meta-analysis of observational studies comparing patients exposed or unexposed to RT in the course of treatment for PCa demonstrates an increased risk of developing second cancers for bladder (OR: 1.39), colorectal (OR: 1.68) and rectum (OR: 1.62) with similar risks over lag times of five and ten years. Absolute excess risks over ten years are small (1–4%) but should be discussed with younger patients in particular [1366].

Patient-reported outcomes suggest a temporary drop in the EPIC hormonal and sexual domains when six months af ADT was added to radiotherapy, with a disappearance of any clinical relevant difference at one year [1147, 1367].

8.2.3.2 Side effects from brachytherapy

Some patients experience significant urinary complications following implantation such as urinary retention (1.5-22%), with post-implantation TURP reported as being required in up to 8.7% of cases, and incontinence (0–19%) [1368]. Chronic urinary morbidity is more common with combined EBRT and BT and can occur in up to 20% of patients, depending on the severity of the symptoms before BT. Urethral strictures account for at least 50% of urinary complications and can be resolved with dilation in the majority [719, 726]. Prevention of morbidity depends on careful patient selection and IPSS score, backed up by urodynamic studies.

*8.2.4 **Local primary whole-gland treatments other than surgery or radiotherapy***

8.2.4.1 Cryosurgery

In a SR and meta-analysis there was evidence that the rate of urinary incontinence at one year was lower for cryotherapy than for RP, but the size of the difference decreased with longer follow-up [738]. There was no significant difference between cryotherapy vs. EBRT in terms of urinary incontinence at one year (< 1%); cryotherapy had a similar ED rate (range 0–40%) to RP at one year. There were insufficient data to compare cryotherapy vs. EBRT in terms of ED.

8.2.4.2 High-intensity focused ultrasound

In terms of toxicity there are insufficient data on urinary incontinence, ED, or bowel dysfunction to draw any conclusions, although at one-year HIFU had lower incontinence rates than RP (OR: 0.06, 95% CI: 0.01–0.48) [738].

*8.2.5 **Androgen deprivaton therapy***

A summary of psychological impacts due to the use of ADT such as sexual function, mood, depression, cognitive function, and impact on partners can be found in two clinical reviews [1369, 1370].

A small RCT evaluated the QoL at one-year follow-up in patients with PSA only relapse after primary therapy without evidence of metastasis, between various ADT regimens, or no treatment. Patients treated by ADT reported a significant decline in spatial reasoning, spatial abilities and working memory as well as increased depression, tension, anxiety, fatigue, and irritability during treatment [1371]. Conversely, a prospective observational study with follow-up out to three years failed to demonstrate any association with cognitive decline in men on ADT when compared to men with PCa not treated with ADT and healthy controls [1372]. A prospective observational study of locally advanced PCA or BCR after local therapy found that immediate ADT

was associated with a lower overall QoL compared to deferred treatment [1373]. Another retrospective non-randomised study suggested that men receiving LHRH agonists reported more worry and physical discomfort and poorer overall health and were less likely to believe themselves free of cancer than patients undergoing orchiectomy. The stage at diagnosis had no effect on health outcomes [1374].

8.2.5.1 Sexual function

Cessation of sexual activity is very common in people undergoing ADT, affecting up to 93% [1375]. Androgen deprivation therapy reduces both libido and the ability to gain and maintain erections. The management of acquired ED is mostly non-specific [1376].

Using a specific non-validated questionnaire, bicalutamide monotherapy showed a significant advantage over castration in the domains of physical capacity and sexual interest (not sexual function) at twelve months [1377]. A *post-hoc* analysis, including only patients with sexual interest suggested that bicalutamide was associated with better sexual preservation, including maintained sexual interest, feeling sexually attractive [1378], preserved libido and erectile function [1379].

8.2.5.2 Hot flushes

Hot flushes are a common side effect of ADT (prevalence estimated between 44–80% of men on ADT) [1375]. They appear three months after starting ADT, usually persist long-term and have a significant impact on QoL.

Serotonin re-uptake inhibitors (e.g., venlafaxine or sertraline) appear to be effective in men but less than hormone therapies based on a prospective RCT comparing venlafaxine, 75 mg daily, with medroxyprogesterone, 20 mg daily, or cyproterone acetate, 100 mg daily [1380]. After six months of LHRH (n = 919), 311 men had significant hot flushes and were randomised to one of the treatments. Based on median daily hot-flush score, venlafaxine was inferior -47.2% (interquartile range -74.3 to -2.5) compared to -94.5% (-100.0 to -74.5) in the cyproterone group, and -83.7% (-98.9 to -64.3) in the medroxyprogesterone group. Another RCT (n = 78) compared oestradiol (transdermal 0,9mg or 0,1% gel) to placebo. After six months oestradiol reduced daily hot flushes frequency (mean adjusted difference MAD -1,6, p=0.04) but the effect on weekly hot flushes was not significant (MAD -19,6 p=0.11) [1381].

With a placebo effect influencing up to 30% of patients [1382] , the efficacy of clonidine, veralipride, gabapentin [1383] and acupuncture [1384] need to be compared in prospective RCTs.

8.2.5.3 Non-metastatic bone fractures

Due to increased bone turnover and decreased BMD in a time-dependent manner, ADT use is linked to an increased risk of fracture (up to 45% RR with long-term ADT) [1385]. Severe fractures in men are associated with a significant risk of death [1386]. A precise evaluation of BMD should be performed by DEXA, ideally before starting long-term ADT. An initial low BMD (T-score < -2.5 or < -1, with other risk factors) indicates a high risk of subsequent non-metastatic fracture and causes should be investigated. Other risk factors include increasing age, BMI of 19 or less, history of previous fracture or parent with fractured hip, current smoking, use of glucocorticoids, rheumatoid arthritis, alcohol consumption > two units per day, history of falls and a number of other chronic medical conditions [1387]. Fracture risk algorithms which combine BMD and clinical risk factors such as FRAX score can be used to guide treatment decisions, but uncertainty exists regarding the optimal intervention threshold, therefore no specific risk algorithm can be recommended for men on ADT for PCa. Obesity (increase in body fat mass by up to 10% and/or BMI > 30) and sarcopenia (decrease in lean tissue mass by up to 3%) as well as weight loss are common and occur during the first year of ADT [1388]. These changes increase the fracture risk [1389]. It is suggested that adding ARTA to ADT will increase this risk. This was also seen in a SR and meta-analysis [1390]. It was found that the use of ARTA was associated with an increase in fractures. Eleven studies were included with a total population of 11,382 men (median [range] age: 72 [43-97] years), with 6,536 in the ARTA group and 4,846 in the control group. Participants in the ARTA group could have received enzalutamide, apalutamide, or darolutamide in combination with androgen deprivation therapy or other enzalutamide combinations; patients in the control group could have received placebo, bicalutamide, or abiraterone. The incidence of fracture was 242 fractures (4%) in the ARTA group and 107 fractures (2%) in the control group. Use of an ARTA was associated with an increased risk of fractures: all-grade fracture (RR, 1.59; 95% CI, 1.35-1.89; p <.001), and likely grade 3 or greater fracture (RR, 1.71; 95% CI, 1.12-2.63; p =.01).

Bicalutamide monotherapy may have less impact on BMD but is limited by its suboptimal efficacy for M1 disease [1391, 1392]. The intermittent LHRH-agonist modality might be associated with less bone impact [1393].

8.2.5.4 Metabolic effects

Lipid alterations are common and may occur as early as the first three months of treatment [1388]. Androgen deprivation therapy also decreases insulin sensitivity and increases fasting plasma insulin levels, which is a marker of insulin resistance. In diabetic patients, metformin appears to be an attractive option for protection against metabolic effects based on retrospective analysis [1394], but there is insufficient data to recommend its use in non-diabetic patients.

Metabolic syndrome is an association of independent cardiovascular disease risk factors, often associated with insulin resistance. The definition requires at least three of the following criteria [1395]:

- waist circumference > 102 cm;
- serum triglyceride > 1.7 mmol/L;
- blood pressure > 130/80 mmHg or use of medication for hypertension;
- high-density lipoprotein (HDL) cholesterol < 1 mmol/L;
- glycaemia > 5.6 mmol/L or the use of medication for hyperglycaemia.

The prevalence of a metabolic-like syndrome is higher during ADT compared with men not receiving ADT [1396]. Skeletal muscle mass heavily influences basal metabolic rate and is in turn heavily influenced by endocrine pathways [1397]. Androgen deprivation therapy-induced hypogonadism results in negative effects on skeletal muscle health. A prospective longitudinal study involving 252 men on ADT for a median of 20.4 months reported lean body mass decreases progressively over three years; 1.0% at one year, 2.1% at two years, and 2.4% at three years which appears more pronounced in men at ≥ 70 years of age [1398].

8.2.5.5 Cardiovascular morbidity

Cardiovascular mortality is a common cause of death in PCa patients [1030, 1399, 1400]. Several studies showed that ADT after only six months was associated with an increased risk of diabetes mellitus, cardiovascular disease, and myocardial infarction [1401]. The RTOG 92-02 [1402] and 94-08 [1403] trials confirmed an increased cardiovascular risk, unrelated to the duration of ADT and not accompanied by an overall increased cardiovascular mortality. No increase in cardiovascular mortality has been reported in both a secondary analysis of PLCO trial, even among subgroups with pre-existing cardiovascular disease [1404] and a meta-analysis of trials RTOG 8531, 8610, 9202, EORTC 30891 and EORTC 22863 [1405]. However, serious concerns about the conclusions of this meta-analysis have been raised due to poor consideration of bias in the included studies [1406, 1407]. A meta-analysis of observational data reports consistent links between ADT and the risk of cardiovascular disease patients treated for PCa, e.g., the associations between LHRH agonists and non-fatal or fatal myocardial infarction or stroke RR: 1.57 (95% CI: 1.26–1.94) and RR: 1.51 (95% CI: 1.24–1.84), respectively [1408]. In an updated meta-analysis on the cardiometabolic effects of ADT, ADT was not associated with metabolic syndrome RR: 1.60 (95% CI: 1.06-2.42), had a lower association with diabetes RR 1.43 (95% CI: 1.28-1.59) as previously reported, and an increased risk of hypertension by 30%, RR 1.30 (95% CI: 1.08-1.55). After adjustment for publication bias ADT was associated with a 25% increased risk for diabetes but was not associated with metabolic syndrome [1409].

An increase in cardiovascular mortality has been reported in patients suffering from previous congestive heart failure or myocardial infarction in a retrospective database analysis [1410] or presenting with a metabolic syndrome [1411]. It has been suggested that antagonists might be associated with less cardiovascular morbidity compared to agonists, but, as yet there is no definite evidence [1320, 1412]. In a phase III RCT the use of relugolix, an oral LHRH antagonist, was associated with a reduced risk of major adverse cardiovascular events when compared to leuprolide, an injectable LHRH agonists, at 2.9% vs. 6.2%, respectively, over a follow-up time of 48 weeks (HR 0.46, 95% CI: 0.24–0.88) [1053].

Concerns about LHRH agonists resulted in an FDA warning and consensus paper from the American Heart, Cancer Society and Urological Associations [1029]. Preventive advice includes non-specific measures such as loss of weight, increased exercise, minimising alcohol intake, improved nutrition and smoking cessation [83, 1413].

The adverse-effects of different ARTAs (abiraterone, apalutamide, darolutamide, enzalutamide) in the treatment of mCRPC, nmCRPC, and mHSPC were systematically reviewed in a multi-variate network meta-analysis. Here it is suggested that the ARTAs adverse effect profiles do not significantly differ from each other, except that enzalutamide was ranked the most toxic regarding hypertension in mCRPC and nmCRPC, and the most toxic regarding headache across all prostate cancer settings [1414].

8.2.5.6 Fatigue

Fatigue often develops as a side effect of ADT. Regular exercise appears to be the best protective measure. Reporting clinically significant fatigue is associated with severe psychological distress and should prompt screening for anxiety and/or depression [1415]. Anaemia may be a cause of fatigue [1375, 1416]. Anaemia requires an aetiological diagnosis (medullar invasion, renal insufficiency, iron deficiency, chronic bleeding) and individualised treatment. Regular blood transfusions may be required in patients with severe anaemia.

8.2.5.7 Neurological side effects

Castration seems also to be associated with an increased risk of stroke [1417], and is suspected to be associated with an increased risk for depression and cognitive decline such as Alzheimer disease [1418].

8.2.5.8 Osteonecrosis during bisphosphonates or denosumab

Bisphosphonates are synthetic pyrophosphate analogs and used in conditions such as malignancy and osteoporosis. Infrequent side effects associated with bisphosphonate use include pyrexia, renal function impairment, hypocalcemia, and avascular osteonecrosis of the jaw. Denosumab is a human monoclonal antibody that is used in the treatment of osteoporosis and bone metastasis [1419, 1420]. It acts by inhibiting osteoclast activity, reducing bone resorption, and increasing bone density [1419]. Its highly specific mechanism of action is the inhibition of receptor activator of nuclear factor-kappa B ligand (RANKL). It has been shown to be effective at increasing bone mineral density and decreasing fractures in men with prostate cancer on ADT [1421].

Both drugs are associated with osteonecrosis of the jaw (ONJ) According to the American Society of Bone and Mineral Research, ONJ is described as exposed bone in the maxillofacial region that does not heal within eight weeks of being identified by a healthcare provider in a patient that is currently or has been on bisphosphonates who does not have a history of radiation therapy in the craniofacial region [1422]. The incidence of ONJ is related to the dose and duration of treatment. The risk ranges from greater than 1% at twelve months to 11% after four years of treatment - taking zoledronic acid alone increases the risk of osteonecrosis to 21% after the third year. A SR on denosumab [1423] showed in a total of 8,963 patients with a variety of solid tumours in seven randomised controlled trials (RCTs) that the overall incidence of ONJ in patients with cancer receiving denosumab was 1.7% [95% CI: 0.9–3.1%]. The use of denosumab was associated with a significantly increased risk of ONJ in comparison with bisphosphonates (BPs)/placebo treatment (RR 1.61, 95% CI: 1.05–2.48, P = 0.029). Subgroup analysis based on controlled therapies demonstrated an increased risk of ONJ in denosumab therapy, when compared with BPs (RR 1.48, 95% CI: 0.96–2.29, p = 0.078) or placebo (RR 16.28, 95% CI: 1.68–158.05, p = 0.017). Similar results were observed for prostate cancer (RR 3.358, 95% CI: 1.573–7.166, p = 0.002). Denosumab combined with risk factors such as dental extraction, poor oral hygiene, use of removable apparatus, and chemotherapy may favour the development of ONJ. Therefore, before starting these drugs the patients should undergo a dental examination and maintain good oral hygiene.

8.3 Overall quality of life in men with PCa

Living longer with PCa does not necessarily equate to living well [1342, 1344]. There is clear evidence of unmet needs and ongoing support requirements for some individuals and partners after diagnosis and treatment for PCa [1424, 1425]. Fear of cancer recurrence and PSA anxiety has a prevalence of 16% and 22%, respectively, across studies [1426]. Combined cognitive- and education-based psychological interventions improve depression, anxiety, and distress [1427]. Cancer impacts on the wider family and cognitive behavioural therapy can help reduce depression, anxiety, and stress in caregivers [1428]. Radical treatment for PCa can negatively impact long-term QoL (e.g., sexual, urinary and bowel dysfunction) as can ADT used in short- or long-term treatment, e.g., sexual problems, fatigue, psychological morbidity, adverse metabolic sequelae and increased cardiovascular and bone fracture risk [1370, 1429]. Direct symptoms from advanced or metastatic cancer, e.g., pain, hypercalcaemia, spinal cord compression and pathological fractures, also adversely affect health [1430, 1431]. Patients' QoL including domains such as sexual function, urinary function and bowel function is worse after treatment for PCa compared to non-cancer controls [1432, 1433]. A PCa diagnosis commonly results in financial strain both for the individual and their families. This financial toxicity is associated with younger age at diagnosis, black race, low socio-economic status, low educational attainment and living in a rural area. Clinicians should discuss financial strains and signpost to support services so that quality of life and adherence to treatment can be maintained [1434].

As QoL is subjective and can mean different things to different people it can be difficult to measure and compare. Nevertheless, there are some generally common features across virtually all patients. Drawing from these common features, specific tools or PROMs have been developed and validated for men with PCa. These questionnaires assess common issues after PCa diagnosis and treatment and generate scores which reflect the impact on perceptions of HRQoL. During the process of undertaking two dedicated SRs around

cancer-specific QoL outcomes in patients with PCa as the foundation for our guideline recommendations, the following validated PROMs were found in our searches (see Table 8.3.1). The tools with the best evidence for psychometric properties and feasibility for use in routine practice and research settings to assess PROMs in patients with localised PCa were EORTC QLQ-C30 and QLQ-PR25. Since EORTC QLQ-C30 is a general module that does not directly assess PCa-specific issues, it should be adopted in conjunction with the QLQ-PR25 module [1435].

Table 8.3.1: PROMs assessing cancer specific quality of life [1435]

Questionnaire	Domains/items
European Organisation for Research and Treatment of Cancer QLQ-C30 (EORTC QLQ-C30) [1436]	Five functional scales (physical, role, cognitive, emotional, and social); three symptom scales (fatigue, pain, and nausea and vomiting); global health status/QoL scale; and a number of single items assessing additional symptoms commonly reported by cancer patients (dyspnoea, loss of appetite, insomnia, constipation and diarrhoea) and perceived financial impact of the disease.
European Organisation for Research and Treatment of Cancer QLQ-PR 25 (EORTC QLQ-PR 25) [1437]	Urinary, bowel and treatment-related symptoms, as well as sexual activity and sexual function.
Functional Assessment of Cancer Therapy-General (FACT-G) [1438]	Physical well-being, social/family well-being, emotional well-being, and functional well-being.
Functional Assessment of Cancer Therapy-Prostate (FACT-P) [1439]	12 cancer site specific items to assess for prostate-related symptoms. Can be combined with FACT-G or reported separately.
Expanded prostate cancer index composite (EPIC) [1440]	Urinary, bowel, sexual, and hormonal symptoms.
Expanded prostate cancer index composite short form 26 (EPIC 26) [1441]	Urinary, sexual, bowel, and hormonal domains.
UCLA Prostate Cancer Index (UCLA PCI) [1442]	Urinary, bowel, and sexual domains.
Prostate Cancer Quality of Life Instrument (PCQoL) [1443]	Urinary, sexual, and bowel domains, supplemented by a scale assessing anxiety.
Prostate Cancer Outcome Study Instrument [1433]	Urinary, bowel, and sexual domains.

*8.3.1 **Long-term (> twelve months) quality of life outcomes in men with localised disease***

8.3.1.1 Men undergoing local treatments

In the updated results of the ProtecT trial [1444] treatment-received analyses revealed different impacts of treatments over six years. Men remaining on AM experienced gradual declines in sexual and urinary function with age with increases in ED from 35% at baseline to 53% at six years and nocturia from 20% to 38%. Radical treatment impacts were immediate and continued over six years. After RP, 95% reported ED persisting for 85% at six years, after EBRT this was 69% and 74%, respectively ($p < 0.001$ compared with AM). After RP, 36% reported urinary leakage requiring at least one pad/day, persisting for 20% at six years, compared with no change in men receiving EBRT or AM ($p < 0.001$). Worse bowel function and bother such as bloody stools 6% at six years and faecal incontinence 10%, was experienced by more men after EBRT than after RP or AM ($p < 0.001$) with lesser effects after BT. No treatment affected mental or physical QoL. In another paper on the twelve years outcome this trial [1364], it was seen that the generic quality-of-life scores were similar in randomised groups over seven to twelve years, urinary leakage requiring pads occurred in 18-24% of patients In the prostatectomy group over seven to twelve years, compared with 9-11% in the AM group and 3-8% in the radiotherapy group. Erections sufficient for intercourse were reported in 18% at seven years in the prostatectomy group, compared with 30% in the AM and 27% in the radiotherapy groups; all converged to low levels of potency by year twelve. Nocturia (voiding at least twice per night) occurred in 34% in the prostatectomy group compared with 48% in the radiotherapy group and 47% in the AM group at twelve years. Faecal leakage affected 12% in the radiotherapy group compared with 6% in the other groups by year twelve. The AM group experienced gradual age-related declines in sexual and urinary function, avoiding radical treatment effects unless they changed management.

Other observational studies [668, 1243, 1354, 1445-1448] also report findings regarding RP and RT. The Prostate Cancer Outcomes Study (PCOS) studied a cohort of 1,655 men, of whom 1,164 had undergone RP and 491 RT [1354]. The study reported that at five years of follow-up, men who underwent RP had a higher prevalence of

urinary incontinence and ED, while men treated with RT had a higher prevalence of bowel dysfunction. However, despite these differences detected at five years, there were no significant differences in the adjusted odds of urinary incontinence, bowel dysfunction or ED between RP and RT at fifteen years. Investigators have reported that although EBRT was associated with a negative effect in bowel function, the difference in bowel domain score was below the threshold for clinical significance twelve months after treatment [1365]. As 81% of patients in the EBRT arm of the study received IMRT, these data suggest that the risk of side effects is reduced with IMRT compared to older 3D-CRT techniques. This is supported by five-year prospective, population-based cohort study where PROMs were compared in men with favourable- and unfavourable-risk localised disease [1447]. In the 1,386 men with favourable risk, comparison between AS and nerve-sparing prostatectomy, EBRT or LDR BT demonstrates that surgery is associated with worse urinary incontinence at five years and sexual dysfunction at three years when compared to AS. External beam RT is associated with changes not clinically different from AS, and LDR BT is associated with worse irritative urinary-, bowel- and sexual symptoms at one year. In 619 men with high-risk localised disease, comparison between non-nerve sparing RP and EBRT with ADT demonstrates that surgery is associated with worse urinary incontinence and sexual function through five years. A SR demonstrates that the risk of post-radiotherapy ED has reduced to a median of 25% at two years with utilisation of IMRT and is now similar to that noted after LDR BT [1449].

A few prospective studies have reported specific long-term urinary functional outcomes after RP and RT even if the studies are not comparative between the two treatment modalities. Considering incontinence and ED after RP the prospective randomised PIVOT trial, comparing RP to observation, reported that 40% of men wore pads, of which 20% wore more than > one pad/day, and an increased rate of ED in the RP group as compared to observation from 70% to approximately 87%, after a median follow-up of 12.7 years [1243]. The corresponding figures from the prospective non-randomised LAPPRO-trial, comparing open- to robot-assisted RP, were 27–29% of the patients reporting urinary incontinence of some degree after eight years and 66–70% reporting ED [1448]. Data on urinary, sexual and bowel function after RT has been reported from the HYPO-RT-PC-trial, a prospective randomised non-inferiority trial comparing ultra-HFX to conventional fractionation RT. In this trial 52–55% of the patients reported urinary problems (RTOG toxicity grade ≥ 1) at five years, of which 4.2–4.7% reported a RTOG grade ≥ 3 urinary morbidity and 7–8% reported moderate-to-severe incontinence at six years. Bowel toxicity of any level (RTOG toxicity grade ≥ 1) was reported in 53–54% of the patients at five years, of which 1.5–1.9% reported a RTOG grade ≥ 3 bowel morbidity, and 66–71% reported to have little or no erection without aids after six years follow-up [668, 1446].

8.3.1.2 Guidelines for quality of life in men undergoing local treatments

Recommendations	Strength rating
Advise eligible patients for active surveillance that global quality of life is equivalent for up to five years compared to radical prostatectomy or external beam radiotherapy (RT).	Strong
Discuss the negative impact of surgery on urinary and sexual function, as well as the negative impact of RT on bowel function with patients.	Strong
Advise patients treated with brachytherapy of the negative impact on irritative urinary symptomatology at one year but not after five years.	Weak

*8.3.2 **Improving quality of life in men who have been diagnosed with PCa***

8.3.2.1 Men undergoing local treatments

In men with localised disease, nurse-led multi-disciplinary rehabilitation (addressing sexual functioning, cancer worry, relationship issues, depression, managing bowel and urinary function problems) provided positive short-term effects (four months) on sexual function (effect size 0.45) and long-term (twelve months) positive effects on sexual limitation (effect size 0.5) and cancer worry (effect size 0.51) [1450].

Exercise programs during RT combined with ADT result in consistent benefits for cardiovascular fitness (standardised mean difference [SMD], 0.83; 95% CI: 0.31–1.36; $p < 0.01$) and muscle function (SMD, 1.30; 95% CI: 0.53–2.07; $p < 0.01$) with a reduction in urinary toxicity (SMD, -0.71; 95% CI: -1.25 to -0.18; $p < 0.01$) [1451]. In men undergoing AS, twelve weeks of high-intensity interval training may improve cardiovascular fitness and suppress PSA progression [1452].

In men with post-surgical urinary incontinence, conservative management options include pelvic floor muscle training with or without biofeedback, electrical stimulation, extra-corporeal magnetic innervation (ExMI), compression devices (penile clamps), lifestyle changes, or a combination of methods. Uncertainty around the effectiveness and value of these conservative interventions remains [1453]. Surgical interventions including

sling and artificial urinary sphincter (AUS) significantly decrease the number of pads used per day and increase the QoL compared with before intervention. The overall cure rate is around 60% and results in improvement in incontinence by about 25% [1454]. Other alternatives, such as the Adjustable Transobturator Male System (ATOMS) and the Adjustable Continence Therapy (proACT) may be an option but seems less efficacious than AUS [1455]. For a more detailed overview of management of urinary incontinence in these men see Chapter 5.6 in the EAU Guidelines for Management of Non-neurogenic Male LUTS [1456].

The use of PDE5 inhibitors in penile rehabilitation has been subject to some debate. A single-centre, double-blind RCT of 100 men undergoing nerve-sparing surgery reported no benefit of nightly sildenafil (50 mg) compared to on-demand use [1457]. However, a multi-centre double-blind RCT (n = 423) in men aged < 68 years, with normal pre-treatment erectile function undergoing either open, conventional or robot-assisted laparoscopic nerve-sparing RP, tadalafil (5 mg) once per day improved participants EPIC sexual domain-scores (least squares mean difference +9.6, 95% CI: 3.1–16.0) when compared to 20 mg 'on demand' or placebo at nine months of follow-up, even though the difference vanished after the end of study [1458]. Therefore, based on discordant results, no clear recommendation is possible, even if a trend exists for early use of PDE5 inhibitors after RP for penile rehabilitation [1459]. A detailed discussion can be found in the EAU Sexual and Reproductive Health Guidelines [1460].

In a SR of genitourinary cancers with mostly prostate cancers it is evident that sexual well-being concerns for men and their partners are evident from diagnosis and into survivorship. Both (patient and partners) benefited from interventions but many articulated difficulties with initiating the topic due to embarrassment and limited access to interventions in cancer services [1461].

Testosterone
Regarding supplementation of testosterone there seems to be some hesitation by HCP. Although the evidence is limited, men who are managed expectantly for PCa, or who received radical local therapy, do not have worse outcomes when receiving testosterone supplementation [77]. We therefore advise to not hesitate to give testosterone substitution to symptomatic hypogonadal men with prostate cancer where ADT is not the treatment of choice.

8.3.2.2 Men undergoing systemic treatments
Similar to men treated with a radical approach (see above), in men with T1-T3 disease undergoing RT and ADT, a combined nurse-led psychological support and physiotherapist-led multi-disciplinary rehabilitation has reported improvements in QoL. Specifically, this intervention involved action planning around patients' needs related to lifestyle changes, weight control, toilet habits, sexuality, and psychological problems. This was complemented with pelvic floor muscle therapy. Improvements in urinary (adjusted mean 4.5, 95% CI: 0.6–8.4), irritative (adjusted mean 5.8, 95% CI: 1.4–10.3) and hormonal (adjusted mean 4.8, 95% CI: 0.8–8.8) EPIC domains were found up to 22 weeks of follow-up [1462]. In a three-year follow-up with 92% response rate from the initial study, fewer participants had moderate-severe bowel problems in the intervention (n = 2; 3%) vs. control group (n = 10; 14%) (p = 0.016) but the benefits in terms of urinary function were maintained only in those participants with moderate-severe urinary problems at baseline [1463].

Providing supervised aerobic and resistance exercise training of a moderate intensity improves EORTC QLQ-C30 role (adjusted mean 15.8, 95% CI: 6.6–24.9) and cognitive domain outcomes (adjusted mean 11.4, 95% CI: 3.3–19.6) as well as symptom scales for fatigue (adjusted mean 11.0, 95% CI: 20.2–1.7), nausea (adjusted mean 4.0, 95% CI: 7.4–0.25), and dyspnoea (adjusted mean 12.4, 95% CI: 22.5–2.3) up to three months in men treated with ADT [1464]. Such interventions have also reported clinically relevant improvements in FACT-P (mean difference 8.9, 95% CI: 3.7–14.2) in men on long-term ADT [1465, 1466]. These findings are supported by a SR which reported improvements up to twelve weeks in cancer-specific QoL in a meta-analysis of high-quality trials (SMD 0.33, 95%, CI: 0.08–0.58) [1416]. Supervised exercise interventions delivered over twelve months are effective in reducing psychological distress; particularly in those men with highest levels of baseline anxiety and depression [1467]. In untrained older men, SR suggests lower volume exercise programs at moderate-to-high intensity are as effective as higher volume resistance training for enhancing body composition, functional capacity and muscle strength and may reduce barriers to exercise and enhance adherence [1468].

Another SR and meta-analysis of randomised trials shows that exercise interventions for patients on ADT result in higher lean body mass (mean difference: 0.88, 95% CI 0.4 to 1.36, p < 0.01), a lower body fat mass (mean difference: -0.93, 95% CI: -1.10 to -0.10, p < 0.05), and a lower body fat rate (mean difference:-0.93, 95% CI: -1.39 to -0.47, p < 0.01). Greater efficacy was noted for exercise duration of ≥ six months (vs. < six months) and exercise immediately after starting ADT (vs. delayed exercise) [1469]. A SR and meta-analysis in patients with prostate cancer undergoing ADT, on supervised exercise therapy vs. no therapy shows that supervised exercise

therapy is probably superior to no exercise therapy in improving 'disease-specific quality of life' 0.43 (95%CI: 0.29, 0.58) and 'walking performance' −0.41 (95% CI: −0.60, −0.22) with a moderate certainty of evidence [1470]. A SR and meta-analysis on determining the factors that affect adherence to exercise programs, found that exercise had no effects ($p < 0.05$) on quality of life and fatigue. For aerobic fitness, and upper- and lower-body strength significant effects (all $p < 0.05$) were observed. Adherence to exercise-based interventions was 80.38%, with improvements observed in aerobic fitness and strength. Subgroup analysis revealed exercise adherence impacted fatigue and strength, with greater improvements observed in programs > twelve weeks [1471].

If dietary intake is not adequate, vitamin D and calcium supplementation should be offered, as there is evidence that vitamin D and calcium have modest effects on bone in men on ADT [1457]. Online tools are available to calculate daily calcium intake for individual patients. For vitamin D deficiency a dose of at least 800 IU/day colecalciferol can be recommended. Use of a 25(OH) assay may be helpful to measure vitamin D levels [1472, 1473].

Anti-resorptive therapy is recommended for men on ADT for > six months with either a BMD T-score of < -2.5 or with an additional risk factor for osteoporosis or annual bone loss confirmed to exceed 5%, or in cases of severe fracture. Referral to a bone specialist should be considered in complex cases with severe fracture and/or multiple risk factors. Alendronate, risedronate, zoledronate and denosumab have all been shown to prevent bone loss in men with hormone-sensitive locally-advanced and metastatic PCa on ADT [1474-1477]. Patients should be warned about the < 5% risk of osteonecrosis of the jaw and/or atypical femoral fractures associated with these drugs. Bisphosphonates increase BMD in the hip and spine by up to 7% in one year [1476, 1478]. The optimal regimen for zoledronic acid for men on ADT with hormone-sensitive locally-advanced and metastatic PCa remains unclear: quarterly [1479] or yearly [1480] injections. The question is relevant as the risk of jaw necrosis is both dose- and time-related [1481]. A quarterly regimen should be considered for a BMD ≤ 2.5 as a yearly injection is unlikely to provide sufficient protection [1482, 1483]. Care should be taken when discontinuing treatment as rebound increased bone resorption can occur.

In M0 patients, denosumab has been shown to increase the lumbar BMD by 5.6% compared to a 1% decrease in the placebo arm after two years, using 60 mg subcutaneous regimen every six months [1421]. This was associated with a significant decrease in vertebral fracture risk (1.5% vs. 3.9%, $p = 0.006$). The benefits were similar whatever the age (< or > 70 years), the duration or type of ADT, the initial BMD, the patient's weight, or the initial BMI. This benefit was not associated with any significant toxicity, e.g., jaw osteonecrosis or delayed healing in vertebral fractures. In M0 patients, with the use of a higher dosage (120 mg every four weeks), a delay in bone metastases of 4.2 months has been shown [1280] without any impact on OS, but with an increase in side effects. Therefore, this later regimen cannot be recommended.

In the SPARTAN phase III study (apalutamide in nmCRPC) [1267], patients receiving apalutamide experienced falls more frequently vs. those receiving placebo (15.6% vs. 9.0%). In the final multivariable model, the baseline patient characteristics of older age, poor ECOG, history of neuropathy, and α-blocker use before study treatment, remained significantly associated with fall. After-baseline clinical characteristics significantly associated with time to fall were development of neuropathy, arthralgia, and weight loss before fall. Preventive interventions should be considered when the identified baseline conditions and post-treatment neuropathy, arthralgia, or weight decrease are present, to reduce risk of fall.

8.3.2.3 Decision regret

Several treatments with curative intent for localised PCa are available all with comparable ten-year OS [489]. They vary in terms of the incidence of major side effects, including urinary symptoms, bowel symptoms and compromised sexual functioning [1364, 1365, 1484]. For this reason, patients' treatment preferences, in which they weigh expected benefits against likely side effects, are a central consideration in shared decision-making and in making informed treatment decisions [1485-1487].

It remains challenging, however, to evaluate whether the decision-making process can be viewed as successful; that is, whether the choice of treatment best reflects the patient's preferences and expectations [1488, 1489]. According to Decision Justification Theory (DJT), it is the more specific information on which treatment experiences lead to regret that decision regret needs to be better understood and to minimise it in future patients [1490]. About 25% of men with PCa undergoing either single or combined modality treatments report experiencing worse side effects than expected [1491]. Urinary incontinence most strongly correlates with regret after prostatectomy [1492].

Unmet expectations are comparable among the treatment groups, except for fatigue. Fatigue is less frequently reported as worse than expected by patients who received BT when compared to patients who received RP or EBRT. This could be explained by the less invasive treatment course of BT in comparison to EBRT

with or without ADT and RP [1493]. Unmet expectations were more frequently reported by patients with positive surgical margins following surgery; having had a passive role in the decision-making process; and who had higher scores on the decisional conflict scale (i.e., more uncertainty about the treatment decision). Interestingly, positive surgical margins are not directly associated with an increased risk of PC-related mortality [960]. Active participation and support in the process of forming a preference increases the chance of choosing a treatment that is in line with patients' expectations [1487, 1494-1496].

While it may seem desirable to tailor the patients' role in decision-making to their initial preference, and particularly to a preference for deferring to the advice of the clinician, this does not result in less decisional conflict or regret. Increasing patients' knowledge regardless of initial preference may actually be preferable [1492].

8.3.2.4 Decision aids in prostate cancer

Shared decision-making can increase patients' comfort when confronted with management decisions but has been shown to improve health outcome [1497] and more training seems needed for health care professionals guiding patients [1498]. Patient education decreased PSA testing [1499] and increased adherence to AS protocols [1500, 1501]. Autonomous active decision-making by patients was associated with less regret after prostatectomy regardless of the method chosen and decision aids reduce decisional conflict [1502]. Still, guidance is needed to optimise patients' understanding of the options [1503]. Patients prioritised effectiveness and pain control over mode of administration and risk of fatigue when confronted with treatment choice in metastasised PCa [1504]. When implementing decision aids clinical validity and utility should be carefully evaluated and distinguished [1505]. A decision aid should educate as well as promote shared decision-making to optimise efficacy [1506] and pay attention to communicative aspects [1507].

8.3.2.5 Guidelines for quality of life in men undergoing systemic treatments

Recommendations	**Strength rating**
Offer men on androgen deprivation therapy (ADT), twelve weeks of supervised (by trained exercise specialists) combined aerobic and resistance exercise.	Strong
Advise men on ADT to maintain a healthy weight and diet, to stop smoking, reduce alcohol to ≤ two units daily and have yearly screening for diabetes and hypercholesterolemia. Ensure that calcium and vitamin D meet recommended levels.	Strong
Offer men after any radical treatment specialist nurse-led, multi-disciplinary rehabilitation based on the patients' personal goals addressing incontinence, sexuality, depression and fear of recurrence, social support and positive lifestyle changes.	Strong
Offer men starting on long-term ADT dual emission X-ray absorptiometry (DEXA) scanning to assess bone mineral density.	Strong
Offer anti-resorptive therapy to men on long term ADT with either a BMD T-score of < -2.5 or with an additional clinical risk factor for fracture or annual bone loss on ADT is confirmed to exceed 5%.	Strong
