10. CONFLICT OF INTERESTS

All members of the EAU-EANM-ESTRO-ESUR-ISUP-SIOG Prostate Cancer Guidelines Panel have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publicly accessible through the European Association of Urology website: https://uroweb.org/guideline/prostate-cancer/. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

11. CITATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Paris April 2024. ISBN 978-94-92671-23-3.

If a publisher and/or location is required, include: EAU Guidelines Office, Arnhem, the Netherlands.
http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aim and objectives

The aim of these guidelines is to present the current evidence for the diagnosis and treatment of patients with cancer of the testis. Testicular cancer (TC) represents 5% of urological tumours affecting mostly younger males. This document addresses post-pubertal testicular germ-cell tumours (TGCTs) in the male including spermatocytic tumour and sex cord/gonadal stromal tumours.

It must be emphasised that clinical guidelines present the best evidence available to the experts, but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and references/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The European Association of Urology (EAU) Guidelines Panel on TC consists of a multidisciplinary group of clinicians including, urologists, medical oncologists, a radiation-oncologist, patient representative and a pathologist. When necessary, consultants from other specialties provide input. Members of this Panel have been selected, based on their expertise, to represent the professionals' treating patients with TC. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guideline/testicular-cancer/.

1.3 Available publications

A quick reference document (Pocket guidelines) is available, in print and on the EAU website. These are abridged versions which may require consultation together with the full text version. Several scientific publications are available, as are a number of translations of all versions of the EAU TC Guidelines. All documents are accessible through the EAU website: https://uroweb.org/guidelines/testicular-cancer.

1.4 Publication history and summary of changes

*1.4.1 **Publication history***

The EAU published the first guidelines on TC in 2001. Since 2008, the TC Guidelines contains a separate chapter on testicular stromal tumours. The 2024 TC guideline presents a limited update of the 2023 publication. A summary paper of the EAU TC guideline has been published in the society's scientific journal European Urology in 2023 [1].

*1.4.2 **Summary of changes***

For the 2024 Testicular Cancer Guidelines, the key changes incorporated in this publication include:

- A restructure and update of section 5.2 on Imaging of primary tumours and staging;
- An update on the summary of evidence table 6.1.2.5;
- Restructure and rewrite of section 6.2.2 on Metastatic disease (stage IIA/B);
- New recommendation regarding the treatment of metastatic NSGCT with a poor prognosis section 6.3.6.1;
- New section 8.5 on follow-up of rare and adult para- and testicular cancers.

2. METHODS

2.1 Introduction

For the 2024 EAU Guidelines on Testicular Cancer (TC), new and relevant evidence was identified, collated and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the TC Guidelines was performed. The search was limited to studies representing high levels of evidence, i.e. systematic reviews with meta-analysis, randomised controlled trials (RCTs), and prospective non-randomised comparative studies, published in the English language. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between May 1st 2021 and May 1st 2023. A total of 1867 unique records were identified, retrieved and screened for relevance.

Detailed search strategies for the 2024 guideline are available online:
https://uroweb.org/guidelines/testicular-cancer/publications-appendices.

Recommendation within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [2];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact and certainty of patient values and preferences on the intervention.

Strong recommendations typically indicate a high degree of evidence quality and/or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [3].

Additional information can be found in the general Methodology section of this print, and online at the EAU website: www.uroweb.org/guidelines.

A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review

The 2020 Guidelines document was subjected to peer-review following publication. The next peer-review is scheduled for 2025.

2.3 Future goals

- A collaborative systematic review (SR) on hypogonadism following orchidectomy with the EAU Male Sexual Health guidelines panel;
- The development of a TC survivorship plan in collaboration with patient associations;
- Care Pathways on diagnostic, treatment CS I, and treatment of metastatic disease;
- Collaboration with the patient office and patient representatives to develop a care pathway focusing on what the patient needs to know from diagnosis through to follow-up.

3. EPIDEMIOLOGY, AETIOLOGY & PATHOLOGY

3.1 Epidemiology and Aetiology

Testicular cancer represents 1% of adult neoplasms and 5% of urological tumours, with three to ten new cases per 100,000 males/per year in Western societies [4]. The incidence of TC has increased during recent decades, predominantly in industrialised countries [5-8], and it continues to rise. At diagnosis, 1-2% are bilateral and 90-95% of cases are germ cell tumours (GCT) [4]. The peak incidence is in the third decade of life for non-seminomatous germ cell tumour (NSGCT) and mixed GCT patients, and in the fourth decade for seminoma testis (ST) patients. In 5% of GCT patients, the primary site is at an extragonadal location [9].

There are two fundamental categories of GCTs based on their development and epigenetic features. Most malignant post-pubertal GCTs originate from germ cell neoplasia "*in situ*" (GCNIS). Histologically and clinically, these are subdivided into seminomas and non-seminomas, the latter encompassing somatic and extra-embryonal elements of embryonal carcinoma, yolk sac, choriocarcinoma and post-pubertal teratoma [10].

Non GCNIS derived tumours include pre-pubertal type teratoma and yolk sac tumour, which occur in early childhood, and spermatocytic tumours which usually occurs in older men. Although there is overlapping histology between the pre-pubertal type teratoma/yolk sac and the teratoma and yolk sac tumour elements in the GCNIS-derived NSGCT, these have a separate and independent pathogenesis [10].

Risk factors for GCNIS-derived GCTs are components of the testicular dysgenesis syndrome, which encompasses cryptorchidism, hypospadias, decreased spermatogenesis and impaired fertility [11-13] or disorders of sex development [14]. Additional risk factors include a family history of TC among first-degree relatives and the presence of a contralateral testicular tumour or GCNIS [15-23] although the risk was lower if TC patients previously had received platinum-based chemotherapy [24, 25]. Genome-wide association studies revealed detectable susceptibility loci leading to an increased relative risk to develop TC [26].

3.2 Histological classification

General:
The recommended pathological classification shown below is based on the 2022 update of the World Health Organization (WHO) pathological classification [27].

1. **Germ cell tumours derived from germ cell neoplasia** *in situ*
   - Non-invasive germ cell neoplasia
     - Germ cell neoplasia *in situ*
     - Specific forms of intratubular germ cell neoplasia
     - Gonadoblastoma
   - The germinoma family of tumours
     - Seminoma
   - Non-seminomatous germ cell tumours
     - Embryonal carcinoma
     - Yolk sac tumour, postpubertal-type
     - Choriocarcinoma
     - Placental site trophoblastic tumour
     - Epithelioid trophoblastic tumour
     - Cystic trophoblastic tumour
     - Teratoma, postpubertal-type
     - Teratoma with somatic-type malignancy
   - Mixed germ cell tumours of the testis
     - Mixed germ cell tumours
   - Germ cell tumours of unknown type
     - Regressed germ cell tumours

2. **Germ cell tumours unrelated to germ cell neoplasia** *in situ*
     - Spermatocytic tumour
     - Teratoma, prepubertal-type
     - Yolk sac tumour, prepubertal-type
     - Testicular neuroendocrine tumour, prepubertal-type
     - Mixed teratoma and yolk sac tumour, prepubertal-type

3. **Sex cord stromal tumours of the testis**
   - Leydig cell tumour
     - Leydig cell tumour
   - Sertoli cell tumours
     - Sertoli cell tumour
     - Large cell calcifying Sertoli cell tumour
   - Granulosa cell tumours
     - Adult granulosa cell tumour
     - Juvenile granulosa cell tumour
   - The fibroma thecoma family of tumours
     - Tumours in the fibroma thecoma group
   - Mixed and other sex cord stromal tumours
     - Mixed sex cord stromal tumour
     - Signet ring stromal tumour
     - Myoid gonadal stromal tumour
   - Sex cord stromal tumour NOS

4. Tumours of the testicular adnexa

- Ovarian-type tumours of the collecting ducts and rete testis
  - Serous cystadenoma
  - Serous tumour of borderline malignancy
  - Serous cystadenocarcinoma
  - Mucinous cystadenoma
  - Mucinous borderline tumour
  - Mucinous cystadenocarcinoma
  - Endometrioid tumours
  - Clear cell adenocarcinoma
  - Brenner tumour
- Tumours of the collecting ducts and rete testis
  - Adenoma of the collecting ducts and rete testis
  - Adenocarcinoma of the collecting ducts and rete testis
- Paratesticular mesothelial tumours
  - Adenomatoid tumour
  - Well-differentiated papillary mesothelial tumour
  - Mesothelioma
- Tumours of the epididymis
  - Cystadenoma of the epididymis
  - Papillary cystadenoma of the epididymis
  - Adenocarcinoma of the epididymis
  - Squamous cell carcinoma of the epididymis
  - Melanotic neuroectodermal tumour of the epididymis

4. STAGING & PROGNOSIS

4.1 Staging

The 2016 Tumour, Node, Metastasis (TNM) classification of the International Union Against Cancer (UICC) is recommended to assess the anatomical extent of the disease (Table 1) [28].

Table 1: TNM classification for testicular cancer (adapted from UICC, 2016, 8th edn.) [28]

pT - Primary Tumour[1]	
pTX	Primary tumour cannot be assessed (see note[1])
pT0	No evidence of primary tumour (e.g., histological scar in testis)
pTis	Intratubular germ cell neoplasia (carcinoma *in situ*)+
pT1	Tumour limited to testis and epididymis without vascular/lymphatic invasion; tumour may invade tunica albuginea but not tunica vaginalis*
pT2	Tumour limited to testis and epididymis with vascular/lymphatic invasion, or tumour extending through tunica albuginea with involvement of tunica vaginalis**
pT3	Tumour invades spermatic cord with or without vascular/lymphatic invasion**
pT4	Tumour invades scrotum with or without vascular/lymphatic invasion
N - Regional Lymph Nodes – Clinical	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis with a lymph node mass 2 cm or less in greatest dimension or multiple lymph nodes, none more than 2 cm in greatest dimension
N2	Metastasis with a lymph node mass more than 2 cm but not more than 5 cm in greatest dimension; or more than 5 nodes positive, none more than 5 cm; or evidence of extranodal extension of tumour
N3	Metastasis with a lymph node mass more than 5 cm in greatest dimension

Pn - Regional Lymph Nodes – Pathological			
pNX	Regional lymph nodes cannot be assessed		
pN0	No regional lymph node metastasis		
pN1	Metastasis with a lymph node mass 2 cm or less in greatest dimension and 5 or fewer positive nodes, none more than 2 cm in greatest dimension		
pN2	Metastasis with a lymph node mass more than 2 cm but not more than 5 cm in greatest dimension; or more than 5 nodes positive, none more than 5 cm; or evidence of extranodal extension of tumour		
pN3	Metastasis with a lymph node mass more than 5 cm in greatest dimension		
M - Distant Metastasis			
MX	Distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis **		
	M1a Non-regional lymph node(s) or lung metastasis		
	M1b Distant metastasis other than non-regional lymph nodes and lung		
S - Serum Tumour Markers (Pre-chemotherapy)			
SX	Serum marker studies not available or not performed		
S0	Serum marker study levels within normal limits		
	LDH (U/l)	**hCG (mIU/mL)**	**AFP (ng/mL)**
S1	< 1.5 x N and	< 5,000 and	< 1,000
S2	1.5-10 x N or	5,000-50,000 or	1,000-10,000
S3	> 10 x N or	> 50,000 or	> 10,000

N indicates the upper limit of normal.

LDH = lactate dehydrogenase; hCG = human chorionic gonadotrophin; AFP = alpha-fetoprotein.

[1] Except for pTis and pT4, where radical orchidectomy is not always necessary for classification purposes, the extent of the primary tumour is assessed in the radical orchidectomy specimen; see pT. In other circumstances, TX is used if no radical orchidectomy has been performed.

[+] The current "Carcinoma in situ" nomenclature is replaced by GCNIS.

** AJCC eighth edition subdivides T1 Pure Seminoma by T1a and T1b depending on size no greater than 3 cm or greater than 3 cm in greatest dimension [29].*

*** AJCC eighth edition considers hilar soft tissue invasion and epididymal invasion as pT2, while the discontinuous involvement of the spermatic cord is considered as pM1 [29].*

4.2 The Union for International Cancer Control prognostic groups

According to the 2016 TNM classification, the following prognostic groups are defined:

Table 2: Prognostic groups for testicular cancer (UICC, 2016, 8th edn.) [28]

Stage grouping	T	N	M	S
Stage 0	pTis	N0	M0	S0
Stage I	pT1-T4	N0	M0	SX
Stage IA	pT1	N0	M0	S0
Stage IB	pT2 - pT4	N0	M0	S0
Stage IS	Any pT/TX	N0	M0	S1-3
Stage II	Any pT/TX	N1-N3	M0	SX
Stage IIA	Any pT/TX	N1	M0	S0
	Any pT/TX	N1	M0	S1
Stage IIB	Any pT/TX	N2	M0	S0
	Any pT/TX	N2	M0	S1
Stage IIC	Any pT/TX	N3	M0	S0
	Any pT/TX	N3	M0	S1

Stage III	Any pT/TX	Any N	M1a	SX
Stage IIIA	Any pT/TX	Any N	M1a	S0
	Any pT/TX	Any N	M1a	S1
Stage IIIB	Any pT/TX	N1-N3	M0	S2
	Any pT/TX	Any N	M1a	S2
Stage IIIC	Any pT/TX	N1-N3	M0	S3
	Any pT/TX	Any N	M1a	S3
	Any pT/TX	Any N	M1b	Any S

Stage IA: Primary tumours limited to the testis and epididymis, with no evidence of microscopic vascular or lymphatic invasion by tumour cells on microscopy, no sign of metastases on clinical examination or imaging, and post-orchidectomy serum tumour marker levels within normal limits. Marker decline in patients with Clinical Stage I (CS I) disease should be assessed until normalisation occurs on two consecutive measurements.

Stage IB: More locally invasive primary tumour, but no sign of metastatic disease.

Stage IS: Following orchiectomy tumour markers increase, remain persistently elevated or fail to decline as expected by half-lives indicating the presence of subclinical metastatic disease. The presence of a second GCT in the contralateral testis should also be excluded.

In population-based patient series from developed countries, 75-80% of SGCT patients, and 55-64% of NSGCT patients had CS I disease at diagnosis [30, 31]. True CS I, i.e. persistently elevated or increasing serum tumour marker levels after radical orchidectomy, was found in approximately 5% of NSGCT patients [30].

4.3 Risk factors for relapse in clinical stage I testicular cancer

For CS I seminoma germ cell tumour (SGCT), primary tumour size and stromal invasion of the rete testis have been identified to be associated with relapse risk in a pooled analysis of retrospective data [32]. Absence of both factors was associated with a low risk of recurrence (6%) [35]. Whilst the original analysis was not supported by a subsequent retrospective report [33], some prospective series [34-36] have supported the prognostic significance of tumour size and stromal invasion of the rete testis. Two SRs assessed the prognostic value of both risk factors [37, 38]. While tumour size (continuous or dichotomised) and rete testis invasion were associated with a higher risk of relapse, both SRs highlighted the low quality of the studies included and concluded that the level of evidence was too low to be able to recommend the use of both risk factors to drive adjuvant treatment decisions [37, 38].

For CS I NSGCT, invasion of the primary tumour into blood or lymphatic vessels, (i.e. lymphovascular invasion (LVI)), was strongly associated with the risk of relapse disease [39-41]. No other risk factors have the same level of validation for prognostic significance [42]. While interobserver agreement is variable, immunohistochemistry with vascular markers may improve detection of LVI [43]. The percentage of embryonal carcinoma within a tumour may enhance the positive predictive value (PPV) and negative predictive value (NPV) of LVI [40], but there is no definitive prognostic cut-off for percentage [40]. Risk of relapse at five years according to historical figures, for patients with LVI-positive tumours was 50% vs. 15% in patients with LVI-negative tumours.

Table 3: Pathological risk-factors for occult metastatic disease in clinical stage I testicular cancer

Histological type	Seminoma [37]	Non-seminoma [41, 44]
• Pathological risk-factors	• Tumour size • Invasion of the rete testis	• Lympho-vascular invasion in peri-tumoral tissue

4.4 The International Germ Cell Cancer Collaborative Group (IGCCCG) classification for the prognostic risk groups of metastatic germ cell cancer

The 1997 IGCCCG defined a prognostic risk-factor system for metastatic GCT based on identification of clinically independent adverse factors [45]. The classification has been revalidated on a contemporary cohort of metastatic TGCT treated with cisplatin/etoposide based first-line chemotherapy [46].

Compared to the 1997 figures, the five-year progression-free survival (PFS) of NSGCT patients was unchanged for good- and intermediate-risk, but significantly improved for poor-risk patients (from 41% to 54%). The five-year overall survival (OS) was substantially better for all groups. In addition to the traditional components of the IGCCCG risk-prognostic groups previously described, older age (linear association) and lung metastases were confirmed as negative factors for PFS [46].

For SGCT, revalidation of the IGCCCG classification showed that the five-year PFS increased to 89% and 79% in good- and intermediate-risk patients with corresponding OS rates of 95% and 88%. Testicular lactate dehydrogenase (LDH) over 2.5 times the upper limit of normal (ULN) was identified as a possible adverse prognostic factor in regard to reduced three-year PFS, however overall three-year survival was not affected [47].

Table 4: Prognostic-based staging system for metastatic germ cell cancer (IGCCCG) [46, 47]*

Good-prognosis group	
NSGCT 5-year PFS 90% 5-year survival 96%	*All of the following criteria:* • Testis/retro-peritoneal primary • No non-pulmonary visceral metastases • AFP < 1,000 ng/mL • β-hCG < 5,000 IU/L (1,000 ng/mL) • LDH < 1.5 x ULN
SGTC 5-year PFS 89% 5-year survival 95%	*All of the following criteria:* • Any primary site • No non-pulmonary visceral metastases • Normal AFP • Any β-hCG • Any LDH
Intermediate-prognosis group	
NSGCT 5-year PFS 78% 5-year survival 89%	*Any of the following criteria:* • Testis/retro-peritoneal primary • No non-pulmonary visceral metastases • AFP 1,000 - 10,000 ng/mL or • β-hCG 5,000 - 50,000 IU/L or • LDH 1.5 - 10 x ULN
SGCT 5-year PFS 79% 5-year survival 88%	*All of the following criteria:* • Any primary site • Non-pulmonary visceral metastases • Normal AFP • Any β-hCG • Any LDH
Poor-prognosis group	
NSGCT 5-year PFS 54% 5-year survival 67%	*Any of the following criteria:* • Mediastinal primary • Non-pulmonary visceral metastases • AFP > 10,000 ng/mL or • β-hCG > 50,000 IU/L (10,000 ng/mL) or • LDH > 10 x ULN
SGCT	No patients classified as poor-prognosis

** Pre-chemotherapy serum tumour markers should be assessed immediately prior to the administration of chemotherapy (same day).*

AFP = alpha-fetoprotein; β-hCG = human chorionic gonadotrophin; LDH = lactate dehydrogenase; PFS = progression-free survival.

5. DIAGNOSTIC EVALUATION

5.1 Physical examination

Testicular cancer usually presents as a painless testicular mass or incidental finding on ultrasound (US). Pain, either scrotal or abdominal/back, may occur and result in delayed diagnosis [48]. Gynaecomastia may be present in a small number of patients. Clinical assessment should thus include abdominal, chest and supraclavicular examination.

5.2 Imaging

*5.2.1 **Primary tumour***

The primary tumour and contralateral testis need to be assessed radiologically to

1. confirm the presence of a mass;
2. determine whether it is intra- or extra-testicular;
3. assess its volume and anatomical location;
4. characterise the contralateral testicle – to exclude other lesions and identify risk factors for GCNIS (see section 5.4.4).

High-frequency (>10 MHz) testicular US is recommended. Scrotal US is also recommended for all men with retroperitoneal or visceral masses with/or without elevated serum β-hCG or Alpha-fetoprotein (AFP) in the absence of a palpable testicular mass [49].

Small, usually non-palpable masses may be incidental findings on scrotal US which may be benign. Of lesions with small diameter virtually all < 3mm, 87% of those < 5mm and 70% < 10mm are benign [50-52]. With small masses US features may assist in discriminating between benign and malignant tumours although none are completely reliable [50].

Scrotal magnetic resonance imaging (MRI) provides higher sensitivity and specificity than US in the diagnosis of TC, but its high cost does not justify its routine use for this purpose [53]. It should only be considered when US is inconclusive as local staging for potential testis-sparing surgery (TSS), to differentiate between paratesticular and intratesticular lesions, and/or to characterise intratesticular masses (e.g., distinctive features of Leydig tumours) [53].

*5.2.2 **Staging***

Cross-sectional imaging of the chest, abdomen and pelvis is recommended in patients with elevated markers or clinical suspicion of metastases for staging before orchidectomy and remains standard practice. This may be postponed in patients with small or indeterminant masses until histopathological confirmation of malignancy. Contrast enhanced CT scan (CECT) and MRI are the imaging modalities used. Evidence does not support the use of Fluorodeoxyglucose-positron emission tomography (FDG-PET) for initial staging of TC [54, 55].

a. Abdomen and Pelvis

Contrast enhanced CT scan is the long-established imaging modality used to assess the abdomen and pelvis to identify nodal and visceral metastases. The size of metastases should be described in three dimensions, or at least by the greatest diameter. The expected patterns of nodal spread in TC should be considered when evaluating small and borderline nodes.

A SR of a number of small studies, with a total of 102 evaluable patients, has suggested that MRI appears comparable to CECT in detecting nodal metastases [56]. It is significantly more expensive and less available than CECT for routine use. It clearly has utility in patients who have contra-indications to iodine-based contrast media or likely to require numerous subsequent scans.

b. Thorax

The chest and supraclavicular fossa should also be imaged with CECT to assess for nodal and pulmonary disease. Magnetic resonance imaging appears equivalent to CT in detecting supra-diaphragmatic lymph nodes but less sensitive in detecting pulmonary nodules. Thus, it is not recommended as a routine alternative to CT [57].

c. Other Sites

Cerebral and spinal imaging is recommended in GCT patients with either multiple lung metastases or poor-prognosis IGCCCG risk group (especially with β-hCG values > 5,000 UI/L), or clinical symptoms [58]. Data from cerebral and spinal metastasis detection in other malignancies suggest that MRI is far more sensitive than CECT but requires specific expertise [59, 60]. When available, MRI should be used to evaluate for both cerebral and spinal metastases in GCTs if there are clinical concerns. Contrast enhanced computerised tomography may be used if MRI is not available or contraindicated.

5.3 Serum tumour markers

*5.3.1 **Pre-operative serum tumour markers***

Serum AFP, beta subunit of human Chorionic Gonadotropin (β-hCG) and LDH should be determined before orchidectomy as they support the diagnosis of TC and may be indicative of GCT histology.

Up to 90% of NSGCT's have elevated AFP or β-hCG at diagnosis with 39% having an increased level of both [48, 61]. Pure seminomas may also have elevated β-hCG level at diagnosis in up to 30% of cases [61]. Significant elevation of AFP in patients with seminomas should raise concerns of a NSGCT component. Modest stable marker elevations may be considered 'normal' and of no clinical significance [45].

Thus, current tumour markers have limitations due to their low sensitivity as normal levels do not exclude the presence of disease.

*5.3.2 **Serum tumour markers after orchidectomy***

Tumour markers need to be repeated following orchidectomy providing staging and prognostic information [45]. If elevated pre-operatively normalisation may take several weeks as the serum half-lives of AFP and β-hCG are five to seven days and one to three days respectively. If these remain elevated or increase metastatic disease is likely [61]. Marker normalisation after orchiectomy however does not exclude the possibility of metastatic disease.

In addition to staging marker levels are used to define risk stratification and prognosis (Table 4). They are also used to monitor treatment response and detect disease relapse [61]. With follow-up the precise frequency of testing is not well defined [62].

*5.3.3 **Other tumour markers***

Micro RNAs (miRNAs) are emerging as potential new biomarkers. Pre-operative elevation has been reported in 80-90% of both SGCT and NSGCT with higher levels in metastatic compared to localised disease [63]. A number of studies suggest higher discriminatory accuracy for micro-RNA (miRNAs) (particularly miR-371a-3p) compared to conventional GCT markers in diagnosis, clinical staging, treatment monitoring, and predicting of residual or recurrent viable disease [63-65]. Furthermore, they may differentiate between GCT and other (stromal/non-germ cell originated) tumours [65]. Issues which need to be resolved for use in routine clinical practice include laboratory standardisation, availability of the test and, importantly, prognostic validation [66]. As with both AFP and β-hCG miRNA is not expressed in teratoma which will limit its use in NSGCT.

5.4 Inguinal exploration and initial management

*5.4.1 **Orchidectomy***

Orchidectomy including division of the spermatic cord at the internal inguinal ring represents the standard of care for patients with a TGTC. A scrotal approach should be avoided when TC is suspected as it results in a higher local recurrence rate [67].

*5.4.2 **Testis-sparing surgery***

In men with GCTs, orchidectomy represents the standard of care as pathological studies describe multifocal and/or adjacent GCNIS in 20-30% of patients [68]. Testis sparing surgery when feasible, may be considered in synchronous bilateral tumours or in tumours in solitary testis [69]. In these settings, at least two additional testicular biopsies should be taken to exclude GCNIS [70].

Testis-sparing surgery (TSS) is a valid treatment option in men with interstitial cell or benign testicular tumours and may prevent hypogonadism and infertility in young men. These tumours are often small although larger lesions may be difficult to differentiate from GCT.

Thus, TSS may be considered in patients with small or indeterminate testicular masses, negative tumour markers and a normal contralateral testis to avoid over-treatment of potentially benign lesions and preserve testicular function [69, 71]. Patients should be informed that cancer may be present even in small (i.e., < 1 cm) masses [69, 72, 73].

In both settings, TSS should be offered together with frozen section examination (FSE). Frozen section examination has shown to be reliable and highly concordant with final histopathology in expert hands, with a 99% and 96% of sensitivity and specificity respectively and 98% and 97% of PPV and NPV, respectively [71]. In cases of discordance between FSE and final pathology delayed orchiectomy may be required.

In cases of a history of GCT or indeterminate small testicular lesion, patients should be made aware of the following issues regarding TSS practice: that limited data exists regarding oncological safety of TSS; that local recurrence rates have been reported (up to 26.9%), when TC is present in the specimen [69, 74] and that TSS has implications for ongoing surveillance of the testis. Similarly, patients should be informed about the role and impact of adjuvant radiotherapy when GCNIS is present, potential infertility, the need for hormonal supplementation despite parenchyma preservation [69, 75] and that discordance between FSE and final pathology requiring a delayed orchidectomy.

*5.4.3 **Insertion of testicular prosthesis***

Testicular prosthesis should be offered to all patients receiving unilateral or bilateral orchidectomy [76]. The prosthesis can be inserted at orchidectomy or subsequently without adverse consequences, including infection [77].

*5.4.4 **Contralateral biopsy***

Contralateral biopsy has been advocated to exclude GCNIS [78] and routine policy in some countries [79]. It is, however, controversial to recommend routine contralateral biopsy in all patients due to the low incidence of GCNIS and metachronous contralateral testicular tumours (up to 9% and approximately 2.5%, respectively) [80, 81], the morbidity of GCNIS treatment (see section 6.1.1), and the fact that most metachronous tumours are low stage at presentation [82, 83]. Nevertheless, the risks and benefits of biopsy of the contralateral testis should be discussed with TC patients at high risk for contralateral GCNIS, i.e., testicular volume < 12 mL, and/or a history of cryptorchidism. Contralateral biopsy is not necessary in patients > 40 years without risk factors [70, 84, 85]. Patients should be informed that a subsequent GCT may arise despite a negative biopsy [86]. When indicated, a two-site surgical testicular biopsy is the technical procedure recommended [70].

5.5 Pathological examination of the testis

The recommendations for reporting and handling the pathological examination of a testis neoplasm are based on the recommendations of the International Society of Urological Pathology (ISUP) [39, 44, 87, 88].

Mandatory pathological requirements:

- *Macroscopic features:* It must indicate radical or partial orchidectomy, side, testis size, number of tumours, and macroscopic features of the epididymis, cord length, and tunica vaginalis.
- *Sampling:* At least a 1 cm^2 section for every centimetre of maximum tumour diameter including normal macroscopic parenchyma (if present), tunica albuginea and epididymis, with selection of suspicious areas. If the tumour is < 20 mm it should be completely sampled.
- At least one proximal (base of the cord) and one distal section of spermatic cord plus any suspicious area. Cord blocks should preferably be taken prior to tumour sections to avoid contamination.
- *Microscopic features and diagnosis:* Histological types (specify individual components and estimate amount as percentage) according to WHO 2022 [27]:
  - Presence or absence of peri-tumoral lymph and/or blood vessel invasion. In case of doubt, the use of endothelial markers, such as CD31, are recommended.
  - Presence or absence of GCNIS in non-tumour parenchyma.
  - In case of rete testis invasion attention should be paid to distinguishing between pagetoid involvement and stromal invasion [44].
- If microscopic findings are not concordant with serum markers further block samples should be taken.
- Pathological tumour (pT) category according to TNM 2016 [28]. In a multifocal seminoma the largest nodule should be used to determinate pT category.

Immune-histochemical markers in cases of doubt are:

- Seminoma: CD-117 (c-KIT), OCT 3/4, Sall4, PLAP
- GCNIS: CD-117 (c-KIT), OCT 3 / 4, Sall4, PLAP
- Syncytiotrophoblastic: β-hCG
- Embryonal carcinoma: CD30
- Yolk sac tumour: Glypican 3, AFP.
- Sex cord gonadal tumours: Inhibin, calretinin steroidogenic factor 1.

The search for i12p (FISH or PCR) or gain in Chr9 (spermatocytic tumour) are additional molecular techniques which are only rarely required. Confirmation of the utility of other molecular markers such as P53, MDM2, KRAS and HRAS is awaited [89].

In order to facilitate consistent and accurate data collection, promote research, and improve patient care, the International Collaboration on Cancer Reporting has constructed a dataset for the reporting of urological neoplasms. The dataset for testicular tumours encompasses the updated 2016 WHO classification of urological tumours, the ISUP consultation and staging with the 8th edition of the American Joint Cancer Committee (AJCC) [88].

The dataset includes those elements unanimously agreed by the expert panel as "required" (mandatory) and those "recommended" (non-mandatory) that would ideally be included but are either non-validated or not regularly used in patient management [88]. The dataset for handling pathological assessment of TC is shown in Table 5.

Table 5: Recommended dataset for reporting of neoplasia of the testis (modified from the International Collaboration on Cancer Reporting) [88]

Elements	Required	Recommended*	Content	Remarks
Clinical information		√	- Not provided - Previous history of testicular cancer - Previous therapy - Other	Specify each
Serum tumour markers		√	- Not provided - If provided within normal limits or - Specify serum tumour markers used - Specify levels - Specify date markers were drawn	Select all that apply: Serum tumour markers: LDH (IU/L), AFP (ug/L), β-hCG (IU/L)
Operative procedure	√		- Not specified - Orchidectomy partial - Orchidectomy radical - Other	Specify side for partial or radical orchidectomy. Specify other
Tumour focality	√		- Cannot be assessed - Indeterminate - Unifocal - Multifocal	If multifocal specify number of tumours in specimen.
Maximum tumour dimension	√		- Cannot be assessed - Dimensions largest tumour (mm) - Dimensions additional tumour nodules#	Specify at least maximum diameter of largest tumour. Preferably specified 3 dimensions/axes.#

Macroscopic extent of invasion	√		- Cannot be assessed - Confined to testis - Invades epididymis - Invades tunica vaginalis - Invades hilar structures - Invades spermatic cord - Invades scrotum - Other	Select all that apply. If other specify.
Block identification key		√	N/A	List overleaf or separately with indication of nature and origin of all tissue blocks.
Histological tumour type	√		- Germ cell tumour: type and percentage - Other	Use WHO classification (2022) update [27]. If other specify.
Microscopic extent of invasion	√		- Rete testis of stromal/ interstitial type - Epididymis - Hilar fat - Tunica albuginea# - Tunica vaginalis - Spermatic cord - Scrotal wall	For all: - not submitted - not involved - involved
Lymphovascular extension	√		- Not identified - Present	If present specify type.#
Intratubular lesions (GCNIS)	√		- Not identified - Present - Other intratubular lesions#	If other intratubular lesions present identify type.#
Margin status	√		- Partial orchidectomy: . cannot be assessed . involved . not involved - Radical orchidectomy: . cannot be assessed . spermatic cord margin involved . spermatic cord margin not involved - Other margin involved	In partial orchidectomy if margin not involved, distance of tumour from closest margin (mm).# If other margin involved specify.
Coexisting pathology		√	- None identified - Hemosiderin-laden macrophages - Atrophy - Other	If other specify
Ancillary studies		√	- Not performed - Performed	If performed specify
Response to neoadjuvant therapy		√	- Present - Absent - No prior treatment - Cannot be assessed	Explain reasons if cannot be assessed.
Pathologic staging*	√		T classification according to TNM 8th edition (UICC)**	m-multiple primary tumours r-recurrent y-post-therapy

** Not mandatory. Ideally to be included but either non-validated or no regularly used in patient management.*

*** TNM 8th edition (AJCC) used in the original publication.*

 # Recommended, i.p. intratubular seminoma and embryonal carcinoma.

5.6 Screening

No high-level evidence studies supporting screening programs exists [90, 91]. In contrast young males should be informed about the importance of testicular self-examination. Testicular self-examination is recommended in high-risk groups which include a history of cryptorchidism, as well as those with a personal or family history of TC [90, 92].

5.7 Summary of evidence and recommendations for the diagnosis and staging of Testicular Cancer

Summary of evidence	LE
Poor sperm quality is frequently found in TC patients, before and after treatment. Semen preservation is the most cost-effective strategy for fertility preservation.	2b
Serum tumour markers (AFP, β-hCG and LDH) should be determined before and after orchidectomy and throughout follow-up. They are used for accurate staging, risk stratification, to monitor treatment and to detect relapse.	2b
For abdominal staging, CECT has a median sensitivity, specificity, PPV, NPV and accuracy of 67%, 95%, 87%, 73% and 83%, respectively. Sensitivity decreases and specificity increases with increasing lymph node size.	2a
For chest staging, CECT has a median sensitivity, specificity, PPV, NPV and accuracy of 100%, 93%, 68%, 100% and 93%, respectively.	2a
Magnetic resonance imaging and CECT are key image modalities for the detection of brain metastasis. Magnetic resonance imaging is far more sensitive than CECT, though it does require expertise.	2b
Fluorodeoxyglucose-positron emission tomography has a limited diagnostic accuracy for staging before chemotherapy.	2b
There are no high-level evidence studies supporting screening programs.	2b
In testicular sparing surgery, FSE has shown to be reliable and highly concordant with final histopathology.	1b
There is no evidence supporting any size criteria for a testicular lesion to be safely followed-up.	2b
In patients without risk factors, there is low incidence of contralateral GCNIS and of metachronous GCT.	2b

Recommendations	Strength rating
Discuss sperm banking with all men prior to starting treatment for testicular cancer (TC).	Strong
Perform bilateral testicular ultrasound (US) in all patients with suspicion of TC.	Strong
Perform physical examination including supraclavicular, cervical, axillar, and inguinal lymph nodes, breast, and testicles.	Strong
Measure serum tumour markers both before and after orchidectomy taking into account half-life kinetics.	Strong
Perform orchidectomy and pathological examination of the testis to confirm the diagnosis and to define the local extension (pathological tumour (pT) category). In a life-threatening situation due to extensive metastasis, commence chemotherapy prior to orchidectomy.	Strong
Perform contrast enhanced computerised tomography (CECT) scan (chest, abdomen, and pelvis) in patients with a diagnosis of TC. In case of iodine allergy or other limiting factors perform abdominal and pelvic magnetic resonance imaging (MRI).	Strong
Perform MRI of the brain (or brain CECT if not available) in patients with multiple lung metastases, or high beta subunit of human Chorionic Gonadotropin (β-hCG) values, or those in the poor-prognosis International Germ Cell Cancer Collaborative Group (IGCCCG) risk group.	Strong
Do not use positron emission tomography–computed tomography or bone scan for staging.	Strong
Encourage patients with TC to perform self-examination and to inform first-degree male relatives of the need for self-examination.	Weak
Discuss testis-sparing surgery with frozen section examination in patients with a high likelihood of having a benign testicular tumour which are suitable for enucleation.	Strong
Discuss biopsy of the contralateral testis to patients with TC and who are at high-risk for contralateral germ cell neoplasia "*in situ*".	Strong

6. DISEASE MANAGEMENT

6.1 Stage I germ cell tumours

6.1.1 ***Germ cell neoplasia "in situ" (GCNIS)***

If GCNIS is diagnosed and the contralateral testis is normal, options include orchidectomy or close observation, as the five-year risk of developing TC is 50% [93]. In a solitary testis, local radiotherapy (18-20 Gy in fractions of 2 Gy) should be considered [94-97]. Radiotherapy to a solitary testis will result in infertility and increased long-term risk of Leydig cell insufficiency [94]. Fertile patients who wish to father children may defer radiation therapy and be monitored with regular testicular US [70].

Chemotherapy is ineffective to reliably irradicate GCNIS [98, 99].

6.1.2 ***Seminoma germ cell tumour clinical stage I***

Up to 20% of CS I SGCT patients have subclinical metastatic disease, usually in the retroperitoneum, and will relapse after orchidectomy alone [100, 101]. Adjuvant treatment decisions should be based on thorough discussions with the patient, incorporating potential risks and benefits, as well as individual patient circumstances, as 80% of unselected CS I SGCT patients are cured by orchidectomy alone. Regardless of management, survival in CS I disease is almost 100% [102].

6.1.2.1 Surveillance

This requires a strict protocol of repeated cross-sectional imaging, monitoring of serum tumour markers and clinical assessment for the early identification of patients experiencing relapse who must receive salvage treatment (See Table 11).

Several prospective, non-randomised surveillance studies have been conducted over the past decade. These have shown an overall risk of relapse in unselected CS I patients of 12-20% at five years with 17% in the largest series of over 1,500 patients [103]. Most occur in the retroperitoneum during the first two years [104, 105].

According to a SR, active surveillance offers almost identical overall survival as adjuvant management strategies, approaching 100% [102].

The cancer-specific survival (CSS) rate on "active surveillance" (AS) for CS I seminoma is over 99% [103, 105, 106]. Whilst cost effective compared to other management strategies [107], surveillance can represent a burden to the patient due to the need for repeated imaging of the retroperitoneum and clinic visits. These may negatively impact patient compliance which is crucial to an active surveillance strategy.

6.1.2.2 Adjuvant chemotherapy

An RCT comparing one cycle of carboplatin reaching area under curve of 7 mg/mL/min (AUC 7) to adjuvant radiotherapy (RT) showed no difference in relapse-free rates (95% and 96%), time to recurrence and survival after a median follow-up of four years [108]. Adjuvant carboplatin (AUC 7) is therefore an alternative to RT or surveillance in CS I SGCT [108]. Time to relapse after Carboplatin may be longer than with AS, as retrospective data reported a median time to relapse of nineteen months, with 15% of relapses occurring beyond three years. Most patients relapsing after adjuvant carboplatin can be successfully treated by standard, stage-adapted cisplatin-based chemotherapy [109]. In some selected cases, retroperitoneal lymph-node dissection may be adopted in specific protocols (see below).

One cycle of adjuvant carboplatin does not seem to have significant long-term toxicities. In a series of 199 CS I SGCT patients, there was no increase in overall mortality, mortality from cardiovascular events and no excess of haematological or non-testicular solid malignancies compared to the general population in the UK [110].

6.1.2.3 Adjuvant radiotherapy

Radiotherapy should generally be reserved for a highly selective group of patients, who would be unsuitable for systemic chemotherapy in the event of relapse. This relates to the toxicity of RT, specifically the long-term risk of non-germ cell malignancies in the radiation field [111-114]. Generally, adjuvant RT should be avoided, particularly in young patients with a long life expectancy.

Risk-adapted treatment
Prospective trials based on tumour size > 4 cm and stromal rete testis invasion have demonstrated the feasibility of a risk-adapted approach [33-36, 115].

A trial of 897 patients offered surveillance to patients with no or one of these two risk factors whilst patients with both risk factors were offered one dose of carboplatin, AUC 7 [36]. At a median follow-up of 5.6 years, the patients without risk factors, 4% of surveillance relapsed compared to 2% after adjuvant carboplatin. With one or both risk factors 15.5% of surveillance patients relapsed vs. 9% receiving adjuvant carboplatin. Thirty-three per cent of relapses after adjuvant carboplatin occurred more than three years after orchidectomy with 3% occurring after five years [36].

6.1.2.4 Summary of evidence and recommendations for the treatment of clinical stage I seminoma germ cell tumour of the testis

Summary of evidence	**LE**
Patients with CS I SGCT have, in general, a low risk of recurrence	2a
A combination of tumour size category and rete testis invasion correlate with the risk of relapse at 5 years.	2a
Evidence and ease of use are limited for a routine use in guiding adjuvant treatment decisions upon risk factors.	2a
Active surveillance is a feasible approach with conditional relapse risk in unselected series of between 12-20%. Disease-free survival approaches 100% independently of treatment.	2a
In patients without conventional risk factors (tumour size < 4 cm and no rete testis invasion), the five-year relapse rate under surveillance is up to 6-8%, respectively; whereas in the presence of one or two risk factors, five-year relapse rate in contemporary surveillance series is 15-20%.	2b
In non-randomised prospective series five-year relapse rates with adjuvant carboplatin are 2% in patients without conventional risk factors and 9% in patients with one or both risk factors.	2b
Adjuvant chemotherapy with one course carboplatin AUC 7 is not inferior to adjuvant radiotherapy when pathological risk factors are considered. Relapse rates with both adjuvant treatments are around 5%.	1b
Adjuvant radiotherapy is associated with an increased risk of developing secondary non-germ cell malignancies.	2b

Recommendations	**Strength rating**
Fully inform the patient about all available management options, including surveillance or adjuvant therapy after orchidectomy, as well as treatment-specific recurrence rates and acute and long-term side effects.	Strong
Offer surveillance as the preferred management option if resources are available and the patient is compliant.	Strong
Offer one dose of carboplatin at area under curve 7 if adjuvant chemotherapy is considered.	Strong
Do not perform adjuvant treatment in patients at very low risk of recurrence (no risk factors).	Strong
Do not routinely perform adjuvant radiotherapy.	Strong
Adjuvant radiotherapy should be reserved only for highly selected patients not suitable for surveillance and with contraindication for chemotherapy.	Strong

*6.1.3 **Non-seminomatous germ cell tumours clinical stage I***
Management options for CS I NSGCTs include surveillance and adjuvant chemotherapy. Retroperitoneal lymph node dissection has a limited role.

Overall, approximately 70% of CS I NSGCTs are cured with orchiectomy alone. In those with the high-risk feature of LVI, historical figures reported relapse in 50% compared to 15% in those without LVI. A thorough discussion should be undertaken with the patient outlining the potential advantages and disadvantages of treatment options, as well as individual co-morbidities, disease features, risk factors, specific circumstances, and personal preferences, to guide their treatment decision.

6.1.3.1 Surveillance

Surveillance for CS I NSGCT entails a strict protocol of repeated cross-sectional imaging, monitoring of serum tumour markers and clinical assessment for the early identification of patients experiencing relapse who must receive salvage treatment (See Table 11).

The largest reports of surveillance indicate a cumulative relapse risk in about 30% of CS I NSGCT (five-year conditional risk of relapse 42% and 17% for high- and low-risk CS I-NSGCT, respectively) [101, 103]. Of these, 92% present within the first two years [101, 103, 116-118].

6.1.3.2 Retroperitoneal lymph node dissection

Since the introduction of cisplatin-based chemotherapy the role of adjuvant primary retroperitoneal lymph node dissection (RPLND) in men with CS I NSGCTs has decreased. According to data from high-volume and expert centres, primary RPLND is associated with a risk of relapse < 15% [119]. More recent data report on a relapse rate of 10% in case of negative nodes (pathologic stage (PS) – I) and < 30% in case of nodal metastases (PS II) [119-121], possibly due to selection or stage migration.

The few indications in CS I disease include men with teratoma with somatic malignant component, or patients who are not willing or suitable to undergo chemotherapy in case of recurrence, in particular in those when vascular invasion is present.

Recent publication supports the safety of surveillance alone, in PS II disease following RPLND, as 75-80% are relapse free at two and five years [120-122]. Those with relapse can be rescued with standard chemotherapy [123, 124]. With PS II, both adjuvant chemotherapy comprising two cycles of (B)EP (except for cases of ppt (post pubertal teratoma) only) and AS are standard option to be discussed with each individual.

Strategies to reduce the morbidity of primary RPLND include nerve-sparing and minimally invasive approaches. In a multi-centre setting, higher rates of in-field recurrences and complications have been reported with nerve-sparing RPLND [125, 126]. This suggests that primary RPLND, when indicated and chosen, should be performed by an experienced surgeon in a specialist centre. Minimally invasive (laparoscopic or robot-assisted) primary RPLND, appears feasible and safe (e.g., low-complication rate) in experienced hands. This must only be performed in high-volume RPLND centres with appropriate minimal-invasive surgery expertise [127-134]. There is limited recent data on mid-term follow-up.

Despite some advantages, including good efficacy, a less-demanding and costly follow-up due to the reduced need for cross-sectional imaging [135], RPLND for CS I NSGCT has diminished its role in view of the high CSS rates of surveillance, the low relapse rates with adjuvant chemotherapy, and the lower reproducibility of primary RPLND on a large scale.

6.1.3.3 Adjuvant chemotherapy

Adjuvant chemotherapy has been evaluated with both one and two cycles of BEP (cisplatin, etoposide, bleomycin) in CS I NSGCT. A prospective trial from 1996, as well as subsequent studies, used two cycles of BEP in high-risk patients (LVI present) [136-138]. In these series, including 200 patients, some with a median follow-up of nearly 7.9 years [136], a relapse rate of only 2.7% was reported, with minimal long-term toxicity. Two cycles of cisplatin-based adjuvant chemotherapy do not appear to adversely affect fertility or sexual activity [139].

Other studies have shown one cycle of adjuvant BEP results in similar very low recurrence rates (2-3%) [140, 141]. Reduction from two to one cycle of BEP improves the risk-benefit ratio of adjuvant chemotherapy considerably. A randomised phase III trial has also compared two-year recurrence free survival with adjuvant BEP x 1 to RPLND. Results favoured chemotherapy with recurrence free survival of 99.5% vs. 91% [126]. No clinically relevant differences in quality of life (QoL) were detected [142].

A community based prospective study of 490 unselected patients with CS I NSGCT that received adjuvant single cycle BEP had five-year relapse rates of 3% and 2% for LVI+ and LV- patients, respectively. After a median follow-up of eight years these rates were sustained, no relapses were observed beyond 3.3 years [140, 141]. These numbers imply that > 90% of relapses are prevented by single cycle BEP which is now the recommended strategy if adjuvant chemotherapy is considered [140, 141]. The very-long term (> 20 years) side effects of adjuvant chemotherapy, particularly cardiovascular, are yet to be fully defined and this should be considered during shared decision-making [143, 144].

Limited data are available on outcomes with relapse after adjuvant BEP. A retrospective analysis indicated that about one third of these relapses were late and that the outcome may be slightly worse compared to those presenting with *de novo* metastatic disease [145].

6.1.3.4 Risk-adapted treatment

A risk-adapted strategy is an alternative to any single approach for patients with CS I NSGCT. The advantages and disadvantages of treatment options must be discussed with patients in the context of their specific circumstances including disease risk factors, co-morbidities, and personal preference, as well as clinician recommendation in reaching a treatment decision. Lympho-vascular invasion is the strongest and most reproducible predictive factor for relapse and should be carefully outlined to the patient to assist in their decision-making.

Patients without LVI should be guided to consider surveillance, although some patients with significant co-morbidities or concerns regarding salvage chemotherapy with multicycle cisplatin-based chemotherapy may opt for adjuvant therapy. Those with LVI should have their high risk of relapse (up to 50%) highlighted and be guided to consider adjuvant management, and chemotherapy with BEP X 1 as the "preferred" option.

Some patients may wish to consider primary RPLND although they need to be aware of the potential additional requirement of adjuvant chemotherapy if nodes contain active disease (pN1), as well as the 10% risk of systemic relapse, even if pN0, requiring subsequent chemotherapy treatment (BEP X 3).

6.1.3.5 Post-pubertal teratoma with somatic malignant component

A multi-institutional study analysing retrospective datasets of CS I patients with post-pubertal teratoma with somatic malignant component (TSMC) suggested these patients had inferior five-year OS of approximately 10% compared to other CS I GCT patients. Furthermore, CS I TSMC cases undergoing primary RPPLND had a much higher proportion of nodal metastases (PS II) than expected (37.5%). Despite its limitations, this study provides the only evidence on this issue and supports primary RPLND in CS I NSGCT with TSMC [146].

For patients presenting with CS I pure post-pubertal teratoma without a somatic malignant component, surveillance provides comparable survival outcomes to primary RPLND [147]. A mixed population based study on 237 CS I with pure teratoma in the testis, showed an increasing trend favouring surveillance over RPLND as well as a not significant difference in overall survival at a median follow-up of 54 months [147].

However, subtype discrepancies in primary diagnostic of post-pubertal teratoma are not infrequent and consist in addition of subtype and involve secondary somatic type of malignancy in 83% of cases. As such, central review by expert genitourinary pathologist is recommended when teratoma is diagnosed in the orchidectomy specimen [148].

6.1.3.6 Summary of evidence and recommendations for the treatment of clinical stage I non-seminoma germ cell tumour of the testis

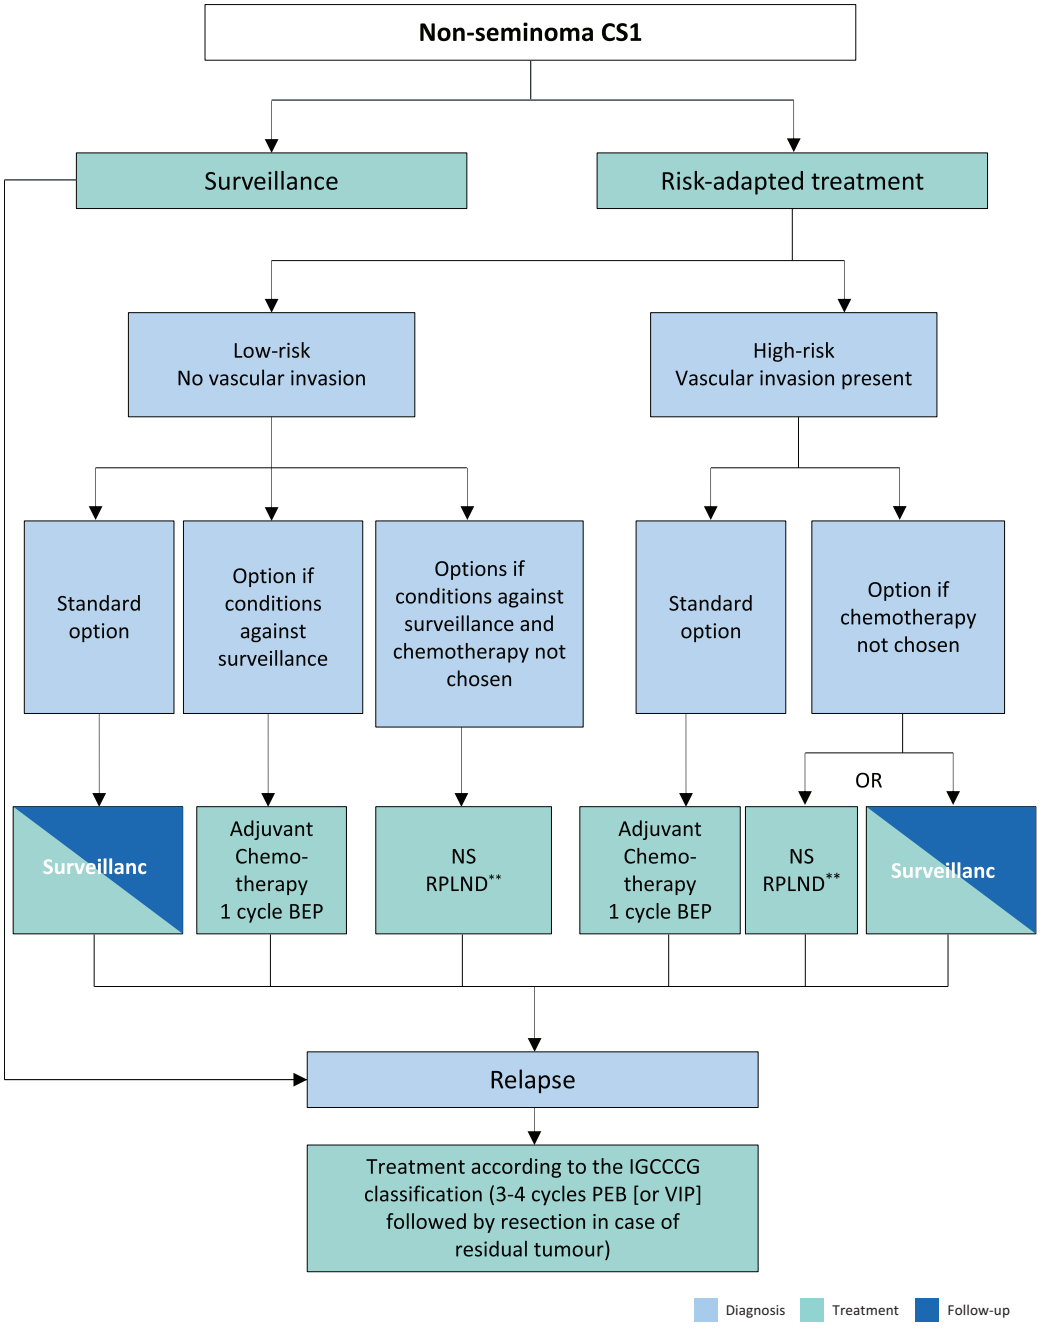
Summary of evidence	**LE**
Lymphovascular invasion increases the risk of relapse.	2a
The relapse rate with active surveillance is up to 50%, when LVI is present.	2a
The relapse rate in patients who receive adjuvant chemotherapy with BEP (x 1 cycle) is up to 3%.	2a
Adjuvant chemotherapy with BEP x 1 is superior to adjuvant RPLND in terms of the risk of relapse when the 2 strategies are not centralised in expert centres.	1b
A risk-adapted approach, based on LVI invasion is feasible.	2b
The acute toxicity of one cycle adjuvant BEP is low.	1b

Recommendations	**Strength rating**
Inform patients about all management options after orchidectomy: surveillance, adjuvant chemotherapy, and retroperitoneal lymph node dissection, including treatment-specific recurrence rates as well as acute and long-term side effects.	Strong
Offer surveillance or risk-adapted treatment based on lymphovascular invasion (see below).	Strong
Discuss one course of cisplatin, etoposide, bleomycin as an adjuvant treatment alternative in patients with stage I non-seminomatous germ cell tumour if patients are not willing to undergo or comply with surveillance.	Strong

6.1.3.7 Recommendations for risk-adapted treatment for clinical stage I non-seminomatous germ cell tumour based on vascular invasion

Recommendations	Strength rating
Stage IA (pT1, no vascular invasion): low risk	
Offer surveillance if the patient is willing and able to comply.	Strong
Offer adjuvant chemotherapy with one course of cisplatin, etoposide, bleomycin (BEP) in low-risk patients not willing (or unsuitable) to undergo surveillance.	Strong
Stage IB (pT2-pT4): high risk	
Offer adjuvant chemotherapy with one course of BEP, or surveillance and discuss the advantages and disadvantages.	Strong
Offer surveillance to patients not willing to undergo adjuvant chemotherapy.	Strong
Offer nerve-sparing retroperitoneal lymph node dissection to highly selected patients only; those with contraindication to adjuvant chemotherapy and unwilling to accept surveillance.	Strong

Figure 1: Risk-adapted treatment in patients with clinical stage I non-seminoma NSGCT*



** Discuss all treatment options with individual patients, to allow them to make an informed decision as to their further care.*
*** In case of PS II, the rate of recurrence is higher and chemotherapy can be administered (max. 2 cycles).*
BEP = cisplatin, etoposide, bleomycin; CS = clinical stage; IGCCCG = International Germ Cell Cancer Collaborative Group; NS = nerve-sparing; RLNPD = retroperitoneal lymph node dissection; VIP = etoposide, cisplatin, ifosfamide.

6.2 Metastatic germ cell tumours

The first-line treatment of metastatic GCTs depends on:

I. the histology of the primary tumour;
II. prognostic groups as defined by the IGCCCG (Table 4) [45];
III. serum tumour marker decline at the end of the first cycle of chemotherapy in poor-prognosis patients.

In relapsed patients, a prognostic score has been developed including response to first-line therapy which can be used to estimate patient outcome following salvage chemotherapy [149].

*6.2.1 **Clinical stage I with (persistently) elevated serum tumour markers***

With elevated markers and CS I, weekly measurement of markers are recommended. If AFP or β-hCG increase or fail to normalise following orchidectomy, US examination of the contralateral testicle must be performed. If a contralateral tumour is excluded, unequivocal rising tumour markers indicates CS I, and treatment for good prognosis metastatic GCT should be given. With stable markers, a new staging procedure, 4-6 weeks after orchidectomy, is recommended.

Some patients may have stable but slightly elevated AFP or β-hCG and can be initially monitored. Treatment should be commenced if markers rise or when follow-up imaging demonstrates metastatic disease.

The treatment of true CS I SGCT should be the same as other metastatic GCT. With this, ten-year overall survival of 95%, have been reported [150, 151].

*6.2.2 **Metastatic disease (stage IIA/B)***

6.2.2.1 Stage IIA/B seminoma

Patients with enlarged retroperitoneal lymph nodes < 2 cm in greatest diameter and normal markers may be observed for six to eight weeks with repeat-staging imaging as these may be non-metastatic on average in 10% of cases. Treatment should only be initiated if metastatic disease is unequivocal, based on biopsy, increasing nodal size/number, or subsequent marker rise [46, 150]. A special case are those patients who can undergo primary RPLND within a trial or institutional study (see below for further details).

Historically, radiotherapy has been the primary treatment for stage II A/B seminoma, showing relapse rates between 9-24% [152, 153]. Recommended radiation doses for stage IIA and IIB are 30 Gy and 36 Gy, respectively. With these doses, five-year relapse-free survival rates stand at 92% for stage IIA and 90% for IIB [152, 153]. A reduced dose of 27 Gy for stage IIA has been associated with a higher relapse rate [105].

Chemotherapy is a standard option for stage IIA/B seminoma, with relapse rates of 0-8% for stage IIA disease and 8-14% for stage IIB disease, and an excellent overall survival of 99% [154, 155]. The standard regimen in stage II seminoma is BEP x 3 (see Appendix 4.1.2) or EPx4 if there are concerns with the use of bleomycin [156]. There are no randomised studies comparing radiotherapy and chemotherapy. A meta-analysis of thirteen high-quality studies, comparing efficacy and toxicity of radiotherapy and chemotherapy showed that these appeared similarly effective in both stage IIA/IIB patients although with a non-significant trend towards greater efficacy for chemotherapy (HR: 2.17) in stage IIB seminoma [154]. Acute toxicity was almost exclusively reported following chemotherapy, while long-term toxicity was more frequent following radiotherapy, mainly comprising bowel toxicity and secondary cancers, generally in the irradiated field [154]. Several series have shown an increased risk of developing a second solid cancer of 1.8-2.0-fold with radiotherapy [157]. Long term toxicities of chemotherapy including second cancers are also a concern [157].

6.2.2.1.1 Retroperitoneal lymph node dissection

Several institutional series and a few single-arm phase II studies have explored primary RPLND with or without adjuvant chemotherapy as an alternative to chemotherapy in men with low volume CS II A/B [158-162]. Differences in surgical technique/template, extent of use of adjuvant chemotherapy, patient selection, and length of follow-up make direct comparisons of these surgical series to chemotherapy difficult. In these reports, patients with low-volume CS II A/B seminoma had two-year recurrence rates of 5-30%, with immature OS outcomes owing to short follow-up. Relapse will almost always be cured by standard chemotherapy. Longer

follow-up and ideally, comparative prospective studies are required to ensure this can be recommended as a safe stand-alone treatment option equivalent to chemotherapy alone.

Primary RPLND for men with low volume CS II seminoma should only be performed by surgeons with extensive experience in specialised TC centres. Ideally, the procedure should take place within a prospective cohort or clinical trial in order to maintain surgical quality and monitor long-term oncological outcomes.

6.2.2.1.2 De-escalating approaches

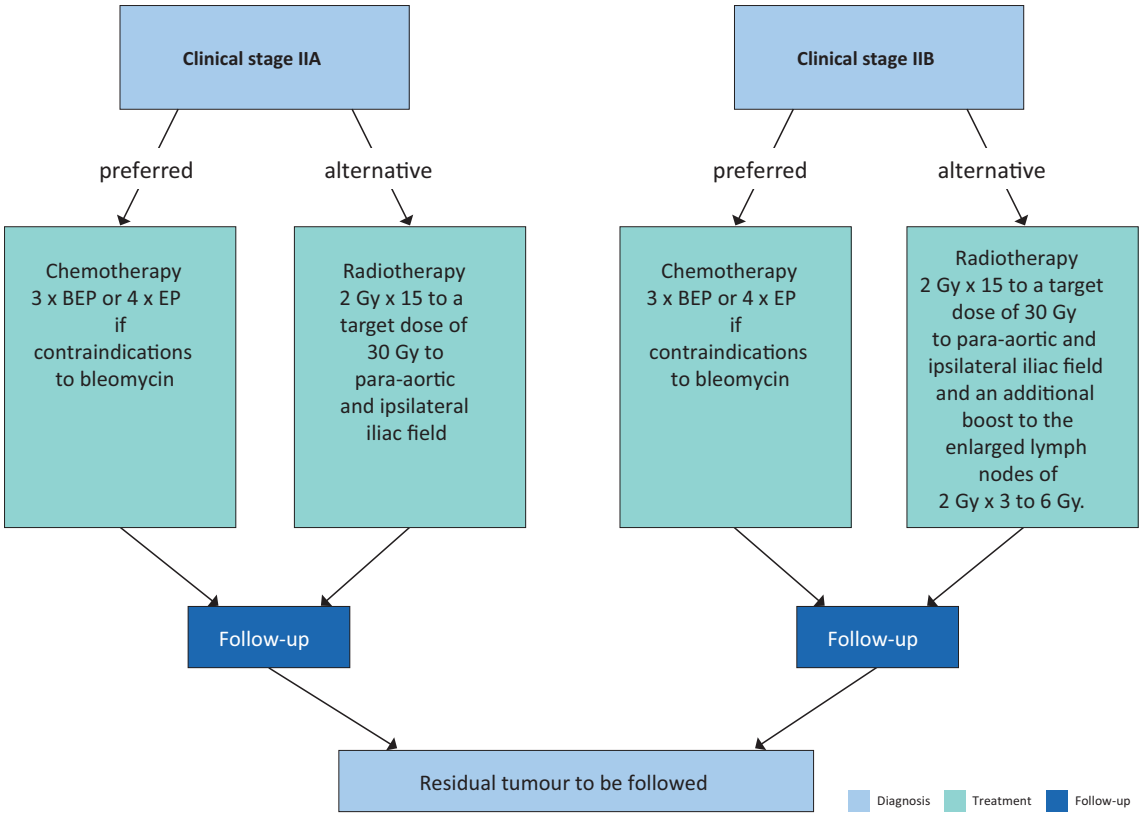
Several trials attempted to de-escalate chemotherapy and RT, aiming at maintaining the traditional excellent oncologic result, while minimising treatment burden and toxicity.

Such an approach was evaluated in a phase II randomised trial, assessing chemotherapy de-escalation in patients guided by metabolic response on FDG-PET/CT after two initial cycles of etoposide, cisplatin (EP) chemotherapy [163]. Patients with complete metabolic response after EP x 2 received de-escalated treatment with one subsequent cycle of carboplatin AUC7, whilst patients with residual metabolic activity completed the initial schedule of EP x 4. The study showed comparable three-year PFS rate of 90% and 91% for the EP and carboplatin groups respectively, and a two-year OS of 100% for both groups. Despite the apparently maintained oncological efficacy, larger studies and longer follow-up is needed. For these reasons and owing to the absence of consensus criteria for FDG-PETC/CT interpretation, making treatment decisions based solely on FDG-PET/CT responses is not currently recommended for routine use [163].

Another de-escalation option emerged, involving one cycle of carboplatin followed by involved-node (small-volume) radiotherapy (30 Gy in 15 sessions for stage IIA and 36 Gy in 18 sessions for stage IIB). This approach has shown a three-year progression-free survival rate of 93.7% in a single-arm phase II trial, narrowly missing its target primary endpoint of 95% three-year PFS [164]. Currently such approaches lack the level of evidence needed for routine use recommendation.

Summary of evidence	**LE**
At this stage all de-escalation strategies, including RPLND remain under evaluation and should only be considered in high volume specialised centres within a prospective cohort or clinical trial.	3

Figure 2: Treatment options in patients with seminoma clinical stage IIA and B*



**when enlarged retroperitoneal lymph nodes are < 2 cm and with normal markers, treatment should not be initiated unless metastatic disease is unequivocal based on biopsy, increasing nodal size/number, or subsequent marker rise.*
BEP = cisplatin, etoposide, bleomycin; EP = etoposide, cisplatin.

6.2.2.2 Stage II A/B non-seminoma (NSGCT)

6.2.2.2.1 Serum tumour marker negative

Patients with normal markers and equivocal lymph nodes (< 2 cm) may be considered for initial surveillance with early re-evaluation at six weeks. If the lesion progresses or fails to resolve it should be regarded and treated as CS II.

With CS IIA NSGCT disease and normal or normalised tumour markers, nerve sparing RPLND performed by an experienced surgeon in a specialised centre is the recommended initial treatment. Patients may be down staged to PS I in up to 20% of cases and require no further treatment. Patients with post-pubertal teratoma alone will avoid unnecessary chemotherapy as surgery alone is curative. The oncological outcomes after RPLND in CS II NSGCT have been evaluated in a SR [165]. Of the included studies the majority were retrospective with included patients differing substantially in histopathology, size and number of retroperitoneal lymph nodes resected, surgical templates, and the use of adjuvant chemotherapy. In men with marker negative CS II NSGCT, PS II is confirmed in 80%. Without adjuvant chemotherapy 12-40% recurred compared to 0-4% in those who received adjuvant chemotherapy.

These findings align with large single centre reports of outcomes following RPLND alone for PS II NSGCT with active disease [116, 123, 124, 166]. These studies reported five-year relapse of less than 30%, with the majority occurring outside the retroperitoneum requiring systemic chemotherapy according to risk group.

Adjuvant chemotherapy may be discussed with the patient to reduce the risk of relapse in this setting. Key issues include risk factors for relapse (as positive lymph node-ratio), the risk of overtreatment in up to 70% of cases and the need for rigorous follow-up. When adjuvant chemotherapy is chosen, standard treatment is BEP or EP for a maximum of two cycles [165, 167].

A recent single institution real world study including 61 CS IIA/B < 3cm NSGCT (out of 66 GCT) with active disease, showed a 77% two-year progression-free survival without adjuvant chemotherapy in stage IIA/B < 3 cm, with the greatest benefit was achieved in stage IIA marker negative cases [166].

Figure 3: Flowchart Nonseminoma CS IIA Mk- at Diagnosis/Staging

*** Most will be good prognostic group (BEP x3 or EP x4) - see Appendix 4*
https://uroweb.org/guidelines/testicular-cancer/publications-appendices.
****In case of PS II A/B patient can be followed-up or receive adjuvant chemotherapy (maximum of 2 cycles).*

6.2.2.2.2 Serum tumour marker positive

Patients with elevated tumor markers and radiological stage IIA/B at diagnosis or relapse should be treated with chemotherapy as outlined in tables 6 and 7 and section 6.2.3.1 based on IGCCCG risk group. Most patients will have a good prognosis for whom BEPX3 is most appropriate or EP x 4 if there are concerns with the use of bleomycin.

Primary RPLND for CS IIA/B disease with elevated markers is not recommended outside a specific study in a referral centre [166, 168].

*6.2.3 **Metastatic disease (stage II C and III)***

6.2.3.1 Primary chemotherapy

6.2.3.1.1 Good-prognosis risk group - seminomatous germ cell tumour

For metastatic seminoma, a cisplatin-based regimen should be used. A cisplatin-based combination chemotherapy has shown superior efficacy over carboplatin-based regimens [169]. The standard regimen in good-risk seminoma is three, twenty-one days cycles of BEP (Table 6). Alternatively, EP x 4 may be considered especially when bleomycin is contraindicated [170]. This achieves similar response rates but may have a slightly higher risk of relapse.

Post-chemotherapy masses should be managed as described in Section 6.5.2.

6.2.3.1.2 Intermediate-prognosis risk group - seminomatous germ cell tumour

For patients with intermediate-risk seminoma, BEP x 4 is the standard regimen. In bleomycin is contraindicated the combination of etoposide, cisplatin, ifosfamide (VIP) should be given. No RCT has focused specifically on this rare group of patients (see Table 4).

6.2.3.1.3 Good-prognosis risk group - non-seminomatous germ cell tumour

The standard regimen in good-risk non-seminoma is BEP x 3 (Table 6) [170].

An RCT support the equivalence of three or five-day regimes with three or four cycles of BEP for projected two-years PFS. Three-day regimes are associated with increased toxicity [171, 172]. Based on these data the BEP x 3 as a five-day regimen is strongly recommended in the good-prognosis risk group.

Two RCTs support the superiority of BEP x 3 over other regimes or schedule intensities [156, 173]. A further RCT has suggested that when EP is used, the mortality rate is twice that of with BEP, although the difference did not reach statistical significance [156].

Patients with a clear contraindication to bleomycin may receive EP x 4 [171]. In all other cases omission of bleomycin is not recommended.

For more information regarding Chemotherapy protocols, please visit the EAU guidelines website:
https://uroweb.org/guidelines/testicular-cancer/publications-appendices

6.2.3.1.4 Intermediate-prognosis risk group - non-seminomatous germ cell tumour

The standard regimen is BEP x 4 [174]. Four cycles of VIP has similar efficacy but is more myelotoxic [175]. Four cycles of VIP including primary G-CSF prophylaxis should be applied in patients with contraindications to bleomycin.

6.2.3.1.5 Poor-prognosis risk group - non-seminomatous germ cell tumour

The standard regimen is four cycles of BEP. Four cycles of VIP have similar efficacy, but is more myelotoxic [175]. Four cycles of VIP including primary granulocyte colony stimulating factor (G-CSF) prophylaxis should be applied in patients with contraindications to bleomycin [176, 177].

Serum tumour marker decline is the only prospectively confirmed predictor for response to cisplatin chemotherapy in metastatic germ cell tumour patients. Patients with inadequate tumour marker decline after the first or second cycle of BEP represent a prognostically inferior subgroup [177, 178]. There are several ways to calculate tumour marker decline kinetics with an example available at:
https://www.gustaveroussy.fr/calculation-tumor/NSGCT.html.

An RCT demonstrated improved PFS when intensifying treatment with dose-dense chemotherapy in patients with an early unfavourable tumour marker decline [179]. The trial was not powered to estimate OS differences. Based on the results from this trial, patients with an unfavourable tumour marker decline after BEP x 1 can be switched to a more intensive (dose-dense) chemotherapy regimen [179]. Additional patient groups with an unfavourable prognosis on standard treatment are primary mediastinal non-seminoma and patients with brain metastases at initial diagnosis [100, 180]. These may also be candidates for upfront intensified treatment, preferably in a prospective study.

In RCTs, primary high-dose chemotherapy (HDCT) with subsequent autologous stem cell transplantation has not shown an OS benefit in the overall poor-prognosis patient population in RCTs [176, 177]. Selected patients, such as primary mediastinal nonseminoma, do have poor survival following standard dose chemotherapy [181]. They may derive a benefit from primary HDCT [182], preferably within a prospective protocol.

Better outcomes are reported for intermediate and poor prognosis patients treated at high-volume centres [183-185]. Due to their unfavourable survival, poor-prognosis patients should be managed at centres with interdisciplinary germ cell tumour expertise and treated in ongoing prospective trials or registries, whenever possible.

There are no general recommendations for treatment modifications for patients with poor performance status (Karnofsky < 50%) or extended liver infiltration (> 50%), although two small patient series indicate that an initial cycle of dose-reduced therapy may reduce acute mortality without compromising long-term outcomes. The number of subsequent cycles of full-dose therapy should, however, not be reduced after an initial low-dose induction cycle [184, 186].

Patients with widespread pulmonary metastases are at risk for pulmonary haemorrhage and subsequent acute respiratory distress syndrome (ARDS) with induction chemotherapy. To reduce this risk, primary cytoreductive induction chemotherapy with EP over two to three days should be administered, followed by the first cycle of standard chemotherapy when the risk of ARDS has passed (typically after ten days) [184].

Table 6: Level of evidence for prognostic group and treatment

Prognostic group IGCCCG	Treatment	LE
Good (SGCT and NSGCT)	BEP x 3 or EP x 4	1b
Intermediate (SGCT and NSGCT)	BEP x 4 or VIP x 4	1b
Poor (NSGCT)	BEP x 4 or VIP x 4 if favourable marker decline	1b
	Dose escalation in selected cases with inadequate serum tumour marker decline	1b

6.2.3.1.6 Prevention of thromboembolism events during chemotherapy

Some RCTs have assessed the risks and benefits of thromboprophylaxis in ambulatory cancer patients receiving chemotherapy and report a relative risk reduction of 30-60% in venous thromboembolic events (VTE) at the cost of a doubling in bleeding risk [187-190]. Based on these results, the most recent American Society of Clinical Oncology (ASCO) Clinical Practice Guideline Update recommends thromboprophylaxis with apixaban, rivaroxaban, or low molecular weight heparin (LMWH) to cancer patients with a high risk of VTE and low risk of bleeding [191]. Metastatic germ cell tumour (mGCT) patients were under-represented in all trials and thus, it is not clear whether this recommendation applies to this group although retrospective data suggests a similar efficacy of VTE prophylaxis [192].

The EAU Guideline panel has discussed a recommendation regarding thromboprophylaxis. All members agreed that men with mGCTs undergoing cisplatin-based chemotherapy are at high-risk for VTE, and with the exception of those with choriocarcinoma and high volume extra-peritoneal disease, are at low risk of bleeding. Given the apparent high VTE incidence* and only non-validated VTE risk factors, the panel preferences were divided between those panel members that favoured thromboprophylaxis in all men and those panel members that restricted thromboprophylaxis to men with certain risk factors. Additionally, the majority of the panel agreed that a central venous-access device should be avoided whenever possible as this represents the only modifiable risk factor, which remained significantly associated with VTE in a multivariable risk-prediction model [193, 194].

**For more information regarding the prevention of thromboembolism events during chemotherapy, please see appendix 2, available online https://uroweb.org/guidelines/testicular-cancer/publications-appendices.*

6.2.3.1.7 Summary of evidence and recommendations for the prevention of thromboembolism events during chemotherapy

Summary of evidence	LE
Thromboembolic events occur more frequently in male patients with GCTs receiving chemotherapy than in young males under chemotherapy for other cancers.	2b
Retrospective studies have identified multiple risk factors for the development of thromboembolic events including increasing stage, size of retroperitoneal lymph nodes at different cut-offs, Khorana score > 3 and indwelling vascular access device (only modifiable risk factor).	2b

Recommendations	Strength rating
Balance the individual patients' potential benefits and risks of thromboprophylaxis during first-line chemotherapy in men with metastatic germ cell tumours.	Weak
Avoid use of central venous-access devices during first-line chemotherapy whenever possible.	Weak

6.3 Treatment evaluation and further treatment

*6.3.1 **Treatment evaluation***

Response to treatment should be assessed after the initial induction cycle by repeat imagining and/or re-evaluation of tumour markers. With marker decline and/or radiologically regressing or stable tumour features, the planned chemotherapy should be completed [192, 194]. If markers decline, but metastases progress on imaging, induction therapy must be completed [195]. If markers have normalised and masses with features of post-pubertal teratoma progress early surgical resection should be considered.

Slow marker-decline with the initial one to two cycles of chemotherapy warrants consideration for dose intensification (see https://www.gustaveroussy.fr/calculation-tumor/NSGCT.html).

Following completion of treatment, cases with a low-level β-hCG plateau should be observed to determine whether complete normalisation subsequently occurs. In patients with a low plateau serum AFP level after chemotherapy, removal of residual masses should be undertaken, with subsequent AFP monitoring. Preoperative AFP levels of > 30 µg/l and viable cancer found in the histological examination of the resected specimen have been described as predictors of relapse after first line chemotherapy [196]. Salvage chemotherapy is thus only indicated for documented marker progression [195, 197].

*6.3.2 **Residual tumour resection***

6.3.2.1 Seminoma

A residual mass of seminoma should initially be monitored with imaging and tumour markers [198-200].

As FDG-PET has a high NPV, in patients with residual masses > 3 cm in largest diameter, this should be considered in order to provide more information on disease viability [201-203]. It should not be performed until at least two months after completion of chemotherapy, as inflammation and the desmoplastic reaction induced by chemotherapy may result in a false positive result [204]. The NPV for active disease is > 90% which can be reassuring [201, 202]. In contrast PPV ranges from 23-69% and thus caution is advised on initiating active therapy driven only by positive findings on FDG-PET-CT [205].

When a post-chemotherapy mass remains positive at reclassification with FDG-PET with no volume increase, repeat FDG-PET should be performed six weeks later. A recent publication shows a low PPV for vital tumours in residual lesions (generally > 3 cm) after chemotherapy in metastatic seminoma (11-38% depending on sub-group). Therefore, caution is recommended with FDG-PET as a single parameter to drive clinical decisions in a persistent mass [205]. In patients with progressive disease on radiological criteria (i.e., a growing mass which enhances with CECT or is FDG-PET avid), salvage therapy is indicated [206-208].

Patients with persistently high and/or progressing β-hCG elevation after first-line chemotherapy should proceed to salvage chemotherapy. Progressing patients without β-hCG progression should undergo histological verification (e.g., by percutaneous or surgical biopsy) before salvage chemotherapy is given. When RPLND is indicated, this should be performed in referral centres, as residual seminoma masses may be extremely difficult to remove due to intense fibrosis [207].

6.3.2.2 Non-seminoma

Following first-line BEP it has be reported that about 7% of residual masses contain active cancer, 33% post-pubertal teratoma, and 40% necrotic-fibrotic tissue only [209]. The remainder comprise rarer entities including malignant transformation of teratoma. Restaging patients following chemotherapy with FDG-PET is not indicated [54, 55, 204]. With complete radiological remission, RPLND is not indicated [210, 211].

Usual timing for restaging is three to four weeks after the beginning of the last cycle. No diagnostic or risk calculator can accurately predict histology of the residual masses. Thus, resection is mandatory in all patients with a residual mass > 1 cm in transaxial long axis at cross-sectional CECT imaging until novel predictive models are externally validated [212-215]. Surgery when indicated should be performed within six to eight weeks after the last chemotherapy cycle.

The role of surgery with residual retroperitoneal lesions < 1 cm is uncertain. It is difficult to distinguish between a true residual node below 10 mm and a complete remission, and many authors consider these situations as equivalent. Residuals containing cancer or teratoma are possible, but the vast majority of patients have fibro-necrotic tissue only [216]. Whilst post-chemotherapy RPLND with residuals < 10 mm in transaxial long axis or complete remission is an option [217], the alternative option is close surveillance with recurrence risk of 6-9% depending on the follow-up duration [209-211, 218]. In the series with the longest follow-up of 15.5 years, twelve (9%) of 141 patients relapsed despite a complete response following primary treatment [211, 218]. Eight of the twelve relapsing patients were cured with subsequent treatment. These cases should be discussed on individual basis considering the orientation and expectations of the patient.

Residual masses after salvage chemotherapy or HDCT in first or subsequent salvage situations have a greater risk of active disease [219]. Surgery is therefore indicated even with residual masses < 1 cm [210, 211].

When resection is indicated, bilateral nerve sparing RPLND is the standard option. Ipsilateral template resection avoids contralateral nerve dissection and may be considered for residuals with a diameter < 5 cm [220], as well as unilateral lymph node metastases on pre- and post-chemotherapy CT scans, left-sided tumours only require para-aortic resection whereas right-side tumours need paracaval and inter-aortocaval resection down to the iliac arteries [221, 222]. Mapping studies indicate the potential risk of contralateral disease with this approach is low at around 1-3% [221, 223]. The mere resection of the residual tumour (so called lumpectomy) should not be performed [211, 215, 216, 219, 220, 222, 224].

Laparoscopic or robotic RPLND may yield comparable outcomes to open procedures in selected cases, with low-volume residual disease and when undertaken by highly experienced surgeons. This should only be considered in specialist TC centres with expertise in open RPLND and minimally invasive surgery to ensure appropriate case selection. In this setting, up to 30% of post-chemotherapy RPLND have been reported via a laparoscopic approach [225-227]. Experience with robot-assisted laparoscopic RPLND, and specifically long-term outcomes remains limited [228]. Atypical recurrences have been reported and occur more often with this approach [128].

6.3.3 ***Sequencing of surgery in the case of multiple sites***

In general, surgery should commence at the site with the highest volume of residual disease. The histology of the mass diverges in different organ sites [212]. In cases of residual retroperitoneal and lung masses, the presence of fibro-necrotic tissue in the retroperitoneum is associated with a probability as high as 90%, that lung masses contain the same histology [229]. When pathologic examination of the lesions from the initial side show complete necrosis, observation may be considered when there are multiple contralateral tumours for which resection may be challenging. Discordant histology between lung sites, however, may occur in up to 20% of cases and thus, patients in this situation should be closely monitored with reconsideration of surgery or biopsy if radiological features change [230, 231].

6.3.3.1 Quality and intensity of surgery

Resection of visceral structures and/or major vessels, requiring vascular reconstruction/replacement may be required to achieve radical resection and patients undergoing adjunctive complex surgery have a greater risk of complications [232, 233]. In patients with intermediate- or poor-risk and residual disease > 5 cm, the probability of vascular procedures is as high as 20% [234]. These cases must therefore be referred to specialised centres capable of interdisciplinary surgery (gastro-enteric and vascular surgery, spinal neurosurgery, thoracic surgery). Even with centralisation of treatment, the median number of RPLNDs performed per surgeon/year in the U.K. is six [235]. Nevertheless, patients treated within such centres benefit from a significant reduction in peri-operative mortality from 6% to 0.8% [236]. In addition, specialised urologic surgeons are capable of reducing the local recurrence rate from 16% to 3% with a higher rate of complete resections [237].

6.3.3.2 Salvage and desperation surgery

Surgery of resectable disease after salvage treatment remains a potentially curative option in patients with any residual mass following salvage chemotherapy. Survival after surgery and first salvage chemotherapy improved by 70% at ten years, following taxane-containing regimens [238]. Even with extensive salvage chemotherapy, surgery remains a fundamental tool to achieve durable complete remissions in up to 20% of patients [239, 240].

Desperation surgery refers to resection of non-responsive or progressive (e.g., rising markers) disease following salvage chemotherapy. When the disease is resectable, a significant proportion of these patients can be rendered disease-free in the long term [241].

6.3.3.3 Consolidation chemotherapy after secondary surgery

After resection of necrosis or post-pubertal teratoma, no further treatment is required. With incomplete resection of viable cancer, two adjuvant cycles of conventionally dosed cisplatin-based chemotherapy may be given in certain subgroups (e.g., poor-prognosis patients) [224]. Caution is required with cumulative doses of bleomycin which should not exceed 12 in total. With complete resection of active disease, comprising < 10% of the total volume of the mass, particularly in patients who initially had a good-prognosis based on IGCCCG criteria, the relapse rate is very low and adjuvant chemotherapy is not beneficial in preventing further relapse [242]. The prognosis is worse if malignant disease is present in masses resected after second- and third-line chemotherapy, although further chemotherapy is not indicated [243].

6.3.4 ***Systemic salvage treatment for relapse or refractory disease***

Cisplatin combination salvage chemotherapy will result in long-term remissions in approximately 50% of patients who relapse after first-line chemotherapy. These results are highly dependent on several prognostic factors [244]. The regimens of choice are four cycles of a three-agent regimen including cisplatin and ifosfamide plus a third drug: etoposide (VIP), paclitaxel (TIP), or potentially gemcitabine (GIP) (Table 7) [245, 246]. No RCT has compared these regimens. Due to their potential risk of lethal haematological toxicity, these regimens should be used with G-CSF support and by well-trained oncologists.

Table 7: Standard VIP, TIP and GIP salvage chemotherapy (interval 21 days)

Regimen	Chemotherapy agents	Dosage	Duration of cycles
VIP	Cisplatin* Etoposide Ifosfamide*	20 mg/m^2 75-100 mg/m^2 1.2 g/m^2	Days 1-5 Days 1-5 Days 1-5
TIP	Paclitaxel Ifosfamide* Cisplatin*	250 mg/m^2 [xx] 1.5 g/ m^2 25 mg/m^2	24 hour continuous infusion day 1 Days 2-5 Days 2-5
	Alternative schedule		
	Paclitaxel Ifosfamide* Cisplatin*	175 mg/m^2 1.2 g/m^2 20 mg/m^2	Day 1, 3 hour infusion Days 1-5 Days 1-5
GIP	Gemcitabine Ifosfamide Cisplatin	1000 mg/m^2 1200 mg/m^2 20 mg/m^2	Day 1 + 5 Days 1-5 Days 1-5

[xx] *An MRC schedule uses paclitaxel at 175 mg/m^2 in a 3 hour infusion infusion [246].*

Please refer to appendix 4 – Chemotherapeutic protocols https://uroweb.org/guidelines/testicular-cancer/publications-appendices for more detailed information.

A retrospective analysis by the International Prognostic Factors Study Group (IPFSG) evaluated the risk of relapse in patients in whom this occurred after at least three cisplatin cycles and subsequent cisplatin conventional-dose or carboplatin-based high-dose salvage chemotherapy [149]. Seven variables: histology, primary tumour location, response, progression-free interval after first-line treatment and level of AFP, β-hCG and the presence of liver, bone or brain metastasis at salvage treatment, were identified as independent prognostic variables of relapse after initial cisplatin chemotherapy [149]. Using these factors, five risk-groups: very low-risk = -1 points; low-risk = 0 points; intermediate-risk = 1-2 points; high-risk = 3-4 points; and very high-risk > 5 points; were identified with significant differences in PFS and OS. Table 9 illustrates these five risk groups and the corresponding two-year PFS and three-year OS rates [149]. Several recent trials have validated this scoring system [247-250]. As in first-line therapy, the prognostic impact of tumour marker decline applies in the salvage setting [251]. While progression to induction chemotherapy was negative for OS, prior use of paclitaxel was not significantly associated with a negative outcome [252].

A secondary analysis of the IPFSG cohort (n = 1,600 patients) showed a 10-15% improvement in OS in all prognostic subgroups when treated with high-dose salvage therapy compared to standard dose therapy. This is being evaluated in an RCT of HDCT vs. conventional dose chemotherapy in patients with first-line relapse is underway (Tiger trial). When HDCT is used as a salvage treatment, sequential treatment cycles of high-dose carboplatin and etoposide (HD-CE) should be preferred to a single high-dose regimen as the former is associated with less toxicity-related deaths [247]. A recent SR confirmed the superiority of using at least two high-dose cycles in the salvage setting over a single high-dose cycle [253]. It is clearly of the utmost importance that these rare patients with relapse are treated within clinical trials and at specialised centres.

Table 8: The International Prognostic Factors Study Group Score for seminoma and non-seminoma that relapse after cisplatin-based first-line chemotherapy [189]

Points	**-1**	**0**	**1**	**2**	**3**
Variable					
Histology	Seminoma	Non-seminoma			
Primary site		Gonadal	Retroperitoneal		Mediastinal
Response		CR/PRm-	PRm+/SD	PD	
PFI		> 3 months	≤ 3 months		
AFP salvage		Normal	< 1000	1000	
hCG salvage		< 1000	1000		
LBB		No	Yes		

AFP = alpha-fetoprotein; CR = complete remission; PRm- = partial remission, negative markers; PRm+ = partial remission, positive markers; hCG = human chorionic gonadotrophin; LBB = liver, bone, brain metastases; PD = progressive disease; PFI = progression-free interval; SD = stable disease.

Table 9: PFS and OS estimates for all patients according to IGCCCG prognostic score for seminoma and non-seminoma that relapse after cisplatin-based first-line chemotherapy [190]

Score (n = 1,435)	**N**	**%**	**HR**	**2-years PFS (%)**	**3-year OS (%)**
Very Low	76	5.30	1	75.1	77.0
Low	257	17.9	2.07	52.6	69.0
Intermediate	646	45.0	2.88	42.8	57.3
High	351	24.5	4.81	26.4	31.7
Very High	105	7.3	8.95	11.5	14.7
Missing	159	-	-	-	-

HR = hazard ratio; PFS = progression-free survival; n = number of patients; OS = overall survival.

*6.3.5 **Second relapse***

No RCTs have been reported for patients with second relapse and conventional therapy appears to have limited effect. For patients who have received two series of conventionally dosed therapy (first line and first-salvage), HDCT with autologous stem cell support should be used although the prospect of cure is < 25% [248]. Retrospective data from Indiana University suggest that patients who completed HDCT may derive additional benefit from daily maintenance therapy with oral etoposide for three months post HDCT [254]. Prospective evaluation of this in a randomised phase II trial is ongoing.

Patients relapsing within four to eight weeks after platinum-based therapy, or who are progressing despite platinum-based therapy, as well as those relapsing shortly after HDCT, are considered as cisplatin refractory. Combinations of gemcitabine and oxaliplatin or the triple combination of gemcitabine, oxaliplatin and paclitaxel have resulted in response rates of 25-45% in this setting. Cisplatin re-challenge in association with gemcitabine and paclitaxel may be considered in patients with adequate renal function [255]. For patients with a second relapse not responding to the combination of oxaliplatin and gemcitabine or the triple combination, inclusion in clinical trials is encouraged.

Patients with a good response undergoing subsequent resection of residual tumour lesions may still have a 15-20% chance of long-term cure [239, 256].

Various targeted agents have generally failed in refractory disease, including immune checkpoint inhibitors [247-253, 257]. Trials combining PD1/PDL-1 and CTLA4 inhibitors are ongoing, however, even for those combinations early results are not encouraging.

6.3.5.1 Late relapse (more than two years after end of first-line treatment)

Late relapse is defined as recurrence more than two years after completion of successful primary treatment of metastatic TC [203, 258]. According to a pooled analysis, this occurs in 1.4% and 3.2% of seminoma and non-seminoma patients, respectively [259].

Based on a population-based study, all late-relapsing seminoma patients have viable GCT [260]. These can be treated with chemotherapy and radiotherapy [261].

In contrast, patients with late-relapsing NSGCT should undergo surgical resection when feasible, alone or in combination with chemotherapy. Some patients, including those with rapidly rising β-hCG, may benefit from induction salvage chemotherapy with subsequent reconsideration of surgery for resection of persisting residual masses [262]. In general, however, surgery represents the mainstay of treatment and it should be performed in most patients when feasible irrespective of the level of their tumour markers, in order to completely resect all viable GCT post-pubertal teratoma [261-265].

Survival strongly relates to the histology of the recurrent lesions rather than that of the initial disease. If not completely resectable, biopsies should be obtained for histological evaluation to direct salvage chemotherapy based on the tumour phenotype. Review by an experienced pathologist is critical to avoid misinterpretation of the therapeutic morphological changes that occur with the treatment of GCT [266]. If the patient responds to salvage chemotherapy, secondary surgery should then be undertaken if feasible. With unresectable, but localised refractory disease, stereotactic or conventional radiotherapy may be considered. To avoid excess mortality, late relapses should be treated only at centres experienced in managing such patients [267].

*6.3.6 **Treatment of brain metastases***

Brain metastases occur in the context of initial metastatic disease, systemic relapse and rarely as an isolated site of relapse. Long-term survival of patients presenting with brain metastases at diagnosis is poor (30-50%) and even poorer when a site of recurrent disease (five-year survival-rate is 2-5%) [268, 269]. A large international database comprising 523 patients reported 48% three-year OS rates in patients with brain metastases at initial diagnosis and 27% three-year OS rates for patients with brain metastases at relapse [58].

Chemotherapy as initial treatment proved effective in a first-line setting (potentially even as dose-intensified therapy upfront) with data also supporting the use of multimodal treatment particularly in relapsed disease [58]. Consolidation RT, even with total response after chemotherapy, should therefore be used in patients with brain metastases at relapse, but must be carefully discussed in a first-line setting [270]. Surgery may be considered in cases with a persistent solitary metastasis, depending on the systemic disease status, histology of the primary tumour and the location of the metastasis.

6.3.6.1 *Summary of evidence and recommendations for the treatment of metastatic testicular germ cell tumours*

Summary of evidence	LE
In the NSGCT good-prognosis-risk group (IGCCG), BEP x 3 is superior to other chemotherapy regimens. Toxicity is lower when treatment is delivered in five-day regimes rather than three-day regimes.	1b
In the NSGCT intermediate-prognosis-risk group (IGCCCG) BEP x 4 is the standard treatment of choice with a five-year survival of 89% in contemporary series.	1b
In pathological stage II NSGCT disease, RPLND performed in specialised centres without adjuvant chemotherapy results in 73-81% of long-lasting remissions.	2b
In patients with a poor-prognosis metastatic NSGCT (defined by IGCCCG), treatment with BEP x 4, results in a five-year PFS of 67%. There is no advantage in OS for high-dose chemotherapy.	1b
Patients with a poor-prognosis metastatic NSGCT and early unfavourable tumour marker decline may benefit from intensification of treatment with dose-dense chemotherapy, with improvement of PFS despite no benefit being observed for OS.	1b
Following first-line BEP chemotherapy, 6-10% of NSGCT residual masses contain active cancer, 50% have post-pubertal teratoma, and 40% comprise of necrotic-fibrotic tissue only. Figures regarding persistence of residual active are slightly lower in post chemotherapy residual masses < 1 cm. Currently there is no accurate prognostication method of histology.	2b
In CS IIA/B seminoma radiotherapy and chemotherapy treatment show similar effectiveness, with a non-significant trend towards greater efficacy of chemotherapy in CS IIB. However, risk of second malignancies and cardiovascular events is higher after radiotherapy.	2a
In metastatic seminoma stage > IIC, primary chemotherapy with BEP, tailored to the IGCCCG risk group, has proven superior to Carboplatin based chemotherapy.	1b
Fluorodeoxyglucose-positron emission tomography has a high NPV in patients with post-chemotherapy seminoma residual masses (> 3 cm) when performed more than two months after chemotherapy.	2b

Recommendations	Strength rating
Treat low-volume non-seminomatous germ cell tumour (NSGCT) stage IIA/B with elevated markers like metastatic good- or intermediate-prognosis risk group IGCCCG with three or four cycles of cisplatin, etoposide, bleomycin (BEP).	Strong
Nerve-sparing retroperitoneal lymph node dissection when performed by an experienced surgeon in a specialised centre is the recommended initial treatment in clinical stage (CS) IIA NSGCT disease without elevated tumour markers.	Weak
Repeat staging after six weeks before making a final decision on further management should be considered in patients with small volume (CS IIA < 2 cm) marker-negative NSGCT.	Weak
Treat metastatic NSGCT (stage > IIC) with an intermediate prognosis with four cycles of standard BEP.	Strong
Treat metastatic NSGCT with a poor prognosis and favourable marker decline with four cycles of BEP.	Strong
Assess tumour marker decline after one cycle of standard chemotherapy in metastatic NSGCT with a poor-prognosis. With unfavourable decline, consider chemotherapy intensification.	Weak
Perform surgical resection of visible (> 1 cm in longest diameter) residual masses after chemotherapy for NSGCT when serum levels of tumour markers are normal or normalising.	Strong
Offer cisplatin chemotherapy according to IGCCCG prognosis groups, or alternatively radiotherapy to seminoma patients with stage II A/B and, inform the patient of potential long-term side effects of both treatment options.	Weak
Treat seminoma stage IIC and higher, with primary chemotherapy according to IGCCCG classification (BEP x 3 in good-prognosis and BEP x 4 in intermediate prognosis).	Strong

7. FOLLOW-UP AFTER CURATIVE THERAPY

7.1 Minimal recommendations for follow-up

Based on different risks of relapse depending on diagnosis and initial treatment, three major follow-up groups can be defined:

1. patients with seminoma stage I;
2. patients with non-seminoma stage I on active surveillance;
3. all patients having received either adjuvant treatment or curative chemotherapy for good- and intermediate-prognosis metastatic disease (according to the IGCCCG) achieving a complete remission with, or without, surgery (for seminoma this includes residual lesions < 3 cm, or residual lesions > 3 cm that are FDG-PET-negative).

It is important to note that patients not achieving a complete remission or presenting with poor-prognosis disease should be followed up individually by specialised centres. Tables 10-12 show the minimal recommendations for follow-up of the three different groups based on recommendations developed at a European Society for Medical Oncology (ESMO) consensus conference [271].

Both MRI and CT can be used to evaluate the retroperitoneum, pelvis and inguinal regions for sites of metastatic disease from GCT [272, 273]. Magnetic resonance imaging benefits from an absence of ionising radiation but is more time consuming and less readily available than CT [274]. Given the frequency of follow-up, over a number of years some studies have estimated a risk of up to 1 in 300 of second malignancy related to CT imaging follow-up alone [275], although more recent dose saving protocols and limitations on field of view will have mitigated this somewhat. Nevertheless, this risk could be excluded by the use of MRI for follow-up.

Both MRI and CT rely predominantly on size cut-offs for evaluation given the excellent spatial resolution of both modalities, with morphological assessment for features such as necrosis and irregular shape an adjunct. Sensitivity and specificity vary according to the size cut-off used [272]. However, studies have shown comparable excellent results between MRI and CT with up to 98% sensitivity on MRI for the detection of retroperitoneal nodal metastases in GCT [276]. It has, however, been demonstrated that reader experience is important when interpreting images [277]. In the setting of GCT, one study demonstrated decreased sensitivity for detection of retroperitoneal nodal disease on MRI when reported by a trainee radiologist with sensitivity of detection of 80% [275]. However, experienced radiologists in the same study again achieved sensitivity for detection of nodal disease of 97% with good interobserver agreement. It was therefore suggested that if MRI is to be used instead of CT for follow-up this be done in centres/units with oncological radiologists who routinely report MRI and CT in patients with GCT rather than general radiologists who may only occasionally see such imaging. Consequently, MRI of the abdomen can be used as an alternative to CECT in experienced centres [278].

The diagnostic accuracy of FDG-PET-CT is best described and therefore recommended in seminoma patients with post-chemotherapy residual masses > 3 cm in largest diameter as outlined in section 6.3.2.1. This should be performed at least 2 months after completion of chemotherapy as earlier scans may be misleading due to inflammation. The changes related to tumour necrosis. The use of FDG-PET-CT is not currently recommended during surveillance. Retrospective analyses have indicated a high diagnostic accuracy for staging and follow-up in patients with CS 1 during surveillance or for determining the stage in more advanced disease [279]. However, to minimise radiation exposure and considering the supporting data for the use of MRI [273], the panel currently do not recommend the use of FDG-PET-CT during surveillance.

Serum tumour markers are the least invasive and most accessible follow-up investigations. The established serum tumour markers, such as AFP, β-hCG, and LDH, may yield false positive results, so their levels should be correlated with imaging findings or repeated in serial measurements [280]. Serum tumour markers can detect microscopic disease that is not yet visible on cross-sectional imaging in a small proportion of patients, and therefore, they should be measured at the recommended prescribed intervals [281].

MiR-371a-3p has a high diagnostic accuracy for detecting all histologies of GCT except teratoma and has potential to detect disease recurrence earlier than AFP, β-hCG, LDH, or cross-sectional imaging [282]. However, before this promising test can be recommended in routine practice, a validated assay and cut-off definitions in prospective cohorts are required to mitigate the risk of false positive findings, unnecessary restaging, anxiety, or over-treatment.

Regarding the use of US examination of the contralateral testis, the majority of the consensus meeting participants did not support repeat US investigation, either with negative biopsy or if no contralateral biopsy has been performed [271].

A very late relapse (VLR) after five years is a rare event occurring in approximately 0.5% of patients based on a population-based analysis [260]. The aim of follow-up beyond five years therefore shifts to detection of late side effects of treatment and imaging tests are not routinely recommended.

Most patients with VLR are diagnosed due to symptoms, although in up to 50% elevated tumour markers are present in NSGCTs [260, 283]. Patient education regarding relapse symptoms and clinician awareness are important elements of survivorship management. Early use of imaging and tumour markers with suspicion of relapse is encouraged.

Table 10: Recommended minimal follow-up for seminoma clinical stage I on active surveillance or after adjuvant treatment (carboplatin or radiotherapy)

Modality	Year 1	Year 2	Year 3	Years 4 & 5	After 5 years
Tumour markers ± doctor visit	2 times	2 times	2 times	Once	Further management according to survivorship care plan
Chest X-ray	-	-	-	-	
Abdominopelvic magnetic resonance imaging (MRI)/ computed tomography (CT)	2 times	2 times	Once at 36 months	Once at 60 months	

Table 11: Recommended minimal follow-up for non-seminoma clinical stage I on active surveillance

Modality	Year 1	Year 2	Year 3	Year 4 & 5	After 5 years
Tumour markers ± doctor visit	4 times*	4 times	2 times	1-2 times	Further management according to survivorship care plan
Chest X-ray	2 times	2 times	Once, in case of LVI+	At 60 months if LVI+	
Abdominopelvic magnetic resonance imaging (MRI)/ computed tomography (CT)	2 times	At 24 months**	Once at 36 months***	Once at 60 months***	

** In case of high-risk (LVI+) a minority of the consensus group members recommended six times.*

*** In case of high-risk (LVI+) a majority of the consensus group members recommended an additional CT at eighteen months.*

**** Recommended by 50% of the consensus group members.*

LVI+ = Lymphovascular invasion present

Table 12: Recommended minimal follow-up after adjuvant treatment or complete remission for advanced disease (excluded: poor-prognosis and no remission)

Modality	Year 1	Year 2	Year 3	Year 4 & 5	After 5 years
Tumour markers ± doctor visit	4 times	4 times	2 times	2 times	Further management according to survivorship care plan**
Chest X-ray	1-2 times	Once	Once	Once	
Abdominopelvic magnetic resonance imaging (MRI)/ computed tomography (CT)	1-2 times	At 24 months	Once at 36 months	Once at 60 months	
Thorax CT	1-2 times*	At 24 months*	Once at 60 months*	Once at 60 months*	

** In conjunction with abdominopelvic MRI/CT in case of pulmonary metastases at diagnosis.*

*** In case of teratoma in resected residual disease: the patient should remain with the uro-oncologist.*

7.2 Quality of life and long-term toxicities after cure of testicular cancer

The vast majority of patients will be cured with five-year relative survival rates of approximately 95% in Western Europe. Testicular cancer patients are usually between 18-40 years of age at diagnosis and life expectancy after cure extends over several decades [284]. Patients should be informed before treatment of common long-term toxicities, which are avoided or minimised by adherence to international guidelines.

During follow-up, patients should be screened and treated for known risk factors such as hypertension, hyperlipidaemia, and testosterone deficiency. Adverse health outcomes (AHOs) are more commonly found in TC patients who received chemotherapy than those cured by surgery alone. Further, modifiable risk factors do contribute to AHOs like hypertension and noise exposure to hearing impairment or smoking to Raynaud phenomenon [285]. Therefore, a healthy lifestyle should be promoted during the follow-up consultations. Adverse health outcomes are associated with unemployment, which is found clearly increased in TC survivors (TCSs) as compared to a male normative population [286]. When follow-up by the TC clinician is terminated, a written cancer survivorship plan addressing late toxic effects, lifestyle recommendations, recurrence risk, and cancer-specific follow-up may be helpful [203, 287].

*For more information regarding long term toxicities and quality of life issues, please see appendix 3, available online https://uroweb.org/guidelines/testicular-cancer/publications-appendices

8. RARE ADULT PARA- AND TESTICULAR TUMOURS

Less than 5% of testicular cancers are unrelated to GCNIS and lack 12p alterations [288, 289]. These tumours are rare with available literature based on case reports and small retrospective series. Given the rarity of non-germ cell para-/testicular cancers, referral of these cases to specialist units for multidisciplinary discussion including central image and pathology review is highly recommended. As a result of publication bias related to these types of study, the risk of metastatic disease may be less than that reported in the literature.

8.1 Classification

These testicular tumours have a similar presentation as TC and are only identified after histopathologic examination. They are classified according to the WHO Classification of Tumours of the Urinary System and Male Genital Organs [290].

8.2 Spermatocytic Tumours

Spermatocytic tumours are GCTs unrelated to GCNIS. They may show a unique amplification of chromosome 9 corresponding to the DMRT1 gene and are never associated with other forms of germ cell tumours [290].

Spermatocytic tumours are rare, occur exclusively in the testis and do not normally show elevated tumour markers [290]. Previously named “spermatocytic seminomas” they have been recently reclassified as spermatocytic tumours [290]. As those tumours cannot be differentiated from seminoma GCT by FSE, radical orchiectomy is the standard treatment option. Outcomes after testis-sparing surgery or adjuvant treatment is unknown and therefore not recommended [291]. Metastatic disease is very rare, usually associated with ‘sarcomatoid change’ and typically presents at or soon after initial diagnosis with limited survival [291].

8.3 Sex cord-stromal tumours

Sex cord–stromal tumours are relatively uncommon but represent the second largest group of primary testicular tumours after GCT’s [292]. As a small subset of these tumours are clinically malignant, a thorough evaluation of those morphological features associated with malignancy should be performed to guide management. Two or more of the following features are associated with malignant potential: size > 5 cm, infiltrative borders, cytological atypia, three or more mitotic figures per ten high-power fields, vascular invasion and necrosis [292].

8.3.1 Leydig cell tumours

Leydig cell tumours comprise about 4% of adult testicular tumours [293]. These mainly present as localised tumours with metastases occurring in only 2.5% [294]. They may present with hormonal manifestations, including gynaecomastia and more rarely are accompanied by Cushing's Syndrome [389]. With testis-sparing surgery a local recurrence rate of 7% has been reported although no adjuvant treatment options can be recommended [295]. Several risk factors for metastatic disease have been proposed which may guide image-guided follow-up intensity [295]. Survival of men with metastatic disease is poor but occasional responses to surgical resection, if feasible, and to a lesser extent systemic treatment have been reported [295].

8.3.2 Sertoli cell tumours

Sertoli cell tumours account for approximately 1% of testicular neoplasms [292]. The risk of metastases is unclear. With testis sparing surgery a local recurrence rate of < 1% has been reported although no adjuvant treatment options can be recommended [296]. Several risk factors for metastatic disease have been proposed which may guide image guided follow-up intensity [296]. Survival of men with metastatic disease is poor although response to surgery has been occasionally reported [296].

8.3.3 Granulosa cell tumour

Granulosa cell tumours, which include adult and juvenile variants, are extremely rare and metastatic potential is unclear [292]. With testis sparing surgery a local recurrence rate of 5% has been reported although no adjuvant treatment options can be recommended [297]. Whereas metastatic disease has never been reported in juvenile granulosa cell tumours, men with adult type may occasionally present with metastatic disease [297]. Survival of men with metastatic disease is poor although rare instances of response to surgical or systemic treatment has been reported [297].

8.3.4 Thecoma/fibroma group of tumours

These tumours derive from the testicular parenchymal stroma or from the tunica albuginea. They seem to be uniformly benign [292, 298].

8.3.5 Paratesticular tumours of the epididymis or spermatic cord

The majority of epididymal masses are benign cystic or inflammatory conditions. Solid epididymal tumours are rare and comprise numerous benign and neoplastic lesions. In the only population-based analyses [299], the majority of neoplastic lesions of the epididymis or spermatic cord were sarcomas, metastases from other organs or primary adenocarcinomas similar to proportions reported in institutional studies [300, 301]. Benign lesions, which may comprise the majority in clinical practice include lipomas, adenomatoid tumours leiomyomas and papillary cystadenomas.

Robust criteria to differentiate between neoplastic benign lesions have not been defined although ultrasonography with or without fine needle aspiration [302] MRI [53, 303] or surgical exploration with FSE or histopathological confirmation can be considered. No clear recommendation can be provided regarding surgical approach, extent of resection and neo- or adjuvant treatment can be given.

8.4 Mesothelioma of the tunica vaginalis testis

Mesothelioma of the tunica vaginalis testis is a rare but aggressive disease [304]. Beside older age, larger tumour size, presence of necrosis, angiolymphatic invasion or a high mitotic index the only modifiable risk factors represents local recurrence. Therefore, aggressive local treatment with hemiscrotectomy is recommended. No clear recommendation can be given regarding adjuvant treatment. In case of metastatic disease, the median overall survival is a few months only and multimodal treatment could be considered.

8.5 Follow-up of rare adult para- and testicular cancers

After local surgical treatment is completed, attention turns to follow-up strategies with the aims of detecting recurrence or secondary cancers at a stage when further curative procedures are possible whilst minimising the burden of follow-up and the potential for over-treatment and concomitant treatment toxicity. Data for rare para- and testicular cancers are limited but recommended follow-up schedules based on published case series have been suggested [305].

10. CONFLICT OF INTEREST

All members of the Testicular Cancer Guidelines working group have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publicly accessible through the European Association of Urology website: http://www.uroweb.org/guidelines.

This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

11. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Paris 2024. ISBN 978-94-92671-23-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, the Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aims and scope

This overview represents the updated European Association of Urology (EAU) Guidelines for primary urethral carcinoma. The aim is to provide practical recommendations on the clinical management of Primary Urethral Carcinoma with a focus on clinical presentation. When the first carcinoma in the urinary tract is detected in the urethra, this is defined as primary urethral carcinoma, in contrast to secondary urethral carcinoma, which presents as recurrent carcinoma in the urethra after prior diagnosis and treatment of carcinoma elsewhere in the urinary tract. Most often, secondary urethral carcinoma is reported after radical cystectomy for bladder cancer [1, 2] (see Chapter 7.3 of the European Association of Urology [EAU] Guidelines on Muscle-invasive and Metastatic Bladder Cancer [MIBC]) [2].

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Guidelines Panel on MIBC is responsible for this publication. This is an international multidisciplinary group of clinicians, including urologists, oncologists, a pathologist, a radiotherapist and a radiologist. Members of this panel have been selected based on their expertise to represent the professionals treating patients suspected of suffering from urethral carcinoma. In the course of 2021 two patient representative have formally joined the MIBC Guidelines Panel. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU Website Uroweb: https://uroweb.org/guideline/primary-urethral-carcinoma/.

1.3 Available publications

A quick reference document (Pocket guidelines) is available in print, presenting the main findings of the Primary Urethral Carcinoma Guidelines. This is an abridged version which may require consultation together with the full text version. The most recent scientific summary was published in 2020 [3].

1.4 Publication history & summary of changes

The Primary Urethral Carcinoma Guidelines were first published in 2013. This is the tenth update of this document.

1.4.1 Summary of changes

The literature for the complete document has been assessed and updated for the 2024 print, resulting in a text update in section 3.3 on histopathology and genomic profiling.

2. METHODS

2.1 Data identification

For the 2023 Primary Urethral Carcinoma Guidelines, new and relevant evidence has been identified, collated, and appraised through a structured assessment of the literature. An updated systematic literature search was performed to identify studies reporting data on urethral malignancies since the prior search, covering a time frame between August 9th 2022 and May 1st 2023. Databases searched included Ovid (Medline), EMBASE and the Cochrane Central Register of Controlled Trials and Cochrane Database of Systematic Reviews. A total of 68 unique records were identified, retrieved, and screened for relevance. Only one reference was updated in this 2023 publication. A detailed search strategy is available online: https://uroweb.org/guidelines/primary- urethral-carcinoma/publications-appendices.

Recommendation within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [4];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact and certainty of patient values and preferences on the intervention.

Strong recommendations typically indicate a high degree of evidence quality and / or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/ or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [5]. The strength rating forms will be available online.

Additional information can be found in the general Methodology section of this print, and online at the EAU website; http://www.uroweb.org/guideline/.

A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review

This document was peer-reviewed prior to publication in 2021.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Primary urethral carcinoma is considered a rare cancer, accounting for < 1% of all genitourinary malignancies [6] (ICD-O3 topography code: C68.0) [7]. In 2013, the prevalence of urethral carcinoma in the 28 European Union countries was 3,986 cases with an estimated annual incidence of 1,504 new cases, with a male/female prevalence of 2.9: 1 [8]. Likewise, in an updated analysis of the Surveillance, Epidemiology and End Results (SEER) database (2004–2016), the incidence of primary urethral carcinoma peaked in the > 75 years age group (7.6/million). The age-standardised rate was 4.3/million in men and 1.5/million in women and was almost negligible in those aged < 55 years (0.2/million) [9]. After matching for tumour and patient characteristics, women present with higher disease stage and exhibited higher cancer-specific mortality (CSM) [10].

3.2 Aetiology

For male primary urethral carcinoma, various predisposing factors have been reported, including urethral strictures [11, 12], chronic irritation after intermittent catheterisation/urethroplasty [13-15], external beam irradiation therapy (EBRT) [16], radioactive seed implantation [17], chronic urethral inflammation/urethritis following sexually transmitted diseases (i.e., condylomata associated with human papilloma virus 16) [18, 19] and lichen sclerosis [12]. In female urethral carcinoma, urethral diverticula [20-22] and recurrent urinary tract infections [23] have been associated with primary urethral carcinoma. Mid-urethral sling meshes have not been associated with an increased risk of primary urethral carcinoma [24]. Clear-cell adenocarcinoma (AC) may also have a congenital origin [25, 26].

3.3 Histopathology and genomic profiling

Both the Surveillance of Rare Cancers in Europe (RARECARE) project and SEER database have reported that urothelial carcinoma (UC) of the urethra is the predominant histological type of primary urethral cancer (54–65%), followed by squamous cell carcinoma (SCC) (16–22%) and AC (10–16%) [8, 27].

A SEER analysis of 2,065 men with primary urethral carcinoma (mean age 73 years) found that UC was most common (78%), and SCC (12%) and AC (5%) were significantly less frequent [28]. In women, AC is the more frequent histology (38–46.7%) followed by SCC (25.4–28%), UC (24.9–28%) and other histological entities (6%) [29, 30]. Primary UC with unconventional histological subtypes are very rare and exhibit a dismal prognosis [31]. An analysis of the SEER database from 2004 to 2016 identified 165 cases of Primary UC with unconventional histological subtypes, 70.3% of which were in women, and reported that Mullerian-type tumor is the most frequent unconventional histology of urethral cancer, followed by melanocytic-type histology [31].

.

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Tumour, Node, Metastasis (UICC/TNM) staging system

In men and women, urethral carcinoma is classified according to the 8th edition of the TNM classification [7] (Table 4.1). It should be noted that there is a separate TNM staging system for prostatic UC [7]. Of note, for cancers occurring in the urethral diverticulum, stage T2 is not applicable as urethral diverticula are lacking periurethral muscle [32].

Table 4.1: TNM classification (8th edition) for urethral carcinoma [7]

T - Primary Tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Urethra (male and female)	
Ta	Non-invasive papillary, polypoid, or verrucous carcinoma
Tis	Carcinoma *in situ*
T1	Tumour invades subepithelial connective tissue
T2	Tumour invades any of the following: corpus spongiosum, prostate, periurethral muscle
T3	Tumour invades any of the following: corpus cavernosum, beyond prostatic capsule, anterior vagina, bladder neck (extraprostatic extension)
T4	Tumour invades other adjacent organs (invasion of the bladder)
Urothelial (transitional cell) carcinoma of the prostate	
Tis pu	Carcinoma *in situ,* involvement of prostatic urethra
Tis pd	Carcinoma *in situ,* involvement of prostatic ducts
T1	Tumour invades subepithelial connective tissue (for tumours involving prostatic urethra only)
T2	Tumour invades any of the following: prostatic stroma, corpus spongiosum, periurethral muscle
T3	Tumour invades any of the following: corpus cavernosum, beyond prostatic capsule, bladder neck (extraprostatic extension)
T4	Tumour invades other adjacent organs (invasion of the bladder or rectum)
N - Regional Lymph Nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node
N2	Metastasis in multiple lymph nodes
M - Distant Metastasis	
M0	No distant metastasis
M1	Distant metastasis

4.2 Tumour grade

Non-urothelial urethral carcinoma is graded by a trinomial system that differentiates between well-differentiated (G1), moderately-differentiated (G2), and poorly-differentiated tumours (G3). In primary urothelial carcinoma histological subtypes are extremely rare. Table 4.2 lists the different grading systems according to the WHO 2022 system [33].

Table 4.2: Histopathological grading of urothelial and non-urothelial primary urethral carcinoma [33]

Urothelial urethral carcinoma	
PUNLMP	Papillary urothelial neoplasm of low malignant potential
Low grade	Well differentiated
High grade	Poorly differentiated

Non-urothelial urethral carcinoma	
Gx	Tumour grade not assessable
G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated

4.3 Handling of tumour specimens

Specimen handling should follow the general rules as published by the International Collaboration on Cancer Reporting [34].

Table 4.3: Required and recommended elements for pathology reporting of carcinoma of the urethra in urethrectomy specimens [7, 34]

Required		Recommended	
Operative procedure		Clinical information	Previous history of urinary tract disease or distant metastasis
Additional specimens submitted			Previous therapy
Maximum tumour dimension	Cannot be assessed		Other clinical information
	No macroscopically visible tumour	Tumour focality	
	Maximum tumour dimension (largest tumour)	Other tumour dimensions (than maximum dimension) of the largest tumour	
Macroscopic tumour site		Block identification key	
Macroscopic extent of invasion		Associated epithelial lesions	
Histological tumour type	Histological subtype/ variant (urothelial carcinoma)	Extranodal spread for involved regional lymph node(s)	
Non-invasive carcinoma		Coexistent pathology	
Histological tumour grade		Ancillary studies	
Microscopic extent of invasion			
Lymphovascular invasion			
Margin status			
Regional lymph node status	No regional lymph nodes submitted		

4.4 Guideline for staging and classification systems

Recommendation	Strength rating
Use the 2017 TNM classification and 2022 WHO grading system for pathological staging and grading of primary urethral carcinoma.	Strong

5. DIAGNOSTIC EVALUATION AND STAGING

5.1 History

When becoming clinically apparent, most patients (45–57%) with primary urethral carcinoma present with symptoms associated with locally-advanced disease (T3/T4) [35]. At initial presentation visible haematuria or bloody urethral discharge is reported in up to 62% of the cases. Further symptoms of locally-advanced disease include; an extra-urethral mass (52%), bladder outlet obstruction (48%), pelvic pain (33%), urethrocutaneous fistula (10%), abscess formation (5%) or dyspareunia [35].

5.2 Clinical examination

In men, physical examination should comprise palpation of the external genitalia for suspicious indurations or masses and digital rectal examination [36]. In women, further pelvic examination and palpation of the urethra should be performed. In addition, bimanual examination, when necessary under general anaesthesia, should be performed for local clinical staging and to assess whether colorectal or gynaecological malignancies are present.

Bilateral inguinal palpation should be done to assess the presence of enlarged LNs, describing location, size, and mobility [37].

5.3 Urinary cytology

Urinary cytology is part of the standard work-up of a patient with suspected primary urethral carcinoma. Reporting of urinary cytology findings should follow the Paris system [38]. However, the role of urinary cytology in primary urethral carcinoma is limited since its sensitivity ranges between 55% and 59% [39]. Detection rates depend on the underlying histological entity. In male patients, the sensitivity for UC and SCC was reported to be 80% and 50%, respectively, whereas in female patients, sensitivity was found to be 77% for SCC and 50% for UC [39].

5.4 Diagnostic urethrocystoscopy and biopsy

Diagnostic urethrocystoscopy and biopsy enables primary assessment of a urethral tumour in terms of tumour extent, location, and underlying histology [36]. Cystoscopic examination is necessary to exclude the presence of concomitant bladder tumours [40].

A cold-cup biopsy enables accurate tissue retrieval for histological analysis and avoids artificial tissue damage. In patients with larger lesions, transurethral resection (optionally in men under penile blood arrest using a tourniquet) can be performed for histological diagnosis [41]. In patients with suspected UC of the prostatic urethra or ducts, resectoscope loop biopsy of the prostatic urethra (between the five and seven o'clock position from the bladder neck and distally around the area of the verumontanum) can contribute to an improved detection rate [42].

To enable accurate pathological assessment of surgical margins, biopsy sites (proximal/distal end) should be marked and sent together with clinical information to the pathologist. To obtain all relevant information, the collection, handling, and evaluation of biopsy specimen should follow the recommendations provided by the International Collaboration on Cancer Reporting (see Table 4.3) [34].

5.5 Imaging for diagnosis and staging

Radiological imaging of urethral carcinoma aims to assess local staging and to detect lymphatic and distant metastatic spread. In a recent multicentre study, the accuracy of cross-sectional imaging for clinical tumour and nodal staging predicting final pathological staging was found to be 72.9% and 70.6%, respectively [43]. Imaging work-up should include computed tomography (CT) of the chest, abdomen and pelvis for staging, including CT urography for urothelial evaluation. Magnetic resonance imaging (MRI) can be used to evaluate tumour location and size, as well as local tumour extent and presence of regional LN metastases, focusing in particular on inguinal and pelvic LNs [44-48].

For local staging, there is evidence that MRI is an accurate tool for monitoring tumour response to neoadjuvant chemoradiotherapy and evaluating the extent of local disease prior to exenterative surgery [49].

^{18}F-Fluorodeoxglucose positron emission tomography/MRI has shown to improve the diagnostic evaluation in patients with metastatic disease [50].

5.6 Regional lymph nodes

In urethral carcinoma enlarged LNs often represent metastatic disease (~84% of patients) [51-53], which is in contrast to penile cancer where this is the case in ~41% of patients [54]. In men, lymphatics from the anterior urethra drain into the superficial- and deep inguinal LNs and, subsequently, to the pelvic (external, obturator and internal iliac) LNs. Conversely, lymphatic vessels of the posterior urethra drain into the pelvic LNs. In women, the lymph of the proximal third drains into the pelvic LN chains, whereas the distal two-thirds initially drain into the superficial- and deep inguinal nodes [55, 56].

5.7 Summary of evidence and guidelines for diagnostic evaluation and staging

Summary of evidence	LE
Patients with clinically enlarged inguinal or pelvic LNs often exhibit pathological LN metastasis.	3

Recommendations	Strength rating
Use urethrocystoscopy with biopsy and urinary cytology to diagnose urethral carcinoma.	Strong
Assess the presence of distant metastases by computed tomography of the thorax and abdomen/pelvis.	Strong
Use pelvic magnetic resonance imaging to assess the local extent of urethral tumour and regional lymph node enlargement.	Strong

6. PROGNOSIS

6.1 Long-term survival after primary urethral carcinoma

According to the RARECARE project, the one- and 5-year relative overall survival (OS) rates in patients with urethral carcinoma in Europe are 71% and 54%, respectively [8]. Based on longer follow-up, an analysis of the SEER database, comparing prognostic factors in rare pathological types of primary urethral carcinoma (n = 257) and common pathological groups (n = 2,651), reported 10-year OS rates of 42.4% and 31.9%, respectively [57]. Cancer-specific survival (CSS) rates at five and ten years were 68% and 60%, respectively [58]. Age (> 60 years), race (others vs. whites), T-stage (T3/T4 vs. Ta–T2) and M-stage (M1 vs. M0) were independent prognostic risk factors for OS and CSS in rare pathological variants [57].

6.2 Predictors of survival in primary urethral carcinoma

Previous series reported no substantial difference in 5-year OS rates between the sexes [8, 30, 59], whereas in a recent SEER analysis female patients showed higher stage disease and 5-year CSM despite higher use of multimodal therapy [10, 60]. Prognostic factors of worse survival in patients with primary urethral carcinoma are:

- advanced age (> 65 years) and black race [8, 30, 60, 61];
- higher stage, grade, nodal involvement [52, 62] and metastasis [28];
- increased tumour size and proximal tumour location [28];
- underlying (non-urothelial or unconventional) histology [8, 28, 31, 61-64];
- presence of concomitant bladder cancer [40];
- extent of surgical treatment and treatment modality [28, 61, 62];
- treatment in academic centres [65];
- location of recurrence (urethral vs. non-urethral) [66].

Some limitations have to be considered when interpreting these results as the number of patients included in most studies were low [63].

6.3 Summary of evidence for prognosis

Summary of evidence	LE
Prognostic factors for survival in primary urethral carcinoma are: age, gender, race, tumour stage and grade, nodal stage, presence of distant metastasis, histological type, tumour size, tumour location, concomitant bladder cancer and type and modality of treatment.	3
In locally-advanced urothelial- and SCC of the urethra, treatment in academic centres improves OS.	3

7. DISEASE MANAGEMENT

7.1 Treatment of primary urethral carcinoma in males

Previously, treatment of male distal urethral carcinoma followed the procedure for penile cancer, with surgical excision of the primary lesion with a wide safety margin [36]. Distal urethral tumours exhibit significantly improved survival rates compared with proximal tumours [67]. Therefore, in the treatment of distal urethral carcinoma the focus of clinicians has shifted towards improving functional outcomes and quality of life (QoL), while preserving oncological safety. A retrospective series found no evidence of local recurrence, even with < 5 mm resection margins (median follow-up: 17–37 months), in men with pT1–3N0–2 distal urethral carcinoma treated with well-defined penile-preserving surgery and additional iliac/inguinal lymphadenectomy (LND) for clinically suspected LN disease [68]. Similar results for the feasibility of penile-preserving surgery have also been reported in recent series [69, 70]. However, a series on patients treated with penile-preserving surgery for distal urethral carcinoma reported a higher risk of progression in patients with positive proximal margins, which was also more frequently observed in cases with lymphovascular and peri-neural invasion of the primary tumour [71].

7.1.1 Summary of evidence and guidelines for the treatment of primary urethral carcinoma in males

Summary of evidence	LE
In distal urethral tumours performing a partial urethrectomy with a minimal safety margin does not increase the risk of local recurrence.	3

Recommendations	Strength rating
Offer distal urethrectomy as an alternative to penile amputation in localised distal urethral tumours, if negative surgical margins can be achieved intra-operatively.	Weak
Ensure complete circumferential assessment of the proximal urethral margin if penile preserving surgery is intended.	Strong

7.2 Treatment of localised primary urethral carcinoma in females

7.2.1 Urethrectomy and urethra-sparing surgery

In women with localised urethral carcinoma, to provide the highest chance of local cure, primary radical urethrectomy should include removal of all the peri-urethral tissue from the bulbocavernosus muscle bilaterally and distally, with a cylinder of all adjacent soft tissue up to the pubic symphysis and bladder neck. Bladder neck closure and appendicovesicostomy for primary distal urethral lesions has been shown to provide satisfactory functional results [37].

Previous series have reported outcomes in women with mainly distal urethral tumours undergoing primary treatment with urethra-sparing surgery, with or without additional radiotherapy (RT) compared to primary urethrectomy with the aim of maintaining integrity and function of the lower urinary tract [72, 73]. In longer-term series with a median follow-up of 153–175 months, local recurrence rates in women undergoing partial urethrectomy with intra-operative frozen section analysis were 22–60%, and distal sleeve resection of > 2 cm resulted in secondary urinary incontinence in 42% of patients who subsequently required additional reconstructive surgery [72, 73].

Ablative surgical techniques, i.e., transurethral resection (TUR) or laser, used for small distal urethral tumours, have also resulted in considerable local failure rates of 16%, with a CSS rate of 50%. This emphasises the critical role of local tumour control in women with distal urethral carcinoma to prevent local and systemic progression [72].

*7.2.2 **Radiotherapy***

In women, RT was investigated in several older series with a medium follow up of 91–105 months [74]. With a median cumulative dose of 65 Gy (range 40–106 Gy), the 5-year local control rate was 64% and 7-year CSS was 49% [74]. Most local failures (95%) occurred within the first two years after primary treatment [74]. The extent of urethral tumour involvement was found to be the only parameter independently associated with local tumour control but the type of RT (EBRT vs. interstitial brachytherapy) was not [74]. In one study, the addition of brachytherapy to EBRT reduced the risk of local recurrence by a factor of 4.2 [75]. Of note, pelvic toxicity in those achieving local control was considerable (49%), including urethral stenosis, fistula, necrosis, cystitis and/ or haemorrhage, with 30% of the reported complications graded as severe [74].

*7.2.3 **Summary of evidence and guidelines for the treatment of localised primary urethral carcinoma in females***

Summary of evidence	LE
In females with distal urethral tumours, urethra-sparing surgery and local RT represent alternatives to primary urethrectomy but are associated with increased risk of tumour recurrence and local toxicity.	3

Recommendations	Strength rating
Offer urethra-sparing surgery, as an alternative to primary urethrectomy, to females with distal urethral tumours, if negative surgical margins can be achieved intra-operatively.	Weak
Offer local radiotherapy, as an alternative to urethral surgery, to females with localised urethral tumours but discuss local toxicity.	Weak

7.3 Multimodal treatment in locally-advanced urethral carcinoma in both males and females

*7.3.1 **Introduction***

Multimodal therapy in primary urethral carcinoma consists of definitive surgery plus chemotherapy with additional RT [76]. Multimodal therapy was often underutilised as shown by Cahn and colleagues in locally-advanced disease (only 16%) notwithstanding promising results [76-79]. In a recent study monotherapy was associated with decreased local recurrence-free survival after adjusting for stage, histology, sex, and year of treatment ($p = 0.017$). Its use has decreased over time [80]. Treatment in academic centres was reported to result in higher utilisation of neoadjuvant- and multimodal treatment and improved OS in patients with locally-advanced urothelial- and SCC primary urethral carcinoma [65].

*7.3.2 **Preoperative cisplatin-based chemotherapy***

Retrospective studies reported that modern cisplatin-based combination chemotherapy regimens can be effective in advanced primary urethral carcinoma providing prolonged survival even in LN-positive disease. Moreover, they emphasised the critical role of surgery after chemotherapy to achieve long-term survival in patients with locally-advanced urethral carcinoma. In a study using the National Cancer Database in men with primary urothelial carcinoma, NAC was reported to decrease the risk of all-cause mortality, while AC was not associated with an OS benefit, as compared to no chemotherapy in men, with primary urothelial carcinoma neoadjuvant chemotherapy (NAC) was reported to exhibit improved OS compared with adjuvant chemotherapy [81].

In a series of 124 patients, 39 (31%) were treated with peri-operative platinum-based chemotherapy for advanced primary urethral carcinoma (twelve patients received NAC, six received neoadjuvant chemoradiotherapy and 21 adjuvant chemotherapy). Patients who received NAC or chemoradiotherapy for locally-advanced primary urethral carcinoma (> cT3 and/or cN+) appeared to demonstrate improved survival compared to those who underwent upfront surgery with or without adjuvant chemotherapy [82]. Another retrospective series including 44 patients with advanced primary urethral carcinoma, reported outcomes on 21 patients who had preoperatively received cisplatin-based combination chemotherapy according to the underlying histologic subtype. The overall response rate for the various regimens was 72% and the median OS 32 months [51].

7.3.3 Chemoradiotherapy in locally-advanced squamous cell carcinoma of the urethra

The clinical feasibility of local RT with concurrent chemotherapy as an alternative to surgery in locally-advanced SCC has been reported in several series. This approach offers a potential for genital preservation [83-87]. The largest, and recently updated, retrospective series reported outcomes in 25 patients with primary locally-advanced SCC of the urethra treated with two cycles of 5-fluorouracil and mitomycin C with concurrent EBRT. A complete clinical response was observed in ~80% of patients. The 5-year OS and disease-specific survival was 52% and 68%, respectively. In this updated series, salvage surgery, initiated only in non-responders or in case of local failure, was not reported to be associated with improved survival [83].

A large retrospective cohort study in patients with locally-advanced urethral carcinoma treated with adjuvant RT and surgery vs. surgery alone demonstrated that the addition of RT improved OS [88].

7.3.4 Salvage treatment in recurrent primary urethral carcinoma after surgery for primary treatment

A multicentre study reported that patients who were treated with surgery as primary therapy and underwent surgery or RT-based salvage treatment for recurrent solitary or concomitant urethral disease, demonstrated similar survival rates compared to patients who never developed recurrence after primary treatment [66].

7.3.5 Treatment of regional lymph nodes

Nodal control in urethral carcinoma can be achieved either by regional lymph node (LN) dissection [36], RT [74] or chemotherapy [51]. Currently, there is still no clear evidence supporting prophylactic bilateral inguinal and/or pelvic LND in all patients with urethral carcinoma [53]. However, in patients with clinically enlarged inguinal/pelvic LNs or invasive tumours, regional LND should be considered as initial treatment since cure might still be achievable with limited disease [36]. It was recently shown that in patients with invasive urethral SCC and cN1–2 disease, inguinal LND conferred an OS benefit [53].

7.3.6 Summary of evidence and guidelines for multimodal treatment in advanced urethral carcinoma in both males and females

Summary of evidence	LE
In locally-advanced urethral carcinoma, cisplatin-based chemotherapy with curative intent prior to surgery might improve survival compared to chemotherapy alone, or surgery followed by chemotherapy.	3
In locally-advanced SCC of the urethra, treatment with chemoradiotherapy might be an alternative to surgery.	3
In locally-advanced urothelial- and SCC of the urethra, treatment in academic centres improves OS.	3

Recommendations	Strength rating
Refer patients with advanced urethral carcinoma to academic centres.	Strong
Discuss treatment of patients with locally-advanced urethral carcinoma within a multidisciplinary team of urologists, radiation-oncologists, and oncologists.	Strong
In locally-advanced urethral carcinoma, use cisplatin-based chemotherapeutic regimens with curative intent prior to surgery.	Weak
In locally-advanced squamous cell carcinoma (SCC) of the urethra, offer the combination of curative radiotherapy (RT) with radiosensitising chemotherapy for definitive treatment and genital preservation.	Weak
Offer salvage surgery or RT to patients with urethral recurrence after primary treatment.	Weak
Offer inguinal lymph node (LN) dissection to patients with limited LN-positive urethral SCC.	Weak

7.4 Treatment of urothelial carcinoma of the prostate

Local conservative treatment with extensive TUR and subsequent BCG instillation is effective in patients with Ta or Tis prostatic urethral carcinoma [89]. A systematic review reported patients treated with TURP before BCG show a better local response in the prostatic urethra with a higher disease-free survival (80–100% vs. 63–89%) and progression free survival (PFS) (90–100% vs. 75–94%) than patients in studies in which no TURP was performed [91]. Risk of understaging local extension of prostatic urethral cancer at TUR is high in patients with ductal or stromal involvement [90]. Some earlier series have reported superior oncological results for the initial use of radical cystoprostatectomy as a primary treatment option in patients with ductal involvement [91, 92]. In 24 patients with prostatic stromal invasion treated with radical cystoprostatectomy, a LN mapping study found that twelve patients had positive LNs, with an increased proportion located above the iliac bifurcation [93].

7.4.1 Summary of evidence and guidelines for the treatment of urothelial carcinoma of the prostate

Summary of evidence	LE
Patients undergoing TUR of the prostate for prostatic urothelial carcinoma prior to BCG treatment show superior complete response rates compared to those who do not.	3

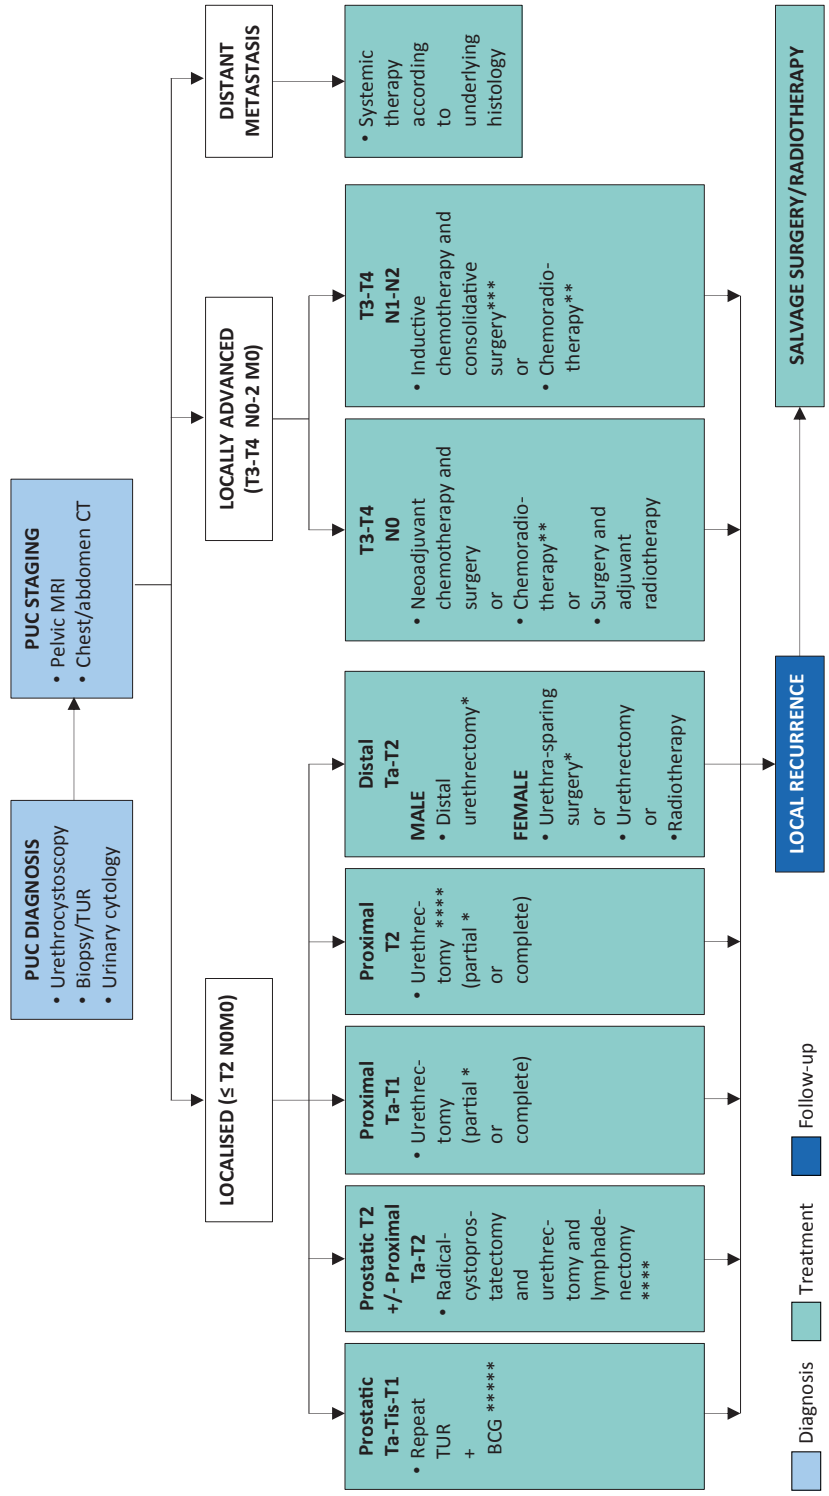
Recommendations	Strength rating
Offer a urethra-sparing approach with transurethral resection (TUR) and bacillus-Calmette Guérin (BCG) to patients with non-invasive urethral carcinoma or carcinoma *in situ* of the prostatic urethra and prostatic ducts.	Strong
In patients not responding to BCG, or in patients with extensive ductal or stromal involvement, perform a cystoprostatectomy with extended pelvic lymphadenectomy.	Weak

7.5 Metastatic disease

A recent analysis of the SEER database reported that patients with M1 disease who underwent primary site surgery did not exhibit any survival benefit [59]. Systemic therapy in metastatic disease should be selected based on the histology of the tumour. The EAU Guidelines on Muscle-invasive and Metastatic Bladder Cancer can be followed if UC is the predominant histology [2]. Even though urethral carcinoma patients have been included in large clinical trials on immunotherapy, so far, in terms of response rates, no subgroup analyses are available [94].

In addition, there is an urgent clinical need to better address the role of local palliative treatment strategies in primary urethral carcinoma including surgery, which has shown to impact positively on QoL aspects in selected patients with advanced genital cancers [95].

Figure 7.1: Management of primary urethral carcinoma



* *Ensure complete circumferential assessment if penile-preserving/urethra-sparing surgery or partial urethrectomy is intended.*

** *Squamous cell carcinoma.*

*** *Regional lymphadenectomy should be considered in clinically enlarged lymph nodes.*

**** *Consider neoadjuvant chemotherapy.*

***** *In extensive or BCG-unresponsive disease: consider (primary) cystoprostatectomy +/- urethrectomy + lymphadenectomy.*

BCG = bacillus Calmette-Guérin; CT = computed tomography; MRI = magnetic resonance imaging; PUC = primary urethral carcinoma; TUR = transurethral resection.

8. FOLLOW-UP

Given the low incidence of primary urethral carcinoma, follow-up has not been systematically investigated. Therefore, it seems reasonable to tailor surveillance regimens to patients' individual risk factors (see Section 6.2). In patients undergoing urethra-sparing surgery, it seems prudent to advocate a more extensive follow-up with urinary cytology, urethrocystoscopy and cross-sectional imaging despite the lack of specific data.

8.1 Research priorities

There are clear gaps in the clinical literature related to the diagnosis, management and follow-up of patients with primary urethral carcinoma. As this is a rare disease, data will likely become available through quality registries and datasets, similar to those currently being set up by the eUrogen initiative.

The Panel identified the following topics as of interest:

- The (long-term) efficacy of urethral-sparing surgery and chemoradiotherapy for genital preservation in localised and locally-advanced tumours;
- The prognostic impact of neoadjuvant and adjuvant treatment modalities in locally-advanced disease;
- The therapeutic benefit and clinical safety of programmed cell death (ligand)-1 inhibitors for the treatment of advanced primary urethral carcinoma;
- The role of MRI in the local assessment of response to therapy.

10. CONFLICT OF INTEREST

All members of the Muscle-invasive and Metastatic Bladder Cancer Guidelines Panel have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is open access available on the European Association of Urology website: http://www.uroweb.org/guidelines/primary-urethral-carcinoma/.

This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

11. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Paris 2024. ISBN 978-94-92671-23-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, The Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aim and objectives

The European Association of Urology (EAU) - American Society of Clinical Oncology (ASCO) Guidelines on Penile Cancer provide up-to-date information on the diagnosis and management of penile squamous cell carcinoma (SCC).

It must be emphasised that clinical guidelines present the best level of evidence available to the experts but following guideline recommendations will not necessarily result in the best treatment-related outcomes for a given patient. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions. Taking patient's personal values and preferences/ individual circumstances into account is of paramount importance. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU-ASCO Penile Cancer Guidelines Panel consists of an international multi-disciplinary group of clinicians, including urologists, pathologists, oncologists, radiation oncologists, and patient advocates. The members of this Panel have been selected based on their expertise and to represent the multi-disciplinary professionals caring for patients suspected of having penile cancer. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU website Uroweb: http://uroweb.org/guideline/penile-cancer/.

1.3 Available publications

A quick reference document (Pocket guidelines) is available. This is an abridged version which may require consultation together with the full text version. This 2023 updated document presents a complete revision of the prior (2018) publication. All prior versions can be viewed at the EAU website: https://uroweb.org/guidelines/archive/penile-cancer.

1.4 Publication history

The EAU Penile Cancer Guidelines were first published in 2000; the current 2023 EAU-ASCO publication presents a complete revision of the prior print. The next update of the Penile Cancer Guidelines will be published in 2026.

1.5 Preface

Penile cancer has a significant impact on quality of life (QoL) in many ways. Patients not only suffer the psychological and emotional stress of a cancer diagnosis and what that means for the rest of their lives, but also the psychological impact and stigma of cancer on an intimate part of the body. The treatments also cause significant physical and emotional changes, resulting in feelings of mutilation, loss of masculinity and coping with the impact on voiding and sexual function, which in turn can result in relationship breakdowns and withdrawal from society. Long-term managing lymphoedema also presents a challenge for many of these men.

As a Guideline Panel, we have chosen to stress the importance of QoL in penile cancer at the beginning of our guidelines, we feel strongly that these significant emotional, social, and physical needs are discussed and addressed early in the patient pathway, through a holistic and multi-disciplinary approach. An important part of a holistic approach is access to palliative care. The World Health Organization (WHO) definition of palliative care states it "*is a crucial part of integrated, people-centered health services. Relieving serious health-related suffering, be it physical, psychological, social, or spiritual, is a global ethical responsibility*" [1]. As a result, access to palliative care should be available to patients throughout their cancer pathway.

It is important to recognise the evolving needs of a patient with a diagnosis of penile cancer, even several months following the completion of treatment, and therefore appropriate follow-up and patient support services are also a critical aspect of penile cancer care.

Reality is that much of the literature on this rare cancer over the last two decades has focused on oncological outcomes rather than functional- and QoL outcomes. So much more needs to be done to investigate these issues and address the many unmet needs of patients diagnosed with penile cancer, some of which are described in Table 1.1 [2].

Table 1.1: Unmet needs of penile cancer patients

Emotional needs	Relationship needs	Medical needs
Loss of masculinity	Impact on relationship with partner	Lack of advice on how to cope
Shock/disbelief	Sexual	Lymphoedema
Depression/sadness	Performance anxiety/cannot satisfy partner	Lack of information on what to expect after surgery
Fear	Concerns on how to tell family	Sit down to urinate/cleanliness of toilets
Anxiety	Relationships damaged or lost	Lack of rehabilitation/supportive care
Embarrassment/stigma	Avoiding meeting friends/new relationships	Missed/incorrect diagnosis

2. METHODS

2.1 Data identification

For the 2023 Penile Cancer Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature. Comprehensive literature searches were done for two major sections: epidemiology, aetiology, pathology and patient support services. Databases searched included Medline, EMBASE and the Cochrane Libraries.

All search histories are available online, as are the protocols and publications of the various systematic reviews (SRs).

For the remaining sections of the text three SRs were conducted:

Review 1. What Is the Most Effective Management of the Primary Tumor in Men with Invasive Penile Cancer: A Systematic Review of the Available Treatment Options and Their Outcomes [3].

Review 2. Management of lymph node-positive penile cancer: a systematic review (in peer review).

Review 3. Systematic review and meta-analysis of minimally-invasive procedures for inguinal nodal staging in penile carcinoma: DSNB and VEIL (manuscript in preparation).

Recommendation within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences [4, 5]. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [6];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention.

Strong recommendations typically indicate a high degree of evidence quality and/or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [7].

Additional information can be found in the general Methodology section of this print, and online at the EAU website; http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review and future goals

This document was subject to independent peer review prior to publication. Publications ensuing from published SRs have all been peer reviewed.

The results of ongoing SRs will be included in the 2026 update of the ASCO-EAU Penile Cancer Guidelines. One such review is currently ongoing:

- Systematic review and meta-analysis of minimally-invasive procedures for inguinal nodal staging in penile carcinoma: DSNB and VEIL.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Definition of penile cancer

More than 95% of penile cancers are SCCs. There are several recognised subtypes of penile SCC with different clinical features and natural history (see Table 3.1). Penile SCC usually arises from the epithelium of the inner prepuce or the glans.

Table 3.1: Histological subtypes of penile carcinomas according to the 2020 WHO Classification [8, 9]**, frequency and outcomes** (Modified from [10])

Subtype	Frequency (% of cases)	Mortality (%)	Other features
HPV-independent SCC			
Usual	45 – 75	20 – 38	Diagnosis of exclusion. Various degrees of differentiation
Pseudohyperplastic*	< 1	0	Well-differentiated, superficially spreading simulating pseudoepitheliomatous hyperplasia
Pseudoglandular*	< 1	30	Poorly-differentiated carcinoma with acantholytic pseudolumina simulating glands
Verrucous	3 – 8	0	Extremely well-differentiated, broad-based, and pushing tumour front. No metastasis reported
Cuniculatum	< 1	0	Endophytic labyrinthine growth pattern with broad-based pushing margins.
Papillary	2 – 15	0 – 6	Papillae covered by well- to moderately differentiated cells without koilocytes
Sarcomatoid	1 -7	45 – 90	Biphasic epithelial and spindle cell neoplasia. Most aggressive and worse prognosis.
Mixed	10 – 19	3 – 7	Two or more subtypes in the same specimen. Prognosis is related to the subtypes involved.
HPV-associated			
Basaloid	4 – 10	21 – 67	Uniform basaloid cells in nests or sheets, with comedonecrosis or abrupt keratinisation.
Warty	5 – 10	0 – 10	Condylomatous papillae with central fibrovascular cores and koilocytes.
Clear cell	< 1	20 – 30	Nests or sheets of cells with ample, clear cytoplasm with central of geographical necrosis.
Lymphoepithelioma-like	< 1	Unknown	Poorly differentiated cells intermixed with dense lymphoplasmacytic and eosinophilic infiltrate.
Mixed	4 - 10	30 - 50	Mainly Warty-basaloid carcinoma according to the WHO 2022.

Others			
SCC NOS (not-otherwise specified)	Unknown	Unknown	Keratinizing carcinoma. This must be used only when evaluation of p16 is not available.
Adenosquamous	1 – 2	0–14	Squamous tumour nests intermixed with a minor mucinous glandular component.
Mucoepidermoid	Unknown	Unknown	Clear separation between adenosquamous and mucoepidermoid is not provided in the WHO classification. Salivary glands criteria can be applied but there is no consensus.

HPV = human papillomavirus; SCC = squamous cell carcinoma; WHO = World Health Organization.
** WHO 2022 classification consider these subtypes part of usual SCC.*
*** This is considered a variant of the cuniculatum carcinoma.*

3.2 Epidemiology

Penile cancer incidence varies across the world (Fig. 3.1). In industrialised countries, penile cancer is uncommon, with an overall incidence of around 0.94/100,000 males in Europe and 0.5 in the USA [11, 12]. In contrast, in South America, Southeast Asia and parts of Africa, the incidence is much higher and can account for 1–2% of malignant disease in men [12]. The annual age-adjusted incidence is 0.7–3.0 in India, 8.3 in Brazil (per 100,000, respectively) and is higher in parts of Africa such as Uganda [12, 13].

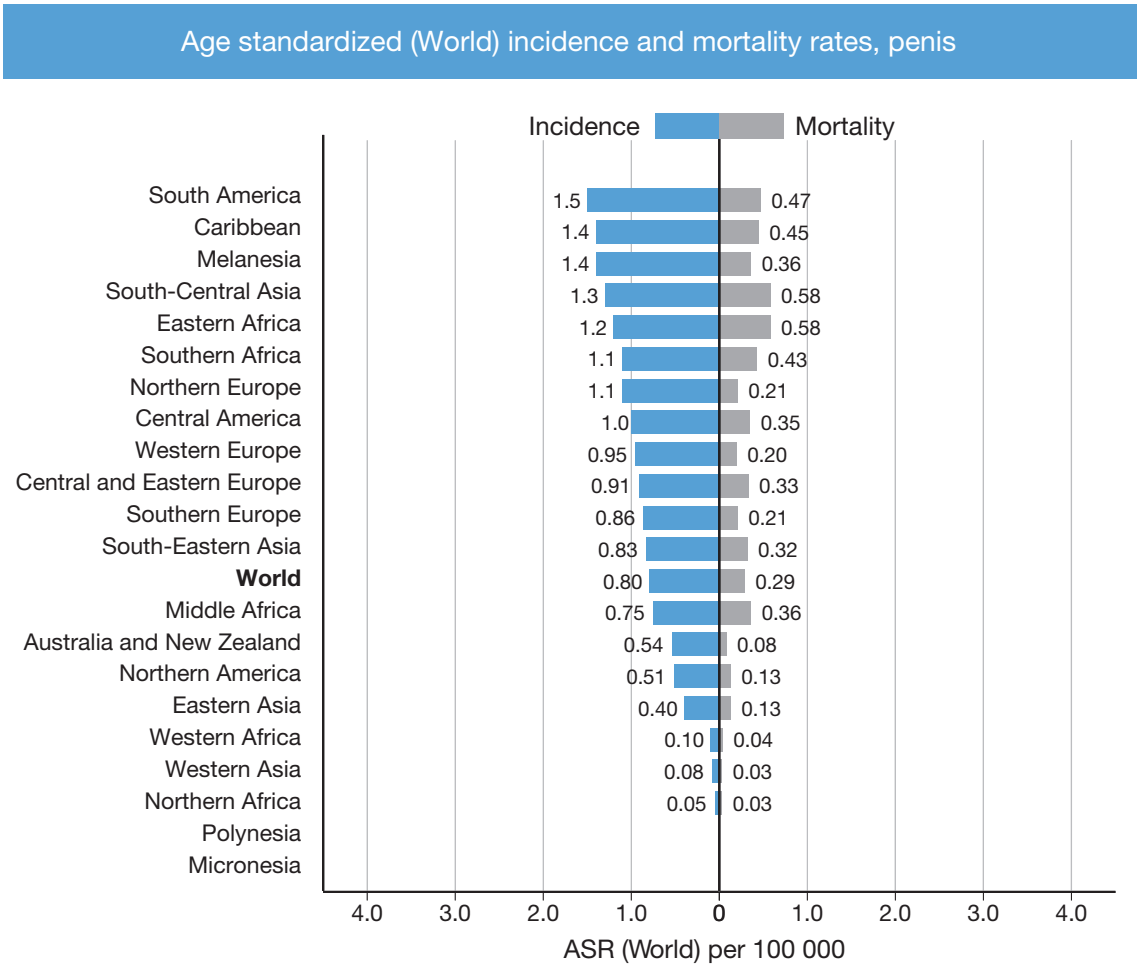
In Europe, there is considerable variation across countries. Data from Norway showed an increase in the age-standardised incidence rates in 5-year periods from 2001-2015 compared to the previous periods (0.65/100,000 in 1956–60 vs. 0.91/100,000, in 2011-2015) with an Estimated Annual Percent Change of +0.80% [14]. In the United Kingdom, the age-standardised incidence rate increased 28% between 1993 and 2018. This trend was seen in age groups from 50–79 years old. Incidence rates remained unchanged for both age extremes (< 50 and > 79 years) [15]. Based on 16 cancer registries in France, incidence rates between 2009 and 2011 were 0.59 per 100,000 men (95% CI: 0.50–0.68) and these rates have remained stable since 1989 [16].

In the USA, the incidence of penile cancer is affected by race and ethnicity, with the highest incidence in white Hispanics (1.01), followed by Alaskans and Native American Indians (0.77), African Americans (0.62) and white non-Hispanics (0.51), per 100,000 males, respectively. The overall age-adjusted incidence rate decreased between 1973 and 2002; per decade from 0.84 (1973–1982), to 0.69 (1983–1992), and 0.58 (1993–2002) per 100,000 males, respectively [17]. An increasing trend, slightly surpassing the previous incidence rates, was described using the Surveillance, Epidemiology and End Result (SEER) 2000–2016 data [18], showing an estimated annual percent change of +3.5% from 2004-2016 [19].

The incidence increases with age [15, 20], with a peak in the sixth decade but it does occur in younger men [21]. Penile cancer is common in regions with a high prevalence of human papillomavirus (HPV), and approximately one-third to half of cancer cases are attributed to HPV-associated carcinogenesis [22, 23]. There are no reports linking this cancer to human immunodeficiency virus (HIV) or acquired immune deficiency syndrome (AIDS).

In summary, it seems that a slight increase in incidence is seen in Western/developed countries, most likely caused by higher infection rates of HPV which is a trend also observed in oropharynx carcinoma [24].

Figure 3.1: Annual incidence rate (world standardised) by world area [25]



3.3 Risk factors, prognosis, and prevention

Several risk factors for penile cancer have been identified, such as phimosis, chronic penile inflammation, lichen sclerosus, smoking, ultraviolet A phototherapy, and low socio-economic status, amongst others [26].

Patient outcome is influenced by clinical and histologic features. United States SEER data from 18 cancer registries indicated an overall 5-year relative survival of 67% with no significant changes when comparing 5-year spans between 2000–2014. Patients with localised disease showed the best outcome with up to 81% 5-year relative survival. Patients with distant metastases have the worst outcomes with only 16% 5-year relative survival [27].

Human papilloma virus infection is the main risk factor for penile cancer [28]. Human papilloma virus deoxyribonucleic acid (DNA) has been identified in intraepithelial neoplasia and invasive penile cancer tissue samples. The HPV virus interacts with oncogenes and tumour suppressor genes (*p16, P53, Rb* genes) [29, 30]. The rate of HPV-positivity differs between different histological subtypes of penile SCC. Human papilloma virus is a co-factor in the carcinogenesis of some subtypes of penile SCC, while others are not related to HPV. The risk of penile cancer is increased in patients with condyloma acuminata [31]. A SR of 52 studies concluded that the overall HPV prevalence in penile cancer is 50.8% (95% CI: 44.8–56.7). Among HPV-associated carcinomas, basaloid carcinoma showed the highest prevalence (84%) followed by warty-basaloid carcinoma (75.7%) and warty carcinomas (58.7%). In histologically HPV-independent carcinomas, HPV prevalence was 19.4%. The most frequent HPV genotypes were HPV16 (68.3%, 95% CI: 58.9–77.1), followed by the low-risk HPV6 genotype (8.1%, 95% CI: 4.0–13.7) [23].

In early studies, HPV has shown an inconsistent association with prognosis. In one study, a significantly better 5-year disease-specific survival (DSS) was reported for HPV-positive vs. HPV-negative cases (93% vs. 78%) [32], while no difference in lymph node (LN) metastases and 10-year survival was reported in another study [33]. This variable relationship with outcome remains unexplained but some studies suggested that it can be related to specific treatment [34] and linked to different histologic subtypes [35]. A meta-analysis published in 2018 [36] reported a pooled HR of 0.61 for penile cancer HPV-positive cases, which is in line with head, neck [37]

and anal cancers [38], with a HR of 0.34 and 0.54, respectively. Positivity for p16 immunohistochemistry (IHC), a surrogate for HPV activity, showed a prognostic value for DSS (hazard ratio [HR]: 0.45) based on two meta-analyses [36, 39]. Similar trends were reported in vulvar and anal cancers [38, 40].

There is no significant association between the incidence of penile and cervical cancer, although half of penile cancer and virtually all cervical cancer cases are linked to HPV [41]. Female sexual partners of patients with penile cancer have not been found to have an increased incidence of cervical cancer [42].

At present, except in a limited number of countries, there is no general recommendation for HPV vaccination in males because of the different HPV-associated risk patterns in penile- and cervical cancer. A meta-analysis showed that the incidence of anal (risk ratio [RR]: 0.42), oral (RR: 0.16), and cervical HPV infections (RR: 0.22) were reduced in vaccinated groups when compared against control groups, indicating that HPV vaccination leads to the prevention of HPV infection [43]. Human papilloma virus vaccination in males showed more than 50% efficacy against anal intraepithelial lesions but no meaningful estimates were obtained for penile, anal, and head and neck invasive carcinomas [44]. Since up to 50% of invasive penile carcinomas and 80% of pre-neoplastic lesions are HPV-associated, HPV vaccination is encouraged [45].

Phimosis is strongly associated with invasive penile cancer [46-49], due to associated chronic infections. However, smegma is not a carcinogen [48]. The incidence of lichen sclerosus is relatively high in penile cancer patients but is not associated with adverse histopathological features, including penile intraepithelial neoplasia (PeIN). Other epidemiological risk factors are cigarette smoking, low socio-economic status, and a low level of education [47, 49].

Neonatal circumcision reduces the incidence of penile cancer; however, it does not seem to reduce the risk of PeIN [46]. The lowest incidence of penile cancer is reported in Israeli Jews (0.3/100,000/year). One matched-pair case-control study reported that the protective effect of neonatal circumcision against invasive penile cancer (OR: 0.41) was much weaker when the analysis was restricted to men without a history of phimosis (OR: 0.79, 95% CI: 0.29–2) [46].

3.4 Pathology

Squamous cell carcinoma accounts for over 95% of penile malignancies. It is not known how often SCC is preceded by premalignant lesions [50-53]. Penile intraepithelial neoplasia is considered the precursor lesion of penile SCC, PeINs are classified into HPV-independent, known as differentiated PeIN, HPV-associated, following the same scheme as the invasive counterparts (see Table 3.2). Clinical terms such as 'Erythroplasia of Queyrat, Bowenoid papulosis and Bowen's disease' are discouraged, based on the 2022 WHO classification [8, 54].

Different histological types of penile SCC with different growth patterns, clinical aggressiveness and HPV associations have been identified (see Table 3.1). Numerous mixed forms exist such as the warty-basaloid form, with 50–60% the most common mixed form, the usual-verrucous (hybrid), usual-warty, usual-basaloid and the usual-papillary, as well as other rarer combinations.

Other malignant lesions of the penis, all much less common than penile SCC, are melanocytic lesions, mesenchymal tumours, lymphomas, and metastases. Penile metastases are frequently of prostatic, urinary bladder or colorectal origin [55]. Different types of penile sarcoma have been reported [8].

Table 3.2: Classification of penile intra-epithelial neoplasia [8]

• **HPV-independent**
o Differentiated PeIN
• **HPV-associated PeIN**
o Common patterns: basaloid (undifferentiated), warty (condylomatous), and mixed
o Other (less frequent) patterns: pagetoid, clear cell, and spindle cell histology

3.4.1 Gross handling of pathology specimens

Tissue sections determine the accuracy of histological diagnosis. Small lesions should be fully included, bigger lesions should have at least 3-4 blocks of tumour with the anatomical landmarks. Specimens should be properly oriented by the surgeons and, in case of circumcision or glans resurfacing, properly pinned to allow clear evaluation of the resection margins. Penectomy specimens must be canalised through the urethra and cut longitudinally in two halves for the evaluation of invasion of the penile structures. In larger tumours identification of distal urethra on gross (as also microscopy) may be difficult. Whole-mount inclusion and sections are recommended as they provide a better background for the appropriate identification of anatomical structures that can improve accurate staging, with a minimal increase in cost [56]. Sentinel LN should be evaluated according to a standardised IHC protocol [57] for detection of micro-metastases; lymphadenectomy/

lymph node dissection (LND) specimens should be inked, and the LNs evaluated properly since extra-capsular extension profoundly influences nodal staging and treatment decisions. Second-opinion pathology review is highly desirable for this rare tumour entity [58], as is setting up comprehensive referral centres for penile cancer management on a national level [58, 59].

*3.4.2 **Pathology report***

For standardisation and data collection purposes the dataset template from the International Collaboration on Cancer Reporting (ICCR) should be used when possible. The pathology report must include the anatomical site of the primary tumour, the histological type of SCC, grade, perineural invasion, depth of invasion, vascular invasion (venous/lymphatic), pattern of invasion, urethral invasion, invasion of corpus spongiosum/corpora cavernosum, surgical margins and p16 IHC results [60-63] (Table 3.3). The confirmation of the presence of HPV in the specimen (e.g., polymerase chain reaction [PCR], *in-situ* hybridization [ISH] for viral DNA/ribonucleic acid [RNA]) is desirable but currently only carried out in research settings.

Table 3.3: Information to include in pathology reports for penile carcinomas

Type of information*	Recommended	required
Clinical information • Prior treatments (topic, radiotherapy, chemotherapy)	x	
Surgical procedure		x
Tumour localisation • Anatomic structures involved externally (e.g.: foreskin, glans, etc.) and in depth (e.g.: dartos, corpus spongiosum, etc.)		x
Macroscopic tumour dimension • Size of tumour • Maximum thickness		x
Photographic documentation	x	
Block identification with description of the localization of the samples		x
Histological tumour type		x
Histological grade		x
Microscopic maximum dimensions • Depth of invasion (i.e., millimetres from basement membrane to deepest point of invasion) • Combination of gross and microscopic if large tumours		x
Extent of invasion (microscopic confirmation of all the involved anatomic structures)		x
Tumour invasion front (Broadly-based pushing, destructive but well-delineated, destructive irregular/finger-like invasion/tumour budding) [64-66]	x	
Lymphovascular invasion [67, 68]		x
Perineural invasion		x
Margin status in mm (margins as per specimen)		x
Lymph node status • Size of largest nodal tumour deposit (not LN size) Total number of LNs, number of positive LNs, extra-capsular spread (ECS), inguinal or pelvic, to be reported in every site separately		x
pTNM Stage		x
HPV assessment (at least p16 IHC based)		x

** See also ICCR dataset: https://www.iccr-cancer.org/datasets/published-datasets/urinary-male-genital/penis/.*

*3.4.3 **Grading***

The tumour, node, metastasis (TNM) classification for penile cancer includes tumour grade based on its prognostic relevance. Tumour grading in penile cancer has been shown to be highly observer-dependent and can be problematic, especially in large tumours which may be heterogeneous. This may have implications on the clinical management, as there may be discordance between biopsy and resection grading [50]. Inter-observer agreement varies according to the experience and specialisation of the pathologist. In general, inter-observer

agreement is poor to moderate (Fleiss' kappa 0.07–0.55) [69]. Nevertheless, until a new methodology to grade penile SCC is developed, grading based on the WHO/The International Society of Urological Pathology (ISUP) classification is recommended (see Table 3.4) with grade 3 and sarcomatoid being considered as poorly differentiated.

Table 3.4: Grading recommendations for penile SCC

Feature	Grade 1	Grade 2	Grade 3	Sarcomatoid
Cytological atypia	Mild	Moderate	Anaplasia	Sarcomatoid
Keratinisation	Usually abundant	Less prominent	May be present	Absent
Intercellular bridges	Prominent	Occasional	Few	Absent
Mitotic activity	Rare	Increased	Abundant	Abundant
Tumour margin	Pushing/well	Infiltrative/ill defined	Infiltrative/ill defined	Infiltrative/ill defined

3.4.4 Pathological prognostic factors

Pathological subtype, peri-neural invasion, lymphovascular invasion [67], depth of invasion and grade in the primary tumour are strong predictors of poor prognosis and high cancer-specific mortality [70]. Higher grade and lymphovascular invasion are predictors of metastatic spread. Lymphovascular space involvement/invasion is often seen in advanced stages but may also be seen in early invasive tumours of high grade and some histologic subtypes [71, 72]. The extent of LN metastasis and extracapsular spread are also strong predictors of prognosis.

Urethral invasion is not considered a prognostic factor (UICC, 8th Edn) [73]. Nevertheless, invasion of the more proximal urethra can signify a highly aggressive SCC with a poor prognosis probably due the invasion of subjacent erectile corpora (see Table 4.1). A SR found that invasion of the corpus spongiosum (pT2) showed better cancer-specific survival (CSS), but no overall survival (OS) benefit compared to invasion of the corpora cavernosa [74]. A modified pT2/T3 has been proposed, taking into consideration high-grade, lymphovascular- and perineural invasion features in response to this inconsistency [75]. Extra-capsular extension in even one single LN carries a poor prognosis and is denoted as pN3 [76-78].

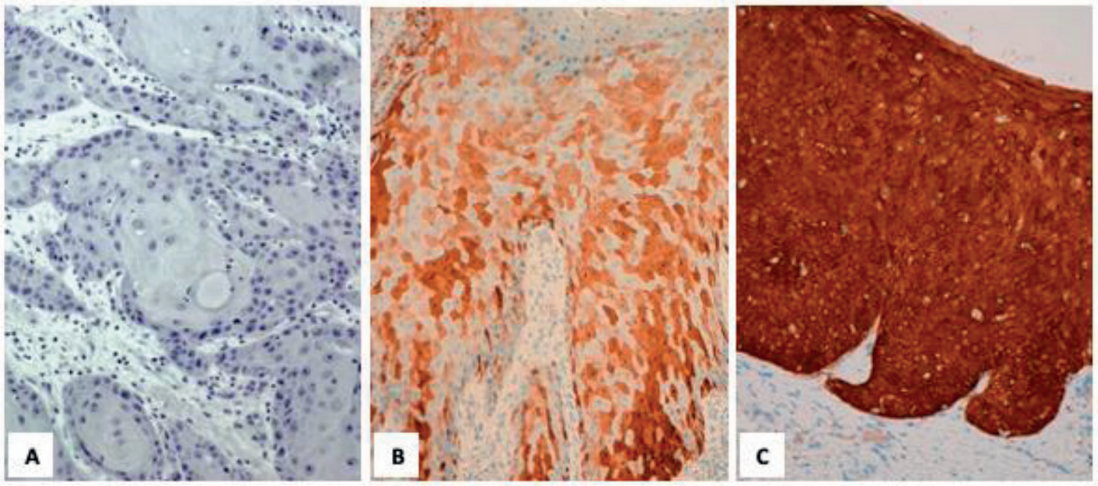
Chaux *et al.*, suggested a prognostic index which incorporates grade, anatomical level of infiltration and perineural invasion to predict the likelihood of inguinal LN metastases and 5-year survival [79]. Sali *et al*., proposed a histopathological risk scoring incorporating grade, anatomical level of involvement and replaced perineural invasion with pattern of infiltration [66]. Other clinical-, pathological- and radiological scores, as well as nomograms have been described but none of these have been comparatively validated which precludes making a recommendation.

3.4.5 Penile cancer and HPV

In the 2022 WHO classification the presence of HPV is a key determinant for the broad classification of penile SCC [8]. However, in most clinical settings, standard molecular assessment of HPV status is not available.

p16 IHC is used as a surrogate for high-risk HPV genotype presence and marker of oncogenic activity. In the absence of more advanced techniques, it is helpful in assigning penile SCC to HPV-associated subtypes. The p16 IHC overall positivity in penile cancer was 41.6% [23]. Higher positivity was seen in morphological HPV-associated SCCs (85.8%) as compared with HPV-independent SCCs (17.1%)[23]. Comparing with RNA ISH, p16 IHC showed a sensitivity of 100% and a specificity of 71%, the latter improved to 89% when considering a high intensity for p16 IHC positivity [80]. These data indicate that sensitivity, specificity, and predictive values for HPV positivity can be improved using the stringent p16 IHC cut-off suggested by Cubilla *et al.* [81] (Figure 3.2). The ISUP reported that 80% of their respondents during a consultation conference on molecular pathology of urogenital cancers used p16 IHC to separate HPV-associated from HPV-independent PeIN and SCCs and made recommendations on the use of p16 IHC [82].

Fig 3.2: Patterns of p16 expression. (A) no staining; (B) mosaic staining pattern: (C) *en-bloc* staining pattern. Only (C) is considered positive for p16.



3.4.6 Penile biopsy: pathological and technical considerations

The quality of biopsy is important [50]. In most cases, acquiring a punch biopsy (e.g., 2–3 mm) under local anaesthesia is sufficient to confirm the diagnosis. In biopsies with an average size of 1 mm, it was difficult to evaluate the depth of invasion in 91% of cases [50]. Furthermore, vascular and lymphatic tumour emboli were detected in only 9–11% of cases [50]. Therefore, in cases where assessment of depth of invasion is necessary, an incisional biopsy which is deep enough to properly assess the degree of invasion and stage is preferable.

3.4.7 Summary of evidence and guidelines for the pathological assessment of tumour specimens

Summary of evidence	LE
Incidence of penile cancer varies according to geographical location, race and ethnicity.	2a
Western developed countries have seen a slight increase in incidence, which may be caused by higher HPV infection rates.	2a
In analogy to other HPV-associated cancers, HPV status may influence DSS of penile cancer, but more data is needed, underlining the importance of routine assessment of HPV status in all penile cancer patients.	2b

Recommendations	Strength rating
The pathological evaluation of penile carcinoma specimens must include the pTNM (see Chapter 4) stage and an assessment of tumour grade.	Strong
The pathological evaluation of penile carcinoma specimens must include an assessment of p16 by immunohistochemistry.	Strong
The pathological evaluation of penile carcinoma specimens should follow the ICCR dataset synoptic report.	Strong

ICCR = International Collaboration on Cancer Reporting.

4. CLASSIFICATION SYSTEMS

4.1 TNM classification

The 8th edition of the UICC/AJCC TNM is the currently used classification system for penile cancer which was last updated in 2017 [73, 83] Compared to the previous (7th) edition, some changes were introduced. The T1 category is stratified into two different risk groups depending on the absence or presence of lymphovascular invasion, perineural invasion, or poor differentiation (T1a vs. T1b, respectively, see Table 4.1) [84]. Furthermore, invasion into the urethra was previously classified as T3 disease. However, a tumour near the meatus

may directly invade into the distal urethra through the corpus spongiosum, which is not associated with worse outcome. In addition, previous studies have shown that corpus spongiosum invasion is associated with a lower incidence of inguinal LN metastasis and has better survival compared to corpus cavernosum invasion. Therefore, invasion into the corpus spongiosum and corpus cavernosum is classified into T2 and T3, respectively [85, 86]. Patients with T4 tumours have extension into adjacent tissues (e.g., prepubic fat, scrotum, spermatic cord, pubic bone, prostate).

The pN1 category was modified to include up to two unilateral inguinal LN metastases, while the pN2 category was modified to be three or more unilateral, or any bilateral LN metastases. This was based on data showing poor outcomes in cases involving three or more unilateral or bilateral LNs compared with those involving one or two unilateral LNs [86, 87]. pN3 stage is defined as pelvic nodes (uni- or bilateral) or presence of extranodal extension (ENE) (inguinal or pelvic, regardless of the number of LN metastases) [73, 83]. Further retroperitoneal LN spread cranial to the pelvic template is classified as extra-regional and therefore as distant metastases.

Table 4.1: UICC/AJCC 8th edition TNM clinical and pathological classification of penile cancer [73, 83]

Clinical classification	
T - Primary Tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Tis	Carcinoma *in situ* (Penile Intraepithelial Neoplasia – PeIN)
Ta	Non-invasive verrucous carcinoma*
T1	Tumour invades subepithelial connective tissue
T1a	Tumour invades subepithelial connective tissue without lymphovascular invasion or perineural invasion and is not poorly differentiated
T1b	Tumour invades subepithelial connective tissue with lymphovascular invasion or perineural invasion or is poorly differentiated
T2	Tumour invades corpus spongiosum with or without invasion of the urethra
T3	Tumour invades corpus cavernosum with or without invasion of the urethra
T4	Tumour invades other adjacent structures
N - Regional Lymph Nodes	
cNX	Regional lymph nodes cannot be assessed
cN0	No palpable or visibly enlarged inguinal lymph nodes
cN1	Palpable mobile unilateral inguinal lymph node
cN2	Palpable mobile multiple or bilateral inguinal lymph nodes
cN3	Fixed inguinal nodal mass *or* pelvic lymphadenopathy, unilateral or bilateral
M - Distant Metastasis	
cM0	No distant metastasis
cM1	Distant metastasis
Pathological classification	
The pT categories correspond to the clinical T categories. The pN categories are based upon biopsy or surgical excision	
pN - Regional Lymph Nodes	
pNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis in one or two inguinal lymph nodes
pN2	Metastasis in more than two unilateral inguinal nodes or bilateral inguinal lymph nodes
pN3	Metastasis in pelvic lymph node(s), unilateral *or* bilateral or extranodal extension of regional lymph node metastasis
pM - Distant Metastasis	
pM1	Distant metastasis microscopically confirmed

G - Histopathological Grading	
GX	Grade of differentiation cannot be assessed
G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated
G4	Undifferentiated

**Including verrucous carcinoma.*

4.2 Cancer stage grouping

In the UICC TNM 8th edition, stage II was newly subdivided into Stage IIA and Stage IIB based on T categories. Stage IIA is defined as T1b–2N0M0, while Stage IIB is defined as T3N0M0 [73] (Table 4.2).

Table 4.2 UICC TNM Stage/Prognostic Groups [73]

Stage	T	N	M
0	Tis	N0	M0
	Ta	N0	M0
I	T1a	N0	M0
IIA	T1b	N0	M0
	T2	N0	M0
IIB	T3	N0	M0
IIIA	T1–3	N1	M0
IIIB	T1–3	N2	M0
IV	T4	Any N	M0
	Any T	N3	M0
	Any T	Any N	M1

5. DIAGNOSTIC EVALUATION AND STAGING

5.1 Primary lesion

5.1.1 Physical examination

Primary penile carcinoma are usually clinically evident lesions often presenting as raised or ulcerous lesions which can be locally destructive [88]. It is critically important to note that the appearance of penile tumours can be heterogeneous and can sometimes be hidden under the foreskin in case of phimosis. Physical examination should include inspection and palpation of the entire penis (to identify potential skip lesions). The dimensions, anatomic location, and extent of local invasion should be noted, and assessment of stretched penile length is recommended.

5.1.2 Imaging of the primary tumour

Physical examination is a reliable method for estimating penile tumour size and clinical T stage [89]. For distinguishing T1 from T2 disease, magnetic resonance imaging (MRI) does not outperform physical examination. However, when there is uncertainty if the tumour invades the cavernosal bodies (cT3), and if organ-sparing treatment options (e.g., glansectomy) are considered, MRI can be helpful [90, 91]. A SR showed a sensitivity and specificity of MRI in predicting corporal invasion of 80% (95% CI: 70–87%) and 96% (95% CI: 85–99%), respectively [92, 93]. Magnetic resonance imaging can also provide useful information regarding resectability in case of large (T4) tumours with invasion in adjacent structures. Magnetic resonance imaging with and without artificial erection showed similar accuracy in local staging [93]. If MRI is not available, penile ultrasound (US) can be considered [94].

5.1.3 Penile biopsy: indications

A biopsy of the penile tumour should be obtained when there is doubt about the exact nature of the lesion. However, even in clinically obvious cases, histological information from a biopsy can facilitate treatment decisions (such as

indications for surgical staging). Histological confirmation is also necessary to guide management when treatment is planned with topical agents, radiotherapy or laser surgery [88]. For technical and histopathological considerations for penile biopsy see Section 3.4.6.

5.2 Lymph node staging

Penile cancer metastasizes in a stepwise manner through the lymphatic system, initially to the inguinal nodes, then the pelvic nodes and finally to distant nodes [95]. Fewer than 5% of patients will present with distant metastases and these are generally accompanied by regional LN involvement. As a result, the most important prognostic factor for survival of penile cancer is the presence and extent of nodal metastases, with a 5-year CSS of approximately 95%, 80%, 65% and 35% for N0, N1, N2 or N3 disease, respectively [96, 97].

In patients with clinically node-negative groins (no suspicious palpable nodes, cN0), a non-randomised controlled trial (RCT) observed that early LN surgery led to a 3-year survival rate of 84% compared to 35% in those receiving delayed LN surgery, with an ENE incidence of 20% compared to 95% in the early vs. delayed surgery groups, respectively [98]. Therefore, detecting lymphatic spread as early as possible is a crucial element in penile cancer management. Since penile cancer disseminates to the inguinal LNs first, initial LN staging is focused on identifying (micro)metastatic disease in the inguinal LNs as early as possible, and imaging for distant metastases is only indicated in clinically node-positive patients.

*5.2.1 **Physical examination***

Careful palpation of both groins for enlarged/pathologic inguinal LNs must be part of the initial physical examination of patients suspected of having penile cancer. However, reliable physical exmination can be challenging in case of obesity and in patients with previous inguinal surgery. Also, enlarged LNs secondary to infection of the primary tumour (rather than metastasis) can occur. The use of antibiotics with the aim to resolve enlarged nodes may delay further staging and treatment and is not recommended [99]. Based on physical examination, patients can be divided into those without suspicious nodes at physical examination (clinically node-negative, cN0), and those with suspicious palpable nodes (clinically node-positive, cN+). In case of suspected pathologic LNs at palpation; the number, location, size and whether the node is fixed or mobile, should be noted.

*5.2.2 **Clinically node-negative patients (cN0)***

If no suspicious nodes are present at palpation (cN0), approximately 20-25% of patients may still harbour occult metastases, so additional staging is warranted [100].

5.2.2.1 Non-surgical staging options

Unfortunately, there are no validated nomograms or tumour markers that can reliably predict LN involvement. Conventional imaging modalities such as US, computed tomography (CT) or MRI cannot detect micro-metastases, and ^{18}F-fluoro-2-deoxy-D-glucose positron emission tomography (^{18}FDG-PET) does not detect LN metastases < 10 mm [101-103]. Therefore, these imaging modalities are of limited value and are not recommended for routine use in clinically node-negative patients in which the aim is to identify small, sub-clinical, LN metastasis [104, 105]. However, these imaging modalities can be of value to detect enlarged/abnormal nodes in patients when physical examination is challenging (e.g., due to obesity).

In centres that offer dynamic sentinel node biopsy (DSNB) as a surgical staging option (see Section 5.2.2.3.), inguinal US is obtained prior to DSNB. If sonographically suspicious nodes are detected, fine needle aspiration cytology (FNAC) can easily be performed in the same session to confirm the diagnosis of inguinal LN metastasis [106]. Studies incorporating US + FNAC as an initial investigation in clinically node-negative patients prior to surgical staging, reported a sensitivity and specificity of 39% and 100%, respectively. Hence, a negative US is unreliable to exclude LN metastasis in clinically node-negative patients and US should be combined with surgical staging when indicated. However, if US + FNAC is positive, it can reduce the need for DSNB by 10–13%, allowing for additional staging and therapeutic LN dissection at an earlier stage [107, 108]. Therefore, it is recommended to perform US + FNAC in clinically node-negative patients, before surgical staging with DSNB.

5.2.2.2 Indications for surgical staging

Since delayed treatment of occult LN metastasis results in a lower CSS rate and current non-invasive staging options (nomograms, imaging) are not reliable enough to detect micrometastatic disease, invasive/surgical staging remains indispensable to identify micro-metastasis before nodal metastases become palpable/visible [98]. However, surgical staging is over-treatment in the majority of patients since only 20–25% of all clinically node-negative patients harbour occult metastasis.

To select patients that are especially at risk of nodal metastases, risk categories have been established based on T stage, grade of differentiation, and the presence of lymphovascular/perineural invasion in the primary tumour. Well-differentiated (G1), pTa, pTis and pT1 tumours without lymphovascular/perineural invasion (pT1a) are considered low-risk tumours. In patients with low-risk tumours, the risk of metastases is too low to justify surgical staging. Moderately differentiated (G2) pT1a tumours are considered intermediate-risk and are associated with a 6–8% probability of (micro-)metastatic LN disease, whereas in pT1b G2 tumours, the risk is 22–30%. Therefore, all tumours that are stage T1b, or higher, are considered high-risk tumours [72, 109].

Based on these predictors, surgical staging is recommended in all high-risk tumours (T1 with presence of lympho-vascular invasion, peri-neural invasion or poorly differentiated, and T2–T4 with any grade). In intermediate-risk tumours (pT1a G2), the risk of LN metastasis should be balanced against the morbidity of surgical staging on a case-by-case basis.

5.2.2.3 Surgical staging options

By definition, radical inguinal lymph node dissection (ILND) is the most accurate surgical staging method. However, ILND is also associated with the highest complication rates (see Section 6.2 - LN management). To lower morbidity while maintaining sufficient sensitivity, modified ILND templates were developed (consisting of a shorter skin incision; no dissection lateral to the femoral artery or caudal to the fossa ovalis, and preservation of the saphenous vein) [110]. However, modified ILND is still associated with considerable complication rates of 35–49% and false-negative rates of 15–20% [111, 112]. More recently, video-endoscopic/robot-assisted radical LND was introduced (see Section 6.2 - LN management). Initial reports indicate a reduction mainly in wound-related complications compared to open ILND [113]. However, a significant reduction of lymphatic complications is not to be expected since the main predictor of lymphatic complications was shown to be the number of removed LNs [114-116], and the LN yield of the video-endoscopic approach is comparable to open ILND [117].

To avoid resecting unnecessary LNs and thereby minimising the morbidity of surgical staging, DSNB was developed [118]. A sentinel node (SN) is defined as the first LN on a direct drainage pathway from the primary tumour. Based on this concept, it is assumed that if the SN is negative, this indicates the absence of lymphatic tumour spread in the corresponding inguinal basin. In case histopathology identifies SN (micro)metastasis, ipsilateral completion ILND is indicated (see Section 6.2.2) [119]. Dynamic SN biopsy is typically performed using a combination of a radioactive tracer and patent blue dye in order to achieve optimal visualization of the lymphatic drainage system prior and during surgery. Recent innovations include the incorporation of single-photon emission computed tomography/CT (SPECT/CT) and hybrid radioactive and fluorescent tracers [120]. Throughout the years, the procedure has matured into a reliable staging technique with high diagnostic accuracy and low complication rates, especially when performed in experienced centres (sensitivity 92–96%, false-negative rates 4–8%, complication rate 6–14%) [108, 114, 121]. A recent meta-analysis reported a higher pooled false-negative rate of 12% and showed that the false-negative rate was lower in high-volume centres [122]. This might indicate a potential learning curve and supports the call for centralisation of penile cancer care.

If DSNB is not available, and referral to a centre with experience with DSNB is not feasible, or if the patient does not want to run the risk of a false-negative procedure, ILND (modified/superficial/video-endoscopic) can be considered after informing the patient of the inherent risk of higher morbidity associated with these procedures.

*5.2.3 **Clinically node-positive patients (cN+)***

In patients with palpable nodes, nodal metastases are present in approximately 45–80% of cases [123]. Lymph node metastasis should preferably be histopathologically confirmed by image-guided biopsy (e.g., US or CT). While in cN0 patients further abdominal and thoracic imaging is not recommended (See Section 5.2.2.1), it is of value in cN+ patients to clinically stage the pelvis and exclude distant metastases. Computed tomography of the chest/abdomen is broadly available, however CT has a sensitivity of only 20–38% for the detection of pelvic LNs. Magnetic resonance imaging constitutes another diagnostic staging modality; in particular in those patients with a contra-indication to iodine-based contrast agents who cannot be staged by CT. A meta-analysis comparing CT and MRI showed comparable results with a pooled sensitivity of 42% for CT and 39% for MRI and pooled specificity was 82% for both [124]. Imaging with ^{18}FDG-PET/CT is likely to be more accurate than CT alone in the pre-operative staging of pelvic LNs, as shown in other malignancies [125]. In penile cancer, ^{18}FDG-PET/CT showed a sensitivity and specificity of 91% and specificity of 100%, respectively, for the detection of pelvic metastases in patients with an US + FNAC-confirmed positive inguinal LN [126]. In patients initially staged as cN0 and who are subsequently upstaged to pN+ at surgical staging, additional imaging of the chest/abdomen should also be considered. Treatment of node-positive disease is further discussed in Section 6.2.

5.3 Summary of evidence and guidelines for the diagnosis and staging of penile cancer

Summary of evidence	LE
For distinguishing T1 from T2 disease, MRI does not outperform clinical staging.	2b
For predicting corporal invasion (T3 disease), MRI showed a pooled sensitivity and of 80% (95% CI: 70–87%) and 96% (95% CI: 85–99%), respectively.	2b
Magnetic resonance imaging with and without artificial erection showed similar accuracy in local staging.	2b
Computed Tomography, PET/CT and MRI imaging cannot detect micro-metastases and are therefore of limited value in clinically node-negative patients in which the aim is to identify small sub-clinical LN metastasis.	2a
Inguinal US + FNAC of sonographically abnormal nodes can reduce the need of DSNB when tumour positive, allowing for earlier therapeutic treatment of node-positive disease.	2a
For surgical staging of cN0 patients, DSNB has shown a high diagnostic accuracy.	2a
Sentinel node biopsy has been shown to lower complication rates compared to modified-, superficial-, or video-endoscopic inguinal LND.	2b
Imaging with ^{18}FDG-PET/CT in clinically node-positive patients showed higher sensitivity/specificity than CT alone in the pre-operative staging of the pelvic LNs and distant metastasis.	2b

Recommendations	Strength rating
Primary tumour	
Perform a detailed physical examination of the penis and external genitalia, recording morphology, size and location of the penile lesion, including extent and invasion of penile (adjacent) structures.	Strong
Perform magnetic resonance imaging (MRI) of the penis/primary tumour (artificial erection not mandatory) when there is uncertainty regarding corporal invasion and/or the feasibility of (organ-sparing) surgery. If MRI is not available, offer ultrasound (US) as alternative option.	Weak
Obtain a pre-treatment biopsy of the primary lesion when malignancy is not clinically obvious, or when non-surgical treatment of the primary lesion is planned (e.g., topical agents, laser, radiotherapy).	Strong
Inguinal lymph nodes (LN)	
Perform a physical examination of both groins. Record the number, laterality and characteristics of any palpable/suspicious inguinal nodes.	Strong
Clinically node-negative (cN0)	
If there are no palpable/suspicious nodes (cN0) at physical examination, offer surgical LN staging to all patients at high risk of having micro-metastatic disease (T1b or higher).	Strong
In case of T1a G2 disease, also discuss surveillance as an alternative to surgical staging with patients willing to comply with strict follow-up.	Weak
When surgical staging is indicated, offer dynamic sentinel node biopsy (DSNB). If DSNB is not available and referral is not feasible, or if preferred by the patient after being well informed, offer inguinal lymph node dissection (ILND) (open or video-endoscopic).	Strong
If DSNB is planned, perform inguinal US first, with fine needle aspiration cytology (FNAC) of sonographically abnormal LNs.	Strong
Clinically node-positive (cN+)	
If there is a palpable/suspicious node at physical examination (cN+), obtain (image-guided) biopsy to confirm nodal metastasis before initiating treatment.	Strong
In cN+ patients, stage the pelvis and exclude distant metastases with ^{18}F-fluoro-2-deoxy-D-glucose positron emission tomography (^{18}FDG-PET) computed tomography (CT) or CT of the chest and abdomen before initiating treatment.	Strong

6. DISEASE MANAGEMENT

6.1 Treatment of the primary tumour

Besides its role in sexual functioning and urination, a fully functional penis is central to a patient's sense of wholeness, desirability and masculinity. Hence, the aims of the treatment of the primary tumour are complete tumour removal with as much organ preservation as possible, without compromising oncological control.

There are no RCTs or observational comparative studies for any of the treatment options for localised penile cancer. Penile preservation appears to be superior in functional and cosmetic outcomes as compared to partial or total penectomy and is considered to be the primary treatment method for localised penile cancer, based on retrospective studies.

Histological diagnosis and local staging must be obtained before non-surgical treatments can be considered. For small tumours, excisional biopsy can equal treatment, while for larger lesions which necessitate more complex or mutilating surgery, an incisional biopsy is advised (see Section 3.4.6). Histology provides confirmation of the diagnosis before treatment and informs on the risk group of the primary tumour which has important consequences for invasive staging of the groins. With surgical treatment, negative surgical margins for invasive carcinoma must be obtained. Treatment of the primary tumour and of the regional nodes can either be simultaneous or staged.

Local treatment modalities for small and localised penile cancer include topical therapy, laser ablation, excisional surgery, external beam radiotherapy (EBRT) and brachytherapy. Unfortunately, the SR of the Guidelines Panel revealed a complete absence of both RCTs and prospective trials assessing and comparing the effectiveness of interventions for managing the primary tumour [3]. Treatment recommendations can therefore only be based on retrospective data and expert opinion. In the absence of comparative evidence supporting treatment modalities, patients should be informed about all appropriate treatment options for their specific tumour and situation, and the potential advantages and disadvantages for each technique which are discussed per disease stage in the following sections.

*6.1.1 **Treatment of superficial non-invasive disease (PeIN, Ta)***

Penile intra-epithelial neoplasia can progress to invasive lesions in 2.6–13% of patients, despite treatment; hence, definitive eradication and diligent follow-up monitoring are important [127-129]. Most PeIN lesions are located on the mucosal surfaces of the glans or prepuce whilst lichen sclerosus also affects the prepuce [128]. Thus, circumcision should be the primary surgical option [129]. Following circumcision, the glans mucosa keratinizes over a period of 3–6 months and any residual PeIN or lichen sclerosus may resolve. Close monitoring before starting additional therapy has been advocated, but to date, data supporting this concept are limited [129]. Considering a median time to progression to malignancy of thirteen months [128], this approach seems reasonable to test in future clinical trials.

6.1.1.1 Topical therapies

Topical therapy with imiquimod (IQ) or 5-fluorouracil (5-FU) are effective non-invasive first-line treatment options which use is increasingly reported [130]. 5-Fluorouracil exerts its effects through inhibition of the enzyme thymidylate synthase. Although no standard protocol exists, leaving the 5-FU ointment on for 12 hours every 48 hours during a 4 to 6-week treatment course is often recommended in reported series of PeIN therapy [131]. Imiquimod acts through several pathways including activation of immune cells via toll-like receptor 7, creating an inflammatory response, and is commonly used 3 times per week for 12 weeks. There is no consensus or comparative data on the optimal treatment schedules for these therapies and the evidence for these treatments is heterogenous as it only relies on retrospective studies. A SR based on the aforementioned low-quality data illustrated that topical agents showed response- and recurrence rates of 40–100% and 20% for IQ, vs. 48–74% and 11% for 5-FU, respectively [132]. Because use of 5-FU typically results in marked erythema, erosions, and crust lasting for a month or longer, decreased patient compliance with treatment regimens may result in diminished effectiveness. Similarly, IQ use is complicated by the resultant tissue effects, including erythema, oedema and erosions, ulceration and crust, that are not consistent from one individual to the next [133]. Discontinuation of topical agents because of side effects was observed in 12% of cases [132]. It is advised that treatment effects must be clinically assessed and in cases of doubt evaluated by biopsy and long-term surveillance is warranted. Insufficient responses and recurrences may signify underlying invasive disease, hence, if topical treatment fails, it should not be repeated.

6.1.1.2 Laser ablation

Laser ablation is an alternative treatment option. Energy-based therapies discussed in the literature include Neodymium:Yttrium-Aluminium-Garnet (Nd:YAG, penetration 4–6 mm, wavelength 1064 nm) or Carbon dioxide (CO_2, penetration < 1 mm, wavelength 10600 nm) lasers and photodynamic therapy [134]. Laser treatment

has shown total response rates of 52–100% with recurrence reported in 7–48% of patients [132]. Altered penile sensitivity following laser treatment has been described, including increased sensitivity in 50% and decreased sensitivity in 15% of patients. Reports show relatively high rates of local recurrence, possibly owing to inadequate penetration, difficulties in assessing borders of affected areas and missing lesions that have invaded the subepithelial tissue [10, 135, 136]. Repeat laser treatment for recurrence has been described in some series without compromising long-term oncological outcomes, which is likely a result of the low risk of the lesions treated in those series [137, 138]. For cryotherapy, with or without topical therapy, and photodynamic therapy, which induces photo-selective cell death, there are only limited data for the treatment of PeIN.

6.1.1.3 Surgery

Extensive PeIN, residual PeIN in resection margins or recurrent disease after ablative or topical therapy, can be treated by surgical excision. Glans resurfacing consists of full thickness removal of the glandular epithelium followed by reconstruction with a graft (split skin [139] or buccal mucosa for urethral reconstruction [140]). Grafts tend to have excellent engraftment rates on this well-vascularized wound bed [141]. Recurrences are reported to be low (0–20%) and cosmesis is acceptable [139, 141, 142]. If feasible, preservation of the coronal ridge helps maintain sexual function and provides excellent cosmetic outcomes as shown by a small retrospective report [143]. Resection, as opposed to ablative or topical treatments, provides the advantage of complete histopathological local staging and detection of areas of invasion; in one study in cases of glans resurfacing for presumed PeIN, up to 20% of patients were found to have invasive disease on histopathological examination [139]. Surgeons and pathologists are urged to discuss appropriate specimen handling (e.g., pinning down the skin as resected) and pathological reporting of these cases to aid further management and avoid over-reporting of positive margins [144].

*6.1.2 **Treatment of invasive disease confined to the glans (cT1/T2)***

When feasible, small and localised invasive lesions should receive organ-sparing treatment. Resection of the primary lesion not only eradicates all disease in localised invasive tumours but also provides definitive pathological staging without the risk of understaging and of missing intra-tumour heterogeneity encountered with incisional or punch biopsy [10]. Foreskin tumours are treated by 'radical' circumcision. For glandular and coronal lesions, wide local excision, partial glansectomy or total glansectomy with reconstruction, are surgical options while additional circumcision is advised in glandular tumours. External beam radiotherapy and brachytherapy are radiotherapeutic options for these patients. Laser therapy of small lesions has been reported but the risk of invasive disease must be recognised, and the recurrence risk is high, possibly as a result of the limited tissue penetration depth of laser ablation. Further research is needed to better establish the comparative safety and effectiveness of surgical and nonsurgical therapies for penile cancer.

Treatment choice depends on tumour size, histology, stage and grade, localisation and patient preference. Over the recent decades, a shift towards organ-sparing surgery has been observed, based on the assumption that local recurrence has little influence on long-term survival. However, in a large series looking at higher-risk tumours treated with glansectomy [145] or partial penectomy [146], it was observed that patients experiencing local recurrence have poorer survival, also in multivariate analysis correcting for poor prognosticators. This, however, does not indicate that these patients may have fared better with more radical excision, as local recurrence in those cases may be a display of a more aggressive disease biology in general. On the other hand, large series are available showing lower local recurrence rates after amputative surgery despite more aggressive tumours, supporting a wider resection [147].

The SR by the Panel found a cumulative 5-year recurrence free rate (RFR) of 82% in case series and 76.7% in non-RCTs for organ-sparing surgery. Similarly, the cumulative 5-year RFR of amputative surgery is reported 83.9% in case series and 93.3% in controlled studies. These variations reflect the differences of study designs as well as the different cohorts analysed at each instance; a larger proportion of patients treated with amputative surgery typically present with advanced disease (≥ T3: 29.4% vs. < T3: 7.8%). The higher RFRs observed after amputative surgery needs to be weighed against the impact on sexual function and QoL. Hence, the limits of organ-sparing surgery are not completely clear, and the higher risks of local recurrence should be discussed with the patient when making a treatment plan.

6.1.2.1 Width of negative surgical margins

The concept of organ-preserving surgery is based on observations of how the distance between tumour and resection margin affects local recurrence. A study found that most lesions do not spread > 5 mm beyond the macroscopic margin and, in line with this finding, subsequent reports show that an excision margin of between 5 mm and 10 mm results in acceptably low recurrence rates [148-150]. Another study from a supra-regional referral centre found that local recurrence rates only increased considerably when the distance from tumour to margin was

< 1 mm [151]. However, comparative evidence is lacking for this topic and there is no clear evidence as to what constitutes an oncologically safe width of macroscopic negative surgical margins. Based on the observation that in lower-risk tumours (1) a local recurrence does not impact survival and (2) minimal section margins > 1 mm do not result in a higher risk for local recurrence, macroscopic margins can indeed be minimal, specifically in smaller and less aggressive lesions. Hence, to ensure complete removal with histologically negative margins, standard excision must include a margin of clinically normal-appearing skin around the tumour and surrounding erythema. However, for bulky or higher-grade lesions where local recurrence may have an impact on survival, adoption of a wider margin or partial penectomy may be prudent and should be discussed with the patient [145, 150].

6.1.2.2 The use of intra-operative frozen section assessment

The role of frozen section and its value in the interpretation of excision margins remains uncertain, potential benefits of adopting frozen section assessment include a decreased risk of local recurrence and a smaller safety margin, allowing maximum preservation of penile tissue. A study in 169 patients treated in a tertiary referral centre in the UK showed that frozen section use during organ-sparing surgery contributed to a very low definitive positive margin rate of 0.6% and a local recurrence rate of 5.3% [152, 153]. These data, however, are contradicted by a large contemporary series, also from a tertiary referral centre in the UK, showing similarly low local recurrence rates of 4% without routine intra-operative frozen section analysis [151]. A SR conducted in 2017 stated that routine frozen section analysis results in lower rates of local recurrence but failed to correct for patient selection, and hence a causal relationship between frozen section analysis and low local recurrence rates is lacking, as is comparative research. Data from one multi-centre study suggests that differentiated PeIN, squamous hyperplasia and lichen sclerosis present at the surgical margins are frequent findings and are not relevant for CSS [77]. As negative surgical margins are aimed for, in cases of doubt on the radicality of the resection, it is the Panel's opinion that frozen section analysis is a helpful tool to achieve definitive tumour-free margins, whereas it is not recommended to be used routinely.

6.1.2.3 Laser ablation

In line with results achieved in non-invasive and superficially-invasive penile lesions, laser ablation has been proposed as an option for smaller invasive lesions. Typically, a CO_2 laser can resect the tumour with ample millimetres of margin, while for coagulation of the tumour bed a Nd:YAG laser is the better option as it provides deeper uniform tissue coagulation. Healing time is fastest after CO_2 laser treatment, with re-epithelization almost complete by three to six weeks post-treatment. Because of the greater depth of tissue coagulation, the healing time for Nd:YAG laser treatment is longer, often up to six weeks [134]. Penetration depth depends on laser type and settings and most commonly used settings are 15–20 W for CO_2 and 15–25 W for Nd:YAG lasers but only very few publications provide technical details [134].

In the Panel's SR, seven studies reported outcomes of laser therapy for invasive penile cancer limited to T1 (81.2%) or T2 (18.5%) disease in a total of 389 patients [3]. Five-year RFR ranged from 34.2-94%. The cumulative mean 5-year RFR was 69.4% (270/389). Three studies reported a 5-year RFR per disease stage of 42.9–73.9% for T1 and 23.5%–84.2% for T2 disease. In nine studies (n = 512), the penile preservation rate following laser therapy was 50–100% (mean 89.2%), indicating that a large proportion of recurrences had to be managed with total amputation, which raises caution on the use of such technique and its use is likely best limited to T1 tumours. Tang *et al*., demonstrated that nodal recurrence was high in a multi-institutional cohort of patients treated with laser ablation as monotherapy, illustrating the importance of pre-ablation biopsy for risk stratification and nodal staging. Clinicians should be aware of the risk of understaging as a result of incision biopsy followed by ablation vs. complete resection [10, 154], and it is advised that patients be informed that laser therapy may result in higher local recurrence rates when compared to surgical excision.

Three studies reported on laser-related complications, with preputial oedema and dysuria reported most frequently. Meatal stenosis was reported in 7.4% and post-operative bleeding in 1–7% of patients. Three studies assessed the sexual function after laser treatment and 46.0–56.5% of men report an impact on their sexual life. A single trial including 46 men found that 72% reported no change in erectile function, 22% reported decreased erectile function and 6% reported improvement [155].

6.1.2.4 Moh's micrographic surgery

Moh's micrographic surgery is a surgical technique by which tissue is excised and processed with en face histological margins in real time to give a complete circumferential and deep margin. It aims at maximal organ-preservation by adopting margin-guided excision. Three studies reported the 5-year RFR in 51 men, most with T1 disease. Recurrence-free rates ranged from 71.4 to 100% with a cumulative mean 5-year RFR of 88.2% (45/51) [3]. As data are very limited, it is not routinely recommended, and the Panel feels it is important to involve a clinician experienced in penile cancer management before referral for Moh's surgery.

6.1.2.5 *Wide local excision and circumcision*

In addition to treating preputial penile cancer, circumcision combined with topical treatment, laser therapy or brachytherapy, facilitates follow-up examinations [153]. For small, distal preputial penile cancer, circumcision alone usually presents adequate treatment. However, lesions located on the corona or glans, limited in size, may be treated with wide local excision which should include a margin of clinically normal-appearing skin around the tumour and surrounding erythema (see Section 6.1.2.1). Few data on wide local excision are available, the technique has, so far, only been described in retrospective series combining various types of organ-sparing treatments.

6.1.2.6 *Glans resurfacing*

Besides its established effects in the therapy of PeIN, total or partial glans resurfacing has been reported to be employed for superficially-invasive lesions combined with deeper resection at the site of invasion. The literature is heterogeneous with many studies reporting miscellaneous techniques of organ-sparing surgery including glans resurfacing without specification of tumour invasiveness in these patients specifically. Five studies have reported results of glans resurfacing specifically in invasive penile cancer in a total of 68 patients, with most being pT1 and a few instances of T2 lesions displaying RFR ranging from 75–96.6% [143, 151, 156-158]. Similar to glans resurfacing as applied to carcinoma *in situ*, graft-related complications are scarce and cosmesis, as assessed by patients, is generally good. Cakir and colleagues have described a small series using a technique for glans resurfacing with preservation of the coronal sulcus for distal tumours not invading the sulcus and show that this option can be considered when aiming for maximally preserved erogenous sensation [143].

6.1.2.7 *Glansectomy*

Patients with tumours confined to the glans and prepuce that are not eligible for wide local excision or glans resurfacing are good candidates for glansectomy. Patients with poor vascular function, diabetes, immunosuppression, or previous radiation to the groin area are less suitable for graft application due to higher failure rates which should be discussed with the patient when making the decision between graft application for primary closure. For cases in which the lesion is confined to the glans and is clearly away from the corporal tips according to imaging or clinical examination, an approach that uses dissection over Bucks' fascia can be used to excise the glans, while in cases of doubt, a plane under the Bucks fascia can be used. In the Panel's SR, glansectomy with or without resection of the outermost tips of the corpora cavernosa was assessed in six studies including 1,681 men, 86.4% of whom with T1–T2 disease. The 5-year RFR ranged from 78.0–95.8% [3]. A split-thickness skin graft is commonly used to reconstruct a neo-glans and the graft loss rate was 1.5–23.5%. The incidence of meatal stenosis in a recent SR was 2.8–14.3%. Good cosmetic outcomes and normal erections were reported in 95–100% and 50–100% of cases, respectively [159]. In a large retrospective study by Roussel and colleagues, describing a multicentre cohort including 230 pT1, 534 pT2 and 108 pT3 patients treated in high-volume centres, the authors found high-grade disease and pT3 to be independent risk factors predicting local recurrence. Three-year local RFS rates were 94.8%, 87.3% and 69.7% in patients with no, one, or both, risk factors, respectively. Moreover, in this population, local recurrence remained a significant predictor of decreased overall- and CSS, even when excluding margin-positive cases, patients with pT3 disease, and patients with clinical LN involvement. Hence, these issues should be discussed with the patient prior to surgical intervention when choosing between glansectomy and the more aggressive partial penectomy.

6.1.2.8 *Partial penectomy*

Amputative and partial amputative surgery is reserved for more advanced disease. Results of partial or total penectomy were reported in 5 heterogeneous studies with a total of 243 patients. 71.6% of men were staged as T1–T2 and the 5-year RFR was 75.8-95.4%. The cumulative mean 5-year RFR was 83.9% (204/243). Two cases series including T1 and T2 men, reported 92% and 95.4% 5-year RFRs after partial penectomy [3]. There is no comparative evidence between partial penectomy and glansectomy for T1–T2 lesions, however most case series report similar RFRs between penile-sparing surgery and amputative surgery. In a series of T1 and T2-only disease, 5-year RFR after amputative surgery were superior to penile-sparing surgery, indicating that a wider resection is protective against local recurrence and should always be discussed as an alternative option, although the higher RFRs observed after amputative surgery needs to be weighed against the impact on sexual function and QoL.

6.1.2.9 *Radiotherapy for T1 and T2 disease*

Radiotherapy is an organ-preserving approach with good results in selected patients with T1–2 lesions [3]. It can be given as external radiotherapy with a minimum dose of 60 Gy EQD2 combined with a brachytherapy boost or as brachytherapy alone [160, 161]. Brachytherapy has been studied only for lesions < 4 cm hence its use should be limited to tumours not exceeding this size. Reported results are best with brachytherapy with

local control rates ranging from 70–90% [160, 161]. The American Brachytherapy Society and the Groupe Européen de Curiethérapie-European Society of Therapeutic Radiation Oncology consensus statement for penile brachytherapy also reported good tumour control rates, acceptable morbidity, and functional organ preservation for penile brachytherapy for stages T1 and T2 disease [160]. Penile preservation rates of 70–88% have been reported [162], with overall penile conservation rates of 87% and 70% at 5 and 10 years. Pulsed-dose-rate brachytherapy can be used interchangeably with traditional low-dose rate and 15% local recurrences have been reported in one series [163]. High-dose rate brachytherapy has been introduced but experience is still limited [164-169].

The Panel's SR identified 21 studies evaluating the efficacy of radiotherapy for the management of primary tumour in men with penile cancer. A total of 1,222 men had low-, pulse-, or high-dose rate brachytherapy after circumcision [3]. The cumulative mean 5-year RFRs were 78.6% (861/1,096) after brachytherapy and 55.2% (37/67) after EBRT. Four studies (including some EBRT and some brachytherapy cohorts) reported RFRs per disease stage, with 5-year RFRs for T1 ranging from 59–94%, 50–67% in T2, and 17–77% in T3 disease [167, 170-172].

In the few studies comparing surgical treatment and radiotherapy, results of surgery were slightly better. In a meta-analysis comparing surgery and brachytherapy, 5-year OS and local control rates were 76–84% for surgery and 73–79% for brachytherapy, respectively [173]. The organ preservation rate for brachytherapy was 74% and there was no difference in survival. Local recurrence after radiotherapy can be salvaged by surgery [170].

Specific complications of radiotherapy for penile cancer are urethral stenosis (20–35%), glans necrosis (10–20%) and late fibrosis of the corpora cavernosa [174]. With brachytherapy, meatal stenosis has been reported to occur in up to 40% of cases but was much lower in a contemporary series of 73 patients with only 6.6%. In that series, 2.6% of patients reported pain with sexual intercourse and 5.3% dysuria over a follow-up of 5 years. Penile amputation for necrosis was necessary in 6.8% of patients [175].

Functional outcome after radiotherapy has not often been reported. In one report, 17/18 patients with normal erections before treatment maintained these after treatment [176]. After a minimum of 3 years (median 5.9) follow-up after brachytherapy treatment, 29/34 patients (median age 63 years) answered a self-reporting questionnaire. Urethral dilatation had been necessary in 30% of patients, self-catheterisation in 13%; erectile dysfunction was mild and 70% continued to maintain sexual activity, and QoL was good.

*6.1.3 **Locally advanced disease (T3–T4)***

6.1.3.1 Resectable disease

In cT2 disease where there is doubt of corporeal or tunica albuginea invasion, rather than continuing the dissection over Buck's fascia to perform glansectomy combined with distal corporectomy, dissection superficial to the tunica albuginea can be adopted after dividing the neurovascular bundle. In these instances, frozen sections of the corporeal tips and urethra may be helpful in assessing the radicality of the procedure peri-operatively. Pre-operative MRI or US can assist in surgical planning as discussed in Chapter 5. For cT3 patients with obvious involvement of the corpora cavernosa, partial amputation is standard. Patients can be offered reconstructive options such as urethral centralisation and/or neo-glans formation with the use of a graft. Two studies in higher-risk patients treated with radical glansectomy or partial penectomy show that local recurrence in these instances is associated with poor survival. Patients should be informed that a wider resection (i.e., partial or radical penectomy) provides a lower risk of local recurrence at the cost of functionality of the penis [145, 177]. Radical amputation and diversion of urination with a perineal urethrostomy is reserved for those patients in whom a resection with a safe margin would result in the inability to void standing upright or without wetting the scrotum. Radiotherapy for locally-advanced penile lesions should be undertaken with concurrent chemotherapy. As with disease in the LNs, traditional radiotherapy dosing recommendations are being reconsidered [178]. Complex treatment planning will be necessary in most cases of T3–T4 primary lesions, with patient-unique immobilization to spare testes and scrotum. A total phallic reconstruction may be offered to patients undergoing total/subtotal amputation. Extensive partial amputation with wide margins or total penectomy with perineal urethrostomy is the standard advisable treatment. In case of locally-advanced and ulcerated cases which are resectable, composite myocutaneous flaps or advancement flaps may be needed to cover the surgical defect [179].

6.1.3.2 Non-resectable disease

In non-resectable disease, induction chemotherapy offers the ability to downstage disease and thereby enable surgical resection among responders, even among men with advanced penile cancer. Several retrospective- and prospective series have evaluated the effects of combination regimens using paclitaxel or docetaxel with cisplatin and ifosfamide or 5-FU. The combination of irinotecan and cisplatinum, and vinflunine as monotherapy, have also been investigated. Although there is considerable heterogeneity in the regimens and cohorts combining advanced nodal disease and unresectable primary tumours, objective responses are observed in

29–60% of patients [177, 180-186] . In two recent SRs pooled ORR were 53–57% [187] with pooled objective response rates of 57% (95% CI: 46–67%) for taxane-platinum combinations and 54% (95% CI: 31–76%) for non-taxane platinum combinations [188], and pathological complete responses in 4–10% [188], at the cost of considerable toxicity. This approach is discussed in more detail in Section 6.4.1.1. In case of not obtaining a response sufficient for resection, palliative chemo-radiotherapy is an option.

Accumulated evidence in anal and vulvar cancer supports the notion that definitive chemo-radiotherapy is an effective treatment for anogenital SCC [189]. In a single study in six node-positive SCC penile cancer patients, 4 of the 6 patients were recurrence-free and two had developed recurrence, of which one patient died [189]. In a currently unpublished observational cohort study in 40 loco-regionally advanced penile cancer patients fit for chemo-radiotherapy and treated with curative intent, Ottenhof and colleagues observed that only half of the patients proceeded to surgery, and one- and 2-year PFS was 32% with a > grade 3 toxicity rate of 40% [190]. Their regimen consisted of integrated boost intensity modulated radiotherapy with a dose of 59.5 Gy to the primary tumour in fractions of 1.8 Gy with mitomycin C on day one and capecitabin on radiation days. In comparison to peri-operative chemotherapy studies, the omission of surgery is a potential advantage of chemo-radiotherapy. As this strategy has only been evaluated in a single observational study without a published full text at the moment of writing, no recommendation can be made supporting this approach in patients suitable for other options.

6.1.4 Local recurrence after organ-sparing surgery

A second organ-sparing procedure can be performed if there is no corpus cavernosum invasion [136, 149, 191-193]. For large or high-stage recurrence, partial or total amputation is required, unless unresectable or concurrent with nodal or distant metastatic recurrence (see respective sections).

6.1.5 Summary of evidence and guidelines for local treatment of penile carcinoma

Summary of evidence	LE
Penile intra-epithelial neoplasia progress to invasive lesions in 2.6–13% despite treatment.	3
Response and recurrence rates of topical therapies for PeIN are 40–100% and 20% for IQ and 48–74% and 11% for 5-FU. For laser therapy, response rates are 52–100% and recurrence rates 7–48%. For glans resurfacing, recurrence rates are as low as 4%.	3
A SR including retrospective studies on organ-sparing surgical treatment of the primary lesion shows that cumulative mean 5-year RFRs are 82% in case series and 76.7% in non-RCTs. For (partial) amputative surgery these are 83.9% in case series and 93.3% in non-controlled studies. The cumulative mean 5-year RFR was 69.4% for patients treated with laser therapy for invasive disease.	3
Current literature on frozen section analysis in organ-sparing surgery is heterogeneous and conflicting.	3
Tumour distance to the resection margin < 1 mm resulted in higher local recurrence rates in a recent large retrospective case series from a tertiary referral centre.	3
Several retrospective series from claims databases and high-volume centres studying non-specified organ-sparing surgical and ablative techniques show no impact of local recurrence on CSS where case mix is pitched towards lower grade, lower stage tumours. However, a recent large retrospective series of glansectomies performed in high-volume centres showed local recurrence was a predictor of poor CSS in a cohort with a high number of T2, T3 and high-grade lesions.	3
The cumulative mean 5-year RFRs are 78.6% after brachytherapy and 55.2% after EBRT.	3
For neo-adjuvant chemotherapy, pooled ORR was 53% (95% CI: 42–64%), the pCR rate in prospective studies was 4–10% (95% CI: 5–30%) in a recent SR and meta-analysis.	2a

Recommendations	Strength rating
Offer a balanced and individualised discussion on benefits and harms of possible treatments options with the goal of shared decision making.	Strong
Inform patients of the higher risk of local recurrence when using organ-sparing treatments compared to amputative surgery.	Strong
Topical therapy	
Offer topical therapy with 5-fluorouracil or imiquimod to patients with biopsy-confirmed penile intra-epithelial neoplasia (PeIN).	Weak

Clinically assess treatment effects after a treatment-free interval and in cases of doubt perform a biopsy. If topical treatment fails, it should not be repeated.	Weak
Laser ablation	
Offer laser ablation using CO_2 or Nd:YAG laser to patients with biopsy-confirmed PeIN, Ta or T1 lesions.	Weak
Organ-sparing treatment: surgery (circumcision, wide local excision, glansectomy and glans resurfacing)	
Offer organ-sparing surgery and reconstructive techniques to patients with lesions confined to the glans and prepuce (PeIN, Ta, T1–T2) and who are willing to comply with strict follow-up.	Strong
Perform intra-operative frozen section analysis of resection margins in cases of doubt on the completeness of resection.	Weak
Offer salvage organ-sparing surgery to patients with small recurrences not involving the corpora cavernosa.	Weak
Organ-sparing treatment: radiotherapy (EBRT and brachytherapy)	
Offer radiotherapy to selected patients with biopsy-confirmed T1 or T2 lesions.	Strong
Amputative surgery (partial- and total penectomy)	
Offer partial penectomy, with or without reconstruction, to patients with invasion of the corpora cavernosa (T3) and those not willing to undergo organ-sparing surgery or not willing to comply with strict follow-up.	Strong
Offer total penectomy with perineal urethrostomy to patients with large invasive tumours not amenable to partial amputation.	Strong
Offer amputative surgery to patients with large local recurrences or corpora cavernosa involvement.	Weak
Multimodal therapy	
Offer induction chemotherapy followed by surgery to responders, or chemo-radiotherapy to patients with non-resectable advanced primary lesions, or to patients with locally advanced-disease who refuse surgical management.	Weak

6.2 Regional lymph node management: clinically evident disease (cN1–cN3)

6.2.1 Introduction

The development of lymphatic metastases in penile cancer follows the route of anatomical drainage from the primary tumour to the superficial and then deep inguinal LNs (which can occur on both or either side), followed by the ipsilateral pelvic LNs. The superficial nodes are located under the subcutaneous fascia and above the fascia lata within Scarpa's triangle. The deep nodes lie within the region of the fossa ovalis where the superficial saphenous veins anastomose with the femoral vein at the saphenofemoral junction. The Cloquet's node (or Rosenmuller's node) is located medial to the femoral vein around the entrance to the femoral canal and marks the transition between inguinal and pelvic regions. Daseler et al., divided the superficial inguinal LNs into five regions centred around the saphenofemoral junction; central, lateral superior, lateral inferior, medial superior and medial inferior [194]. Studies of radical ILND (rILND) as well as single-photon emission computed tomography (SPECT) imaging suggest that sentinel inguinal nodes, i.e., those first affected by lymphatic spread, appear to be located in the medial superior zone followed by the central inguinal zones [194-196].No solitary lymphatic spread has been observed from the penis to the two inferior groin regions and no direct drainage to the pelvic nodes, either [194-196].

Pelvic nodal disease does not occur without ipsilateral inguinal LN metastasis. Also, crossover metastatic spread, from one groin to the contralateral pelvis, is rare [197]. Further lymphatic spread from the pelvic nodes to retroperitoneal nodes (para-aortic, para-caval) is classified as systemic metastatic disease [198].

The management of regional LNs is decisive for patient survival. The presence and extent of nodal involvement is singulary the most important prognostic factor in patients with penile cancer. Cure can be achieved in limited LN-disease confined to the regional LNs. Radical LND is the treatment of choice. Multimodal treatment combining surgery, chemotherapy, or radiotherapy is often indicated for more advanced disease.

In clinically positive LNs (cN1/cN2), more extensive LN metastasis is highly likely and LN surgery with histology is required. Given the very high chance of recurrence, enlarged fixed inguinal LNs (cN3) or clinically evident pelvic metastases require multimodal treatment by induction chemotherapy and consolidative surgery in responding patients. Even if present in only one node, extra-capsular extension/ENE, or pelvic LN metastasis found at surgery carries a high risk of progression and is classified as pN3 and requires multimodal treatment.

Given the complexities of regional node management, the intent of the Panel in the following sections (i.e., Sections 6.2–6.4) is to describe the available evidence-based strategies in the management of clinically evident LN metastases (i.e., cN1–cN3). These include inguinal/pelvic LND, chemotherapy, radiotherapy ± chemotherapy and integrated strategies such as neoadjuvant and adjuvant therapies combined with surgery. The reader is encouraged to review the text sections, summaries of evidence, and recommendation tables collectively in order to better understand recommendations for single vs. multimodal treatment and currently available data utilising various strategies.

*6.2.2 **cN1–N2 disease: radical inguinal lymph node dissection***

6.2.2.1 Indication for radical inguinal lymph node dissection

Radical ILND remains the standard of care for patients with cN1–2 (or cN0 patients with a tumour positive SN at DSNB). In low-volume disease (pN1) rILND is curative with a suggestion of equivalent outcomes in those patients without nodal disease [199-201].

Despite this, several studies have demonstrated continuing non-adherence to accepted international guidance [202-205]. Cindolo *et al*., evaluated adherence of twelve European and American centres to the EAU recommendations [205]. They reported a 26.3% rate of non-adherence in terms of LN management. For those patients managed as per guidance with LND there was a statistically significant association with OS (adjusted HR: 0.48; 95% CI: 0.24–0.96, p = 0.038) [205].

6.2.2.2 What is an acceptable definition?

Daseler's original description of a rILND in 1948 is considered the classical description of a radical inguinal LN dissection (rILND) (see Table 6.1) [194]. Despite this, considerable variation exists across high-volume centres. In an international survey of surgeons' practice in European high-volume centres, consensus was not found in the definition of the superior and lateral borders of the dissection, and whether the fascia lata and saphenous should be preserved [206]. This variation in practice is likely a reflection of clinicians and patients desire to reduce the significant burden of morbidity acknowledged in the literature associated with rILND (see later section on complications). A SR of the literature by the Panel identified only one other description of a modified template used in clinical N1–2 disease by Yao et al. [207] (see Table 6.1). This retrospective cohort study of 201 fascial-sparing inguinal dissections (fsILND) with < N2 disease, demonstrated comparable oncological outcomes to rILND with 3-year DFS of 92.1% (100% for pN0, 91.3% for pN1, 80% for pN2, and 33.3% for pN3 disease, respectively) and a complication rate of 29.3%. To date, however, no direct comparison exists between rILND and fsILND in this group of patients (Table 6.1).

Table 6.1: Variations in radical inguinal lymphadenectomy

	Superior	Lateral	Medial	Inferior	base	Fascia preserved	Saphenous spared	Sartorius transposition
rILND [194]	Superior margin of external ring to the anterior superior iliac spine	Anterior superior iliac spine inferiorly 20 cm	15 cm downwards from the pubic tubercle	Apex of femoral triangle	Sartorius, femoral vessels, adductor longus	No	No	Yes
fsILND [207]	Superior margin of external ring to the anterior superior iliac spine	Anterior superior iliac spine inferiorly 20 cm	15 cm downwards from the pubic tubercle	Apex of femoral triangle	Fascia	Yes. Deep inguinal LNs, medial to the femoral vein, dissected just distal to the fossa ovalis	Yes	No

fsILND = fascia-sparing inguinal lymph node dissection; RILND = radical inguinal lymph node dissection.

6.2.2.3 Quality metrics

To standardise the quality of resections, several studies have attempted to look for surrogate markers to infer complete oncological resection including LN yield (LNY), LN density (LNDen), and time to completion of surgery.

6.2.2.3.1 Lymph node yield and density

In a SR commissioned by the Panel, several studies were identified examining the association between LNY/LNDen and survival as a surrogate marker of adequate dissection in penile cancer [203, 208-212]. However, LNY varied from ≥ 8 to ≥ 15–16 and LND ≤ 6.7 to ≤ 22%. The variance in accepted values is likely because of different surgical templates, variable pathological assessment, and stage migration. Consequently, widespread adoption of LNY and LNDen as a predictor of survival and as quality markers cannot be recommended.

6.2.2.3.2 Timing of surgery

Several studies have highlighted the importance of expedient LN management in patients with cN0 disease vs. surveillance with LND on presentation of clinical disease. Two non-RCTs have demonstrated a survival benefit in patients who underwent early ILND compared with delayed ILND (within six weeks of primary surgical treatment vs. surgery following identification of positive nodes during surveillance), showing 3-year CSS 84% vs. 35% (p = 0.0017) and 3-year CSS 71% vs. 50%, respectively [98, 213].

The evidence in pN1–2 regarding optimal timing of LN management is limited. Chipollini *et al*., examined the effects of early vs. late inguinal LN dissection (> three months following primary surgery) in 84 patients with cN0 and cN+ disease. Overall, those patients undergoing early ILND demonstrated a 5-year DSS of 64.1% vs. 39.5% for late dissection with an unadjusted HR of 0.66 (0.32–1.37). However, when sub-analysis was performed in cN+ patients, the 5-year DSS for early vs. late dissections failed to delineate a statistically significant benefit (31.8% vs. 35.3%, respectively) [214].

Gulia *et al.*, examined 28 patients undergoing rILND stratified by < 6 months (group 1) and more than 6 months (group 2) from treatment of the primary tumour (70% and 50% palpable at presentation, respectively). The 5-year CSS was 91 and 13%, respectively (p = 0.007) [215].

6.2.2.4 Complications

Radical ILND carries a significant morbidity due to impaired lymph drainage from the legs and scrotum, however it can be lifesaving and therefore should not be avoided [216].

Historical morbidity of the procedure has been as high as 61% [217]. Contemporary large series of rILND suggest between 21–55% of men will suffer a complication [115, 218, 219]. The reduction in morbidity is likely due to a better understanding of pre-, intra-, and post-operative management (see Table 6.2). In a SR commissioned by the Panel the most reported complications in recent series were wound infections (2–43%), skin necrosis (3–50%), lymphoedema (3.1–30%), lymphocele formation (1.8–26%), and seroma (2.4–60%) [115, 199, 215, 218-225]. Table 6.2 lists several strategies and conditions associated with increase, decreased or uncertain effects on morbidity outcomes reported in penile cancer, urologic or in other cancers. Future studies specific to ILND and strategies to decrease morbidity are needed.

Table 6.2: Impact of pre-intra- and post-operative factors on morbidity following radical inguinal lymph node dissection

Positive impact	Negative impact	Uncertain benefit
Linear transverse incision [226, 227]	S-shaped incision, vertical incision [217, 226, 228]	Vacuum dressings [229]
Saphenous sparing [227, 230, 231]	Time-controlled drainage [232]	Fibrin glue [233]
Volume-controlled drainage [232]	Ultrasonic device [234]	Advanced bipolar device [235]
Fascial sparing [207]	Sartorius transposition [219]	
Minimally-invasive techniques [236-238]	Raised BMI [219]	
Lymphoedema prevention, e.g., massage, skin care, saphenous vein-sparing surgery [227, 239]	Increased disease burden [115]	
Deep venous thrombosis prophylaxis [240]	Sarcopenia [220]	
Prevention of surgical site infections, e.g., prophylactic antibiotics, shaving, skin prep [241]		

6.2.2.5 Open versus minimally-invasive approach

In recognition of the significant morbidity associated with rILND, clinicians have sought to reduce these through technical modifications. Expanding interest and experience in minimally-invasive techniques have led to the introduction of video-endoscopic inguinal LND (VEIL) and subsequently robot-assisted video-endoscopic inguinal LND (RAVEIL), using rILND or fsILND templates.

Ports are generally placed at the apex of the femoral triangle, although variations include lateral and hypogastric approaches allowing pelvic lymph node dissection (PLND) through the same incisions [242-244].

A review of the literature commissioned by the Panel identified a single incomplete RCT in 2012 which closed prematurely due to poor accrual, with patients preferentially choosing minimally-invasive approaches over open [245]. The remaining studies identified were either retrospective cohort- or comparative series. Narrative review would suggest that although operative time is longer, LN yields can be similar to open ILND, length of hospital stay shorter in VEIL/RAVEIL and wound complications lower, though lymphocele and readmission rates were equivalent [113, 236, 238, 246-248].

Follow-up for the minimally-invasive approaches were short, and there was a high proportion of patients receiving VEILND or RAVEIL as prophylaxis as opposed to clinically node-positive disease, precluding incorporation in the current guidance. In addition, some studies where open rILND was used as a comparator, involved more morbid manoeuvres when using an open approach, such as Sartorius transposition and saphenous vein sacrifice, which were not replicated in minimally-invasive procedures.

6.2.2.6 Summary of evidence and guidelines for radical inguinal lymph node dissection in cN1-2 disease

Summary of evidence	**LE**
Open radical ILND is the standard for cN1–2 disease.	2a
Radical inguinal lymph node dissection carries a significant risk of complications (21–55%).	2a
A single study reported on fsILND, fascial-sparing ILND has been reported (single study) and in cN1–2 disease which appears to offer similar oncological outcomes, and reduced complications.	2b
Lymph node yield and LND appear related to survival, however, variance in accepted values, pathological assessment, and stage migration prevent recommendation of a specific LN count.	2a
Delay in nodal management of more than three to six months may affect DFS.	3
Minimally-invasive approaches for ILND (VEIL/RAVEIL) generally have longer operative times, equivalent LN yields, shorter length of hospital stay and lower wound complications when compared with open ILND. However, since current evidence is very limited in cN1–2 patients, no recommendation for minimally-invasive approaches can be provided.	2b

Recommendations	**Strength rating**
In patients with cN1 disease offer either ipsilateral: • fascial-sparing inguinal lymph node dissection (ILND) • open radical ILND; sparing the saphenous vein, if possible	Strong
In patients with cN2 disease offer ipsilateral open radical ILND; sparing the saphenous vein, if possible.	Strong
Offer minimally-invasive ILND to patients with cN1–2 disease only as part of a clinical trial.	Strong
Offer neoadjuvant chemotherapy as an alternative approach to upfront surgery to selected patients with bulky mobile inguinal nodes or bilateral disease (cN2) who are candidates for cisplatin and taxane-based chemotherapy (see Section 6.4.1).	Weak
Complete surgical inguinal and pelvic nodal management within three months of diagnosis (unless the patient has undergone prior neoadjuvant chemotherapy).	Weak

6.2.3 ***Prophylactic pelvic lymph node dissection***

Prophylactic PLND (pPLND) in most cases represents a staging procedure that can thus identify candidates for early adjuvant therapy, although in select patients may also provide a therapeutic benefit.

6.2.3.1 Indications for prophylactic pelvic lymph node dissection

6.2.3.1.1 Risk factors for pelvic nodal metastasis

To identify patients with pelvic LN metastasis in the absence of radiological evidence for LN involvement, several studies have tried to develop generalized estimating models based on inguinal characteristics using logistic regression and multivariate analysis. Among various predictors, the number of positive inguinal LNs (1–2 vs. 3, or more, with no extra-capsular extension) was associated with positive pelvic LNs in 0–6.5% of patients vs. 33–67% of patients [249, 250]. The presence of extracapsular spread was also consistently significantly associated with positive ipsilateral pelvic LN metastasis in 4 studies [249-252] Strong immunoreactivity of p53, LN density > 30% and primary tumour grade are also reported as predictors of pelvic LN involvement [250].

6.2.3.2 What is an acceptable dissection?

In a study by Yao *et el*., the authors prospectively mapped the distribution of positive pelvic LNs at the time of PLND in 128 patients [197]. Most patients underwent bilateral PLND (86.7%). The median number of nodes retrieved per groin was 18 (interquartile range [IQR] 10–30), with the distribution of positive nodes in the external iliac, obturator, common iliac, internal iliac and presacral packages 50%, 36.6%, 7%, 6.4% and 0%, respectively. Notably two patients were observed to have crossover metastasis from one inguinal region to the contralateral pelvic region, defying the accepted understanding of the historical literature. When the extent of dissection was considered in context of overall- and RFS there was no statistically significant difference [197]. Similar data was seen in a study by Zhu *et al*., with the external iliac package being more commonly involved than the obturator and common iliac packages [253].

To evaluate the prognostic impact of LN yield on survival outcomes for penile SCC, Chipollini *et al.*, examined 198 patients undergoing PLND [208]. In their cohort they found a LN yield of ≥ 9 was a predictor of RFS (HR: 0.53, p = 0.032).

6.2.3.3 Survival and recurrence

The evidence that pPLND has an additional therapeutic effect over surveillance or adjuvant radiotherapy (see Section 6.4.2.2) is limited and significant controversy remains. Djajadiningrat *et al*., estimated the 5-year DSS in all patients treated with pPLND was 51%. Patients with positive pelvic nodes had a significantly worse 5-year DSS than those without pelvic involvement (17%, 95% CI: 6–47 vs. 62%, 95% CI: 50–76, p < 0.001) [251]. A retrospective multicentre study compared the outcomes of bilateral pPLND for N2 or N3 disease vs. no surgery and reported better 5-year OS in the pPLND group (35% vs. 25%) without reaching statistical significance [254]. In N2 patients, 3-year OS was significantly better in the PLND group as compared to the no-surgery group (83.3% vs. 50.2%, p = 0.03) [254]. This difference was not evident in N3 patients.

6.2.3.4 Complications

There is limited data available regarding the reporting of complications from PLND. This is complicated by the fact that most patients will have already undergone a rILND which carries a significant morbidity as discussed above. A single-centre experience of 89 patients, undergoing open PLND for penile cancer reported an overall complication rate of 18%. Nine patients had wound complications including infection, seroma, and dehiscence. The remaining 5 patients had non-wound-related complications such as pneumonia, delirium, and ileus [251].

6.2.3.5 Minimally-invasive versus open pelvic lymph node dissection

In a SR commissioned by the Panel there were no reported studies that examined the role of minimally-invasive pPLND in the setting of penile cancer and PLND. There is, however, a significant body of evidence that exists in other common urological malignancies that demonstrates equivalent oncological outcome as well as improved morbidity profile and recovery profile.

6.2.3.6 Summary of evidence and guidelines for prophylactic pelvic lymph node dissection

Summary of evidence	**LE**
Prophylactic PLND in most cases represents a staging procedure that can thus identify candidates for early adjuvant therapy, although in select patients it may also provide a therapeutic benefit.	3
Three or more positive inguinal nodes or extranodal extension of cancer in inguinal nodes are associated with a significantly higher incidence of pelvic LN metastases.	3

Recommendations	Strength rating
Offer open or minimally-invasive prophylactic ipsilateral pelvic lymphadenectomy to patients if: • three or more inguinal nodes are involved on one side on pathological examination • extranodal extension is reported on pathological examination	Weak
Complete surgical inguinal and pelvic nodal management within three months of diagnosis (unless the patient has undergone neoadjuvant chemotherapy).	Weak

6.3 Clinical N3 disease (cN3)

*6.3.1 **Diagnostic evaluation***

Patients with clinical N3 disease as defined by the presence of a fixed inguinal mass (i.e., to skin or underlying structures) or pelvic lymphadenopathy based upon imaging should undergo a complete staging evaluation including cross sectional imaging (i.e., PET/CT or CT, see Section 5.2.3), if not already performed [255]. Biopsy of the inguinal mass in the setting of a patient with a known diagnosis of penile cancer is not required but should be performed in a previously undiagnosed patient, as needed, to establish the diagnosis and facilitate accurate staging.

*6.3.2 **Management strategy***

Neoadjuvant chemotherapy (NAC) is a reasonable strategy among cN3 patients based on the results of a recent SR which reported radiological response rates of approximately 53% and pathological complete response in approximately 12.8% of patients [187, 256]. This review consisted mostly of retrospective series; complete response rates in the intention to treat population were 10% (paclitaxel, ifosfamide, and cisplatin [TIP]) and 4% (docetaxel, cisplatin and fluorouracil [TPF]) in prospective trials [177, 180]. In responding patients, and those with no evidence of disease progression, surgical resection to remove all residual disease utilizing radical inguinal and PLND techniques is the preferred strategy. For a detailed examination of peri-operative chemotherapy please see Section 6.4.1.

Pre-operative radiotherapy was used in a single study among a cN3 cohort of 12 patients and reported an objective response in only 2 patients with 7 of 12 patients subsequently undergoing ILND. Only 2 patients (17%) survived 5 years [257]. It is worth recognising that this data, however, utilises historical radiotherapy techniques precluding meaningful extrapolation to modern practice (see Section 6.4.2 for further details).

Surgery as the initial treatment in patients with a fixed inguinal mass or clinically evident pelvic adenopathy (cN3) at presentation or recurrence is discouraged in routine management. While often technically feasible a “surgery first approach” often results in large skin/soft tissue defects, the need for myocutaneous flap reconstruction, prolonged hospital stays (mean or median 8.5–23 days) and is associated with high overall complication rates (65–77%) [258, 259]. In a single-centre study among 24 patients treated with surgical debulking alone in the advanced disease setting, the median CSS and DFS were only six and three months, respectively [259]. In the same study 17.5% of patients exhibited rapid progression of disease post-surgery and never received adjuvant therapy [259].

*6.3.3 **Patient selection for consolidative radical inguinal/pelvic lymphadenectomy***

Patients whose tumours respond to NAC and subsequently undergo surgical consolidation represent a favourable subgroup of patients with a mean 5-year survival of 56.9% according to a SR [256]. Among cN3 patients who are not candidates for conventional multi-agent chemotherapy, pre-operative chemo-radiation/radiation can be offered in an attempt to downsize tumours to improve resectability. The evidence for this, however, is recognised to be weak but is being prospectively investigated in the InPACT study [260].

*6.3.4 **Surgical technique***

6.3.4.1 Inguinal lymph node dissection

Surgical resection should proceed 5–8 weeks after completion of chemotherapy to provide time for haematologic recovery and other therapy related symptoms to improve.

Pre-operative planning to remove all residual disease taking into consideration the size of the mass, involvement of surrounding structures, and the anticipated skin and soft tissue defects as well as plastic surgical consultation (as appropriate) is required for successful outcomes.

6.3.4.2 Lymphadenectomy boundaries

Surgical boundaries should follow that of a ‘radical inguinal lymph node’ dissection” (described in Table 6.1). Wide resection of involved skin is often required with *en bloc* ILND. Considering the extent of inguinal

metastases along with fixation to adjacent structures, minimally-invasive techniques (i.e., robotic-, laparoscopic ILND) are considered inappropriate in cN3 inguinal metastases.

6.3.4.3 Pelvic lymph node dissection

Simultaneous PLND should be performed at the time of ILND if pelvic LN metastases were clinically evident at diagnosis. Ipsilateral PLND should also be performed in a simultaneous (preferred) or delayed fashion in the setting of advanced bulky inguinal metastases without clinically evident pelvic metastases as well (i.e., prophylactic). In the latter setting, microscopic pelvic metastases were noted quite frequently (44–100%) in the setting of extracapsular disease and especially when an inguinal mass was present in one series [249].

6.3.4.4 Surgical complications in cN3 disease

Resection of bulky/fixed inguinal masses with or without prior chemotherapy is associated with a variety of complications. Minor complications not requiring hospitalization or surgical intervention are common and tolerable when cure or significant palliation can be achieved. Major post-surgical complications requiring medical or surgical intervention or associated with disability, or death, in several series included infection/sepsis (1.5–4.5%), lymphocele requiring drainage (0–3.8%), wound dehiscence or necrosis requiring debridement (1.5–5.6%), pneumonia (0–2.9%), deep venous thrombosis/pulmonary embolus (0–8.7% and death (0–5.6%) [180, 258, 259]. Overall, in the three selected series of patients treated at experienced centres the incidence of major complications as described above was less than one in ten patients with 3/82 (3.9%) patients succumbing to sepsis or other early peri-operative complications.

*6.3.5 **Summary of evidence and guidelines for the surgical management of cN3 disease***

Summary of evidence	**LE**
Surgery alone will rarely cure patients with cN3 disease.	3
Even when technically feasible, upfront surgery is associated with significant complications which may delay or prevent delivery of adjuvant therapy.	3
About half of the patients with advanced (cN2–cN3) penile cancer respond to combination chemotherapy. Responders that subsequently undergo consolidative inguinal/PLND have an OS chance of about 50% at 5 years.	2a
Inguinal LND in cN3 patients often requires resection of overlying skin to effectively remove a fixed bulky nodal mass.	4
The available literature includes virtually no cN3 patients to assess the efficacy or safety of minimally-invasive ILND.	4

Recommendations	**Strength rating**
Offer neoadjuvant chemotherapy (NAC) using a cisplatin- and taxane-based combination to chemotherapy-fit patients with pelvic lymph node involvement or those with extensive inguinal involvement (cN3), in preference to up front surgery. (see Section 6.4.1).	Weak
Offer surgery to patients responding to NAC in whom resection is feasible.	Strong
Offer surgery to patients who have not progressed during NAC, but resection is feasible. See also (chemo)radiation.	Weak
Do not offer Video Endoscopic Inguinal lymphadenectomy.	Strong

6.4 Role of multimodal chemotherapy/radiotherapy in the management of (regional) lymph nodes

*6.4.1 **Systemic therapy***

6.4.1.1 Neoadjuvant chemotherapy

Bulky inguinal LN enlargement indicates extensive lymphatic metastatic disease for which few patients will benefit from surgery alone. Neoadjuvant chemotherapy before inguinal LN surgery allows for early treatment of systemic disease and down-sizing of the inguinal LN metastases. In responders, complete surgical treatment is possible with reasonable clinical outcome.

Cisplatin/5-FU (PF) chemotherapy achieved a response rates of 25–50% with acceptable toxicity [261, 262]. Over a period of 30 years, five different NAC regimens including PF were used in twenty patients, with long-term survival in 37% of responders who underwent radical LN surgery after NAC [263]. In the EORTC cancer study

30992, 26 patients with locally-advanced or metastatic disease received irinotecan and cisplatin chemotherapy. Although the study did not meet its primary endpoint (response rate), there were three cases of pathologically complete remissions (pCRs) [186].

Hypothetical similarities between penile SCC and head and neck SCC led to the evaluation in penile cancer of chemotherapy regimens with an efficacy in head and neck SCC, including taxanes. A phase II trial evaluated treatment with 4 cycles of neoadjuvant paclitaxel, cisplatin, and ifosfamide (TIP) in patients with clinical N2 or N3 LN metastases [180]. An objective response rate (ORR) of 50% was reported in 30 patients, including three pCRs. The estimated median time to progression (TTP) was 8.1 months and the median OS was 17.1 months. Long-term DFS was observed in 67% of responding patients and 7% of non-responding patients.

The combination of PF plus a taxane has been used in neoadjuvant and adjuvant settings [183, 184, 264, 265]. A phase II trial with docetaxel, cisplatin, and 5-FU (TPF) reported an objective response of 38.5% in 29 locally-advanced or metastatic patients, although the study did not meet its primary endpoint, and there was significant toxicity [184]. A prospective study testing neoadjuvant TPF in 26 patients with loco-regionally advanced penile cancer showed a pathologic complete response in one patient, with a 2-year PFS and DSS probability of 12% and 28%, respectively [177]. Treatment was discontinued in 23% of patients because of toxicity. In a recent meta-analysis analysing 10 studies (n = 182 patients, mostly retrospective), the pooled ORR was 53% (95% CI: 42–64), and the overall mortality was 55% (95% CI: 40–70) [187]. The available evidence favours a cisplatin- and taxane-based combination (doublet or triplet) as the preferred approach.

Overall, these results support the activity of pre-operative chemotherapy in patients with clinically-involved regional LNs from penile SCC. However, randomised studies are lacking and substantial concerns remain regarding the selection of patients who are best suited for a systemic therapy approach upfront. A large retrospective study including 743 patients who received a LND from several international institutions suggested patients with a clinical N3 stage constituted the cohort with the most appreciable benefit from NAC use, compared to LND alone [266]. Bilateral inguinal LN involvement emerged as a strong negative predictor of clinical outcome in patients with penile SCC, together with pelvic nodal involvement.

In summary, given the poor outcome of upfront surgery, NAC is a potentially-suitable approach for patients having pelvic LN (cN3) metastases or fixed inguinal LN involvement (cN3), or bulky or bilateral involvement (cN2). In nonresponding patients, the potential benefits of surgery should be re-evaluated as prognosis is poor in these patients. See also section on chemo-radiotherapy.

6.4.1.2 Adjuvant chemotherapy

There are known poor prognostic characteristics for a subset of patients with resected high-risk disease (such as involved pelvic LNs), indicating the likely presence of micrometastatic disease. Data exists on response rates for those with metastatic disease and there is possible benefit for pre-operative chemotherapy for those with unresectable locally advanced disease as described above. With extrapolation from other diseases, it stands to reason that systemic therapy following resection (i.e., adjuvant therapy) may improve outcomes.

A retrospective multicentre analysis of patients with resected pathologically involved pelvic LNs suggested a potential benefit of adjuvant chemotherapy [264]. In this series, 84 patients were analyzed. Patients who received chemotherapy for relapsed disease were excluded. Compared to those not receiving adjuvant chemotherapy, patients who received adjuvant chemotherapy were younger, had lower T stage, more likely to have unilateral (rather than bilateral) LN involvement, and were less likely to receive adjuvant radiation. On multivariable analysis, receipt of adjuvant chemotherapy was associated with improved OS (HR: 0.40, 95% CI: 0.19–0.87, p = 0.021). Additional series have also been reported, including a series of 611 patients from the National Cancer Database reported in abstract form [267]. After adjusting for co-variates, there was no difference in survival for those receiving adjuvant chemotherapy.

A recent meta-analysis examined this issue. After a systematic search, 7 studies were identified examining the use of peri-operative chemotherapy, 4 of which examined adjuvant chemotherapy (n = 771) [268]. There was no difference in survival for those receiving adjuvant chemotherapy vs. observation (HR: 0.95, 95% CI: 0.48–1.80).

Upon examination of the overall data, there is no strong data supporting the use of adjuvant chemotherapy to improve OS following surgical resection of the primary tumour and involved LNs. However, given the fact that RFS is a relevant endpoint that has been suboptimally studied and there is a subset of patients at very high risk of recurrence, the Panel recommends a balanced discussion of risks and benefits of adjuvant chemotherapy

in those thought to be healthy candidates. As previously stated for the neoadjuvant setting, the benefit from adjuvant chemotherapy is expected to be highest in the population of patients with pathological N3 stage, in particular for those patients with pelvic nodal involvement [266]. See also Section 6.4.1.2 on adjuvant radiation and chemo-radiotherapy.

6.4.1.3 Summary of evidence and guidelines for neoadjuvant and adjuvant chemotherapy

Summary of evidence	**LE**
Results support the activity of NAC in patients with clinically involved regional LNs from penile SCC. However, randomised studies are lacking, and substantial concerns remain regarding the selection of patients who are best suited for a systemic therapy approach upfront.	2b
The available evidence favours a cisplatin- and taxane-based combination (doublet or triplet) as the preferred approach.	2b
Limited data support the use of adjuvant chemotherapy to improve OS following surgical resection. However, it could be offered to patients with pN3 disease post-LND if NAC has not been received, upon careful consideration of risks and benefits with the patient.	4

Recommendations	**Strength rating**
Offer neoadjuvant chemotherapy using a cisplatin- and taxane-based combination to chemotherapy-fit patients with pelvic lymph node involvement or those with extensive inguinal involvement (cN3), in preference to up front surgery.	Weak
Offer chemotherapy as an alternative approach to upfront surgery to selected patients with bulky mobile inguinal nodes or bilateral disease (cN2) who are candidates for cisplatin and taxane-based chemotherapy.	Weak
Have a balanced discussion of risks and benefits of adjuvant chemotherapy with high-risk patients with surgically resected disease, in particular with those with pathological pelvic LN involvement (pN3). See also section on post-operative radiotherapy.	Weak

*6.4.2 **Radiotherapy***

6.4.2.1 Pre-operative radiation therapy

The role of pre-operative chemo-radiotherapy is being investigated in the ongoing InPACT trial [260]. Since surgical therapy of enlarged LNs is of paramount importance, it is unlikely that pre-operative radiotherapy alone would provide sufficient benefit. Should a patient who is otherwise unfit for chemotherapy require treatment to LNs while awaiting surgery, radiotherapy alone may be considered using conventional daily fractionation to 45–50Gy. Radiotherapy to the groins in penile cancer conceptually requires inclusion of the pre-pubic fat a in order to cover in transit lymphatics [269].

6.4.2.2 Post-operative radiation therapy

Adjuvant radiation therapy for node-positive penile cancer remains controversial. Since there is no level 1 evidence to support the benefit of radiation therapy in terms of disease recurrence and survival, it is not recommended in prior guidelines [270, 271]. Radiotherapy is being used in some institutions in the management of regional LNs for penile SCC, based on evidence and experience with other SCC sites (such as head/neck and vulvar carcinomas) [174, 272, 273].

Jaipuria *et al*., reported that following inguinal- and pelvic LND, patients with > 2 positive LNs but negative pelvic nodes (n = 32) had increased OS with adjuvant radiation therapy compared to adjuvant chemotherapy (48 months vs. 14 months $p < 0.0001$) [274]. Although 68% of patients had ENE, there were no in-field failures. The radiation dose was higher than that commonly used under these circumstances, 54 Gy for ENE and up to 57–60 Gy for gross residual disease. With a lower radiation dose of 50 Gy, Johnstone *et al.*, reported a high rate of in-field failures (32/39) [275]. At this dose, adjuvant radiation therapy (either groin: $p = 0.016$ or inguinal-pelvic: $p = 0.006$) improved RFS only for patients *without* ENE. Ager *et al*., reporting on the experience with pN3 disease (either ENE or pelvic LN+) in two tertiary referral centres in the UK also found dose to be critically important [276]. A 121 of 146 patients received adjuvant radiotherapy. The 5-year RFS was 51%. Twenty-six of 55 recurrences were in-field, but the risk of in-field failure was twice as high for lower doses < 50 Gy.

For 92 patients with positive pelvic LN from 4 international centres, adjuvant radiation was found to prolong DSS by 6 months and delay the time to recurrence [277].

The data collated in Table 6.3 reveal variable results with conventional radiotherapy delivered in the adjuvant setting, potentially impacted by HPV status and presence/absence of ENE. Also notable in the data is the fact that traditional radiotherapy doses delivered to microscopic disease may be insufficient. Recent genomic data analyses have modelled that a higher radiation dose may be necessary for management of penile cancer primary lesions and nodal basins [278, 279].

Table 6.3: Adjuvant conventional radiotherapy for node-positive penile cancer

Author	n	stage	aRT	Adj CT	RT	LR	OS	Study type
Jaipuria 2020 [274]	45	anyT pN2-3 pelvis pN-	25	7	VMAT/IMRT, 45 Gy basic, 54 Gy ENE, 57-60 macro	No InF	47 mo. RT vs. 14 mo. CT	Prosp registry
Johnstone 2019 [275]	93	anyTpN3 ENE- ENE+			50/25 no details		↑OS aRT p = 0.037 or aCT p = 0.038 ↑DSS aRT p = 0.04	4 centres
Winters 2018 [280]	136	pT1-3 pN1-2			45 Gy + boost 45%		↑OS aRT 5 yr. 64% vs. 53%	NCDB
Tang 2017 [277]	92	N3 +pelvis	40		63% 50/25, 13% > 50 Gy		↑OS aRT 12.2 vs.8 P=0.04 ↑DSS 14.4 vs.8 p = 0.02	4 centres
Ager 2021 [276]	146	pN3 (ENE or pelvis+)	121		45/20 to 54/25 2X↑LR if < 50	26 inF	OS 44% RFS 5y 51%	2 centres UK
Bandini 2021 [34]	507	ILND	86 HPV+ 40 aRT				↑OS aRT p = 0.015 Also propensity matched analysis	11 centres

ADj = adjuvant; aRT = adjuvant radiotherapy; CT = chemotherapy; ENE = extra-nodal extension; HPV = human papillomavirus; ILND = inguinal lymph node dissection; mo = month; n = number of patients; NCDB = National Cancer Database; OS = overall survival; RFS = recurrence free survival; yr = year.

HPV status could be a suitable selection factor for patients who will benefit from adjuvant radiotherapy after ILND (in analogy to other HPV-related cancers). Bandini *et al.*, reported on 507 patients from 11 centres, 86 of whom were HPV+. Among patients receiving adjuvant radiotherapy, those harbouring HPV-positive tumours appeared to have an increased OS relative to HPV-negative patients. However, more (prospective) studies are needed to validate these findings [34].

As in other SCC sites such as head and neck cancer, HPV status may also predict for increased responsiveness to combined chemo-radiotherapy. Yuan *et al.*, reported improved loco-regional control (LRC) of 83% over 38% (p = 0.038) for node-positive p16+ patients receiving chemo-radiotherapy following LND [273]. Twenty-eight of 51 patients were LN+, of whom 14 received chemo-radiotherapy, 7 of whom were HPV-positive. Overall, regardless of HPV status, 2-year LRC was 54% for those receiving adjuvant chemo-radiotherapy vs. 13% (p = 0.006). Choo *et al.*, found similar efficacy of adjuvant chemo-radiotherapy with improved CSS at one and 2 years, even though the patients selected for adjuvant chemo-radiotherapy had a higher number of positive LNs (64% > 5 vs. 8%),

more pN3 disease (72% vs. 17%) and more ENE (45% vs. 17%) [281]. The OS was the same for the unfavourable group receiving adjuvant chemo-radiotherapy as it was for the more favourable earlier-stage patients not receiving chemo-radiotherapy.

Although PLND is recommended for patients with high-risk groin pathology (N2–N3), this is not the practice in all jurisdictions. Maibom *et al.*, reported from Denmark on the use of inguinal-pelvic chemo-radiotherapy for 21 patients with a median follow-up of 74 months [282]. All patients had ENE and two-thirds had bilateral groin disease, with a median OS of 84 months and 57% 5-year survival. This concept is being tested in the currently accruing InPACT trial where men with high-risk groin pathology can be randomised to chemo-radiotherapy or PLND followed by chemo-radiotherapy [260].

6.4.2.3 Summary of evidence and guidelines for pre- and post-operative radiotherapy

Summary of evidence	**LE**
Adjuvant radiotherapy results in increased OS if greater than two inguinal LN-positive and PLND-dissection negative.	2b
Adjuvant conventional radiotherapy doses are often insufficient for durable control. Increased DSS and RFS in penile cancer requires 54 Gy for ENE and 57–60 Gy for positive margins.	3
Peri-operative chemo-radiotherapy	
chemo-radiotherapy significantly improves loco-regional control over radiotherapy alone for other SCC originating in anal canal or head and neck, whilst in vulvar cancers it improves OS. The evidence is, however, sparse in penile cancer.	1b

Recommendations	**Strength rating**
Offer adjuvant radiotherapy (with or without chemo sensitisation) to patients with pN2/N3 disease, including those who received prior neoadjuvant chemotherapy.	Weak
Offer definitive radiotherapy (with or without chemo sensitisation) to patients unwilling or unable to undergo surgery.	Weak
Offer radiotherapy (with or without chemo sensitisation) to cN3 patients who are not candidates for multi-agent chemotherapy.	Weak

6.5 Systemic and palliative therapies for advanced disease

6.5.1 Introduction

Much of our current standard of care for this rare disease has evolved based upon extrapolated experience with similar cancers. The most common regimens utilized today for advanced disease are similar to those routinely used in the peri-operative setting, consisting of platinum-based regimens. Most data come from institutional or retrospective studies, but cooperative groups have occasionally studied this disease via prospective phase II studies.

6.5.2 Chemotherapy

Phase II cooperative group studies with bleomycin, methotrexate, and cisplatin (BMP) and irinotecan cisplatin yielded response rates of 31–33% [186, 283]. The median OS for BMP was 28 weeks. Toxicity was a concern with both regimens, especially pulmonary toxicity from bleomycin.

A retrospective study of cisplatin and 5-FU (PF) presented a response rate of 32% and median OS of 8 months. Toxicity was manageable for this patient population [284].

Addition of taxanes to cisplatin-based regimens was associated with promising activity including CRs. Docetaxel, cisplatin, and fluorouracil (TPF) was prospectively studied in a cohort with distant metastasis (28%) or locally-advanced disease (72%). The response rate was 38.5% and median OS of 14 months; there were 2/26 patents with CR [184]. The study did not meet its efficacy endpoint and toxicity of TPF was a concern. Another prospective study of TPF in exclusively metastatic (M1) disease showed an objective response rate of 38.5% and median OS of 7 months [285]. The latter study did meet its efficacy endpoint and toxicity was interpreted as acceptable.

Paclitaxel, ifosfamide and cisplatin (TIP) was prospectively studied in patients with metastases confined to LNs (N2–3, M0), having a response rate of 50% in this select population and 3/30 with surgically verified CRs [180]. Toxicity was manageable in this setting, but there are limited data available for TIP in distant metastatic disease.

A SR of cisplatin-based chemotherapy outcomes with and without taxanes suggested a higher toxicity rate with taxanes, 49% vs. 26% [187].

Vinflunine single-agent chemotherapy was prospectively studied in patients with advanced disease who were not eligible for curative surgery or NAC. Patients were required to have ECOG performance status ≤ 2 and estimated glomerular filtration rate (GFR) ≥ 60 mL/min. Median age was 70 years with a 27% response rate and median OS of 8.4 months. Toxicity was manageable.

A retrospective study of paclitaxel single-agent chemotherapy as second line reported a response rate of 20% and median OS 23 weeks [286]. Two studies of various second-line systemic therapy regimens found median OS of 4.5 – 5.6 months [287, 288].

A retrospective study of 101 patients looked at the efficacy of chemotherapy as first-, second- and third-line treatment [287]. The median OS for first-line chemotherapy was 7.2 months and with best supportive care, two months. The second-line regimens in seventeen patients included paclitaxel/carboplatin (41%), cisplatin/capecitabine (12%), paclitaxel (12%), or other (36%). There were two objective responses (12%), three stable disease (18%) and seventeen with progressive disease (71%) as best response. Paclitaxel/carboplatin was also reported in adjuvant and neoadjuvant case series and was well tolerated [289, 290].

These data support the recommendation of platinum-based chemotherapy as the preferred approach to first-line palliative systemic therapy. Choices include triplet regimens (TPF, TIP) and doublets (PF, paclitaxel/carboplatin), where doublets appear to have less toxicity. Both TPF and TIP combine two neurotoxic drugs and are not appropriate for patients with pre-existing neuropathy or low GFR. Other comorbidities and functional status should be carefully considered when selecting a regimen. While data for paclitaxel/carboplatin in advanced penile cancer are limited, it is reasonable to extrapolate from its use as palliative treatment of squamous-cell cancers from other sites. An alternative approach is single-agent chemotherapy with vinflunine or a taxane.

Effective second-line palliative chemotherapy regimens are lacking. Second-line chemotherapy in multiple studies was associated with median OS of 6 months or less. This is an unmet need that also applies to patients with tumour recurrence after adjuvant or neoadjuvant chemotherapy.

6.5.2.1 Immunotherapy

Immune-based therapies such as immune-checkpoint blockade, HPV-directed vaccines and adoptive T-cell therapies have emerged as potential treatment options for advanced penile cancer [291]. Given the relatively high expression of PD-L1 in penile SCC, several trials in progress assess checkpoint inhibition in advanced disease. None of these anti-PD(L)1 monotherapy trials has been published thus far. Trials presented at conferences reported response rates of 14–17% [292, 293].

Basket studies testing combination therapies have included penile SCC patients. In a phase I-II study of nivolumab combined with cabozantinib, with or without ipilimumab, 3 penile SCC patients were included: one partial response (PR) and 2 stable diseases (SD) were reported [294]. In another study testing the combination of ipilimumab and nivolumab, 5 penile SCC were included reporting 2 patients having SD [295]. In general, inclusion of patients with advanced penile SCC after chemotherapy exposure into early-phase basket trials is highly recommended.

6.5.2.2 Targeted therapies

Beyond chemotherapy, currently limited additional systemic options exist. Specific actionable genetic alterations appear rare in this disease. Targeted therapy against epidermal growth factor receptor (EGFR) has been tested, similar to SCCs originating from other anatomical regions.

Evidence of sporadic activity of several EGFR inhibitors have been reported from a few small clinical studies or case-series [296-298]. Dacomitinib, an orally-available pan-HER inhibitor, was tested as monotherapy in a phase II study including patients with locally-advanced and distant metastatic penile SCC. Twenty-eight patients were included in this study, and the ORR was 32.1% with one patient benefiting with a complete response [299].

Despite PIK3CA gene alterations have been reported as the most frequently identified potentially 'actionable' genomic alterations in SCC of the pelvic region, no data currently support the use of selected targeted agents in this disease [300].

6.5.3 Role of radiotherapy in palliation

Radiotherapy is frequently necessary for palliation of penile cancer and should be customized for unique presentations as necessary: e.g., ulcerative fixed LNs or dermal lymphatic spread. While standard palliative regimens should be readily employed, providers should be aware that re-treatment may be necessary for durable disease control [301]. This radio-resistance in some cases has been noted [178].

With respect to chemoradiotherapy for large/inoperable primary tumors, large palpable nodes, or pelvic nodal involvement, a Dutch prospective trial of 33 patients (median age 64: IQR 54-73) was recently released [351]. A response rate of 73% and a complete response rate of 39% (evalutated by FDG-PET/CT) was noted after mitomycin C + capecitabine chemotherapy and 49.5-59.4Gy radiation. The 2-year overall survival was 46% and salvage surgery was feasible if required. Importantly, treatment toxicity was low compared to neoadjuvant chemotherapy (followed by surgery) [351].

6.5.4 Summary of evidence and guidelines for systemic and palliative therapies for advanced penile cancer

Summary of evidence	LE
Low-level data support the use of platinum-based chemotherapy as first-line systemic therapy in advanced disease.	3
Effective second-line palliative chemotherapy regimens are lacking. Second-line chemotherapy in multiple studies was associated with median OS of six months or less.	3
Initial phase II or basket studies assessed anti-EGFR therapy or checkpoint inhibition, as monotherapy or combination therapy, in advanced disease. Early evidence of promising clinical activity has been reported in patients with penile cancer.	2b

Recommendations	Strength rating
Systemic therapies	
Offer patients with distant metastatic disease, platinum-based chemotherapy as the preferred approach to first-line palliative systemic therapy.	Weak
Do not offer bleomycin because of the pulmonary toxicity risk.	Strong
Offer patients with progressive disease under platinum chemotherapy the opportunity to enroll in clinical trials, including experimental therapies within phase I or basket trials.	Strong
Radiotherapy	
Offer radiotherapy for symptom control (palliation) in advanced disease.	Strong

7. FOLLOW-UP AND QUALITY OF LIFE

7.1 Unmet needs

Penile cancer has a significant impact on QoL and unfortunately there remain many unmet needs to address (see Table 1.1 in Chapter 1) [2]. The physical changes, along with the psychological and emotional stress that men with penile cancer suffer requires recognition and professional support before, during and after treatment. Holistic patient support services delivered by a multi-disciplinary team as a routine part of surveillance and follow-up should be standard of care. Patients with cancer endorse of the need for 'adjustment' and dealing with the 'new normal' as part of survivorship [302]. The extent of this and the time it takes varies from person to person and it is important to realise that some unmet needs may not become an issue until much later on.

7.2 Rationale for follow-up

From an oncological perspective, surveillance is important as early detection of recurrence may increase the likelihood of curative treatment. Some studies suggest local recurrence does not significantly reduce long-term survival if successfully treated [147, 303]. However, a recent multi-centre study reported an increased risk of recurrence following glansectomy in men with more aggressive disease (T3 and/or high grade), which in turn resulted in poorer OS and CSS [145]. Disease that has spread to the inguinal LNs greatly reduces the rate of long-term CSS. Follow-up is also important for survivorship, allowing for the detection and management of the physical and psychological impact of treatments. The use of Patient Reported Outcome Measures (PROMS)

related to body image (Male Genital Self-Image Scale MGSIS-5) and lymphoedema (Groin and Lower Limb lymphoedema questionnaire G3L-20) have been proposed as tools to help patients and their healthcare team raise and discuss embarrassing topics during consultations [304].

Local or regional nodal recurrences usually occur within two to three years of primary treatment [147, 305, 306]. A recent study of 509 patients reported 52.3% of local recurrences occurred within two years and 79.5% within three years [306]. Fewer than 5% of regional or distant recurrences occur after two years, with the majority occurring within the first year after treatment [305, 306]. After five years, all recurrences were either local or new primary lesions [147]. This supports an intensive follow-up regimen during the first two years, with a less intensive follow-up later for a total of at least five years. Follow-up after five years may be omitted in motivated patients who will undertake regular self-examination reliably [147].

7.2.1 ***When and how to follow-up***

After local treatment with negative inguinal nodes, follow-up should include physical examination of the penis and groins for local and/or regional recurrence. Additional imaging has no proven benefit. Follow-up also depends on the primary treatment modality. Histology from the glans should be obtained to confirm disease-free status following laser ablation or topical chemotherapy. After potentially curative treatment for inguinal nodal metastases, CT or MRI imaging for the detection of systemic disease (imaging of thorax, abdomen and pelvis) should be performed at 3-monthly intervals for the first two years. Following this, the frequency is usually reduced to 6-monthly for a total of 5 years of follow-up. However, one study of 224 node-positive patients reported only two recurrences in years 3–5 of follow-up, and both of these were pN3 patients [305]. Although rare, late local recurrence may occur. Therefore, regular follow-up can be stopped after 5 years, provided the patient understands the need to report any local changes immediately [98]. In patients unlikely to self-examine, long-term follow-up may be necessary (Table 7.1).

7.2.2 ***Recurrence of the primary tumour***

Local recurrence is more likely with all types of local organ-sparing treatment. Until recently it was not believed to influence the CSS rate, although one study recently challenged this showing a reduction in OS and CSS following local recurrence after glansectomy [145]. Large series of glansectomies have reported local recurrence rates around 10% [145, 307], although others have reported recurrence in up to 27% of patients treated with penis-preserving modalities, usually occurring within the first two years [146]. After partial penectomy, the risk of local recurrence is about 4–5% [146, 147, 303]. Local recurrence is easily detected by physical examination, by the patient himself or his physician. Patient education is an essential part of follow-up, and the patient should be urged to visit a specialist if any changes are seen.

7.2.3 ***Regional recurrence***

Most regional recurrences occur during the first two years after treatment, irrespective of whether surveillance or invasive nodal staging were used. Although unlikely, regional recurrence can occur later than two years after treatment. It is therefore advisable to continue follow up in these patients [98]. The highest rate of regional recurrence (9%) occurs in patients managed by surveillance, while the lowest is in patients who have undergone invasive nodal staging by modified ILND or DSNB and whose LNs were negative (2.3%). The use of US and FNAC in suspicious cases has improved the early detection rate of regional recurrence [106, 107, 308]. Patients who have had surgery for LN metastases without adjuvant treatment have an increased risk of regional recurrence of 19% [147]. Regional recurrence requires timely treatment by rILND with (neo)adjuvant chemotherapy/chemo-radiotherapy.

Table 7.1: Follow-up regime for penile cancer

	Interval of surveillance		**Examinations and investigations**	**Minimum duration of follow-up**
	Years 1–2	Years 3–5		
Recommendations for follow-up of the primary tumour				
Penile-preserving treatment	3-monthly	6-monthly	Regular physician or self-examination. Repeat biopsy after topical or laser treatment for PeIN (optional).	5 years
Amputation	3-monthly	Annually	Regular physician or self-examination.	5 years
Recommendations for follow-up of the inguinal lymph nodes				
Surveillance	3-monthly	6-monthly	Regular physician or self-examination. US ± FNAC optional.	5 years
pN0	3-monthly	Annually	Regular physician or self-examination. US ± FNAC optional.	5 years

pN+	3-monthly	6-monthly	Regular physician or self-examination. US ± FNAC, CT chest/abdomen/pelvis or ^{18}FDG-PET/CT optional.	5 years

CT = computed tomography; ^{18}FDG = ^{18}F-fluoro-2-deoxy-D-glucose; FNAC = fine needle aspiration cytology; PET = positron emission tomography; US = ultrasound.

7.3 Patient support services

Surveillance is not just about assessing for recurrent disease and men may require more frequent appointments than suggested above, with different members of the multi-disciplinary team to deliver patient support services and address QoL challenges. In fact, the latter starts at the first pre-operative consultation, where a needs assessment can identify areas that will be individually more challenging for that patient, be it physical, psychological, emotional, social or financial. Many men with penile cancer reflect that whilst the knowledge of potential functional and psychological impacts of treatment would not have stopped them proceeding with it, they wish they had a better understanding before embarking on the surgery. Pre-habilitation programmes can also help with this. Recently a qualitative study highlighted that men with penile cancer would appreciate more focus on the following themes: "early signs and seeking help", "disclosure of a personal cancer" and "urological (dys)function" [309].

Unfortunately, not all men survive penile cancer and some present with, or recur with, advanced disease, some with extremely challenging symptoms to manage, including pain, odour and discharge. In addition to medical treatments outlined in other parts of these guidelines, early involvement of palliative care services for symptom control can make a huge difference to these patients.

7.3.1 Psychological support

Access to psychological support, counselling and psychosexual therapy are critical components of a holistic and multi-disciplinary survivorship service. Men will often think "why me?" and need help to process their thoughts and try to adjust to their changing situation. Areas for discussion might include identity and self-esteem (lifestyle and role adjustments), being a perceived burden, illness beliefs and perceptions, levels of social support, relationship quality and intimacy, body and self-image and concerns around mortality. Despite these significant psychological challenges, the rate of suicide, based on the SEER database (1973–2013) is amongst the lowest of all urological malignancies; 13 out of 6,155 men [310].

7.3.2 Quality of life

There is very little data on QoL after treatment for penile cancer. In particular, there is heterogeneity of the psychometric tools used to assess QoL outcomes and further research is needed to develop disease-specific PROMS for penile cancer. Some validated questionnaires have been used but none of them were validated in men with penile cancer. Tools used include LYMQOL (lymphoedema) [311], IIEF (erectile dysfunction) [312], SF-36 [313], European Organization for Research and Treatment of Cancer [EORTC] QLQ-C30 [314], Quality of Life Questionnaire-Penile Cancer-Rostock (HRO-PE29) [315], Hospital Anxiety and Depression Scale [316], EQ-5D (Euro QoL tool), Bigelow's questionnaire [317], Male Genital Self-Image Scale MGSIS-5 and Groin and Lower Limb lymphoedema questionnaire G3L-20 [318].

Not surprisingly, published studies and discussions with patient groups demonstrate that penile cancer and its treatments have a significant impact on overall QoL, both physical and psychological. However, there is discrepancy in the literature as to whether partial penectomy impacts QoL more than penile-preserving surgical techniques, as discussed below. Erectile dysfunction, reduced frequency of sexual intercourse and reduced satisfaction with intercourse are reported in some studies [319, 320]. Urinary spraying [321] is another potential significant consequence of penile cancer surgery. Significant anxiety (31%) and depression (6%) has also been reported [322].

A German study reported on 76 patients following primary penile surgery. They reported a global QoL score well below the national average for age-standardised German patients, with voiding, sexuality, body image, lymphoedema all reported as areas of concern [315].

A Dutch study, where 90 patients returned their questionnaires (a return rate of 62%) orgasm, appearance concerns, life interference and urinary function were all significantly poorer following partial penectomy compared with a penile-preserving approach. In the same study, LND had a significant impact on life interference. Interestingly, when compared to an age and gender matched normative sample from the general population the patients reported better outcomes for the SF-36 physical domain and bodily pain sub scale [321].

A recent SR [3] reported on post-treatment QoL from 10 studies involving 346 men [157, 176, 315, 321, 323-328]. Two studies evaluated QoL as the primary endpoint and compared the outcomes among various treatment modalities [323, 327]. One of these studies used EORTC QLQ C-30 and reported on the QoL of men after penile cancer management with different treatment modalities. They observed that the treatment itself was not related to overall wellbeing or to social contact and activity. However, half of the individuals had psychological symptoms at follow-up [327]. In contrast, a retrospective study of men who underwent penile-preserving surgery reported a significant impact of surgery in every domain of EORTC QLQ-C30 questionnaire [315].

Another study used Bigelow's questionnaire and compared the post-operative QoL score to that at two weeks before surgery [328]. It reported that the scores relating to unpleasant feeling, sexual pleasure and familial/ partner relations improved significantly ($p < 0.01$) whereas the domains relating to friend relationships and professional quality were unchanged.

Two non-randomised comparative studies used EORTC QLQ-C30 to assess QoL after penile preserving surgery or amputative surgery [323, 324]. The first trial on 51 men reported a statistically significant negative correlation between aggressiveness of surgery and global health status and physical functioning [323]. Whereas the other reported no significant differences between penile-preserving surgery or partial penectomy in functional scale, symptom scale and in the global health status [324]. A comparison between glans resurfacing, glansectomy and partial penectomy using the EQ-5D tool showed no difference between groups with comparable health status scores of 82.5, 85.0 and 87.5 respectively [157].

Another non-randomised comparative study also compared penile-preserving surgery to partial penectomy and reported no difference in QoL using the SF-36 scores [321]. Those who underwent amputative surgery had significantly more appearance concerns ($p = 0.008$) and they reported more life interference ($p = 0.032$) depending on the degree of disfigurement caused by the procedure.

*7.3.3 **Urinary function***

Urinary function is an important topic to discuss with men before penile cancer treatment. Some will already be experiencing difficulty voiding due to their tumour causing urethral obstruction and many report they sit down to pass urine due to the spraying caused by the tumour. As a result, some report improved function following surgery, often in terms of flow but spraying and needing to sit down to void or use a funnel/bottle can be debilitating for many men.

Urinary function has been objectively assessed in only a few studies. Two case series reported improvement in post-operative urinary function and high satisfaction after penile surgery [326, 329]. Two non-randomised comparative studies reported no difference in urination between penile-preserving surgery or amputation. One demonstrated similar maximum flow rates following surgery (19.5 mL/s vs. 20.8 mL/s) [324] the other reported that urinary function was comparable across the study groups (glans resurfacing, glansectomy and partial penectomy) using the ICIQ-MLUTS score [157]. However, a different study found that urine spraying is more common after partial penectomy as compared to penile-preserving surgery (83% vs. 43%) [321]. Two case series reported no significant changes in urinary function following brachytherapy [166, 176]. A single trial on Moh's micrographic surgery, reported no post-treatment change (66% response rate) [330].

*7.3.4 **Sexual function***

Sexual and erectile function after penile cancer varies between studies and between treatments. Generally, penile-preserving surgery preserves erectile function, although glans sensation and orgasm can be affected. Overall, partial penectomy is associated with poorer sexual outcomes.

A recent SR [3] reported on the sexual and erectile function from 27 studies that involve 991 men. The 5- or 15-question International Index of Erectile Function (IIEF) scores were used by most studies. Other tools used were the Erectile Dysfunction Inventory of treatment satisfaction score (EDITS), the index of male genitalia image (IM-GI), the Life Satisfaction of sexual life, the SELF-Esteem and Relationship (SEAR) or a combination of tools to assess overall sexual function [176, 324, 325, 327, 331]. It is important to acknowledge that only a few studies assessed baseline function and are therefore able to report the difference between pre- and post-treatment. Most studies reported only the post-treatment scores or the mean difference for retrospectively completed pre-treatment scores.

Three non-randomised comparative studies and one case series assessed the impact of penile-preserving surgery vs. amputation on sexual function of 202 men [321, 324, 327, 332]. Two studies that used the 15-question IIEF questionnaire reported significant post-treatment changes in the orgasmic function domain in favour of penile-preserving surgery ($p = 0.033$ and $p = 0.033$) while the other domains remain comparable between the treatment arms [321, 324]. However, in other studies using the 5-question IIEF score, no difference was identified between treatments [157, 332]. An older study that compared the impact of penile-preserving surgery, amputative surgery and radiotherapy on sexual function reported that those treated with amputation had worst sexual outcome [327]. Three trials retrospectively compared penile-preserving surgery techniques using IIEF questionnaire [326, 333, 334]. Wide local excision was superior to glansectomy in all IIEF domains [333]. The impact of primary closure versus preputial flap reconstruction after glans-preserving surgery was similar as seen by IIEF results at 6 months or by rigid-scan parameters [334]. Partial glansectomy was not superior to total glansectomy [326].

Cohort studies have reported similar findings on sexual function. Five studies on patients who underwent penile-preserving surgery and reconstruction reported that 85–100% of men were able to achieve erection and maintain their sexual function [158, 335-338]. However, all patients reported reduced glans sensitivity. Following glans resurfacing for penile cancer (n = 21) or lichen sclerosis (n = 16) one study reported no significant change in urinary or sexual function (using IPPS and IIEF questionnaires) with glans sensitivity preserved in 89.2% of men [339].

Four studies on 167 men who have had partial penectomy reported significant changes in 15-question IIEF score with negative impact in every domain [319, 329, 331, 340]. A single trial reported that 61.7% of men after partial penectomy report erectile dysfunction [340]. However, a study from Brazil, assessing 14 patients following partial penectomy, found that for 64% overall sexual function was normal or slightly decreased and frequency of sexual intercourse was unchanged or slightly decreased [320].

The sexual function after brachytherapy has been assessed in five cohort studies [162, 166, 176, 341, 342]. Among men who were sexually active before treatment, 58.8–70.0% remain sexually active after treatment [162, 176]. Potency was maintained in 81.5–100% of men [162, 166, 176, 341, 342]. Altered glans sensitivity is reported in 52.6% [162].

Three studies assessed sexual function after laser treatment [155, 325, 343] and 46–56.5% of men report an impact of treatment on their sexual life [325, 343]. A single trial on 46 men found that 72% reported no change in erectile function, 22% reported decreased erectile function and 6% reported improvement [155].

One trial on patients who underwent Moh's micrographic surgery reported no change in sexual function after treatment (57.5% response rate) [330].

7.3.5 ***Lymphoedema***

Lymphoedema significantly impacted functional domains in one study of patients 25 months following penile cancer nodal surgical treatment with inguinal and PLND having a much higher impact than ILND alone. Patients who had inguinal and PLND also had a much poorer mood score (38% vs. 0%) [344]. Due to the significant morbidity associated with ILND, many patients are not offered the operation or choose not to have it. An analysis of the US SEER database reported that only 233 out of 943 nonmetastatic penile cancer patients (24.7%) had ILND between 1998 and 2015 [223]. This did not change over time. A similar proportion of men, 606 out of 2224 (27.2%) underwent the surgery between 2004 and 2014 as recorded by the National Cancer Database [345].

Men should be assessed for genital and lower limb lymphoedema at each outpatient clinic appointment, advised about good skin care, compression, exercise, massage, and elevation when resting as the mainstay of treatment. Following nodal surgery, ideally, they would be referred to specialist lymphoedema services for assessment and management before any significant lymphoedema occurs.

Specialist lymphoedema services offer a range of made-to-measure compression garments or multi-layer lymphoedema bandaging for lower limb and genital lymphoedema. The latter not only compress the scrotal lymphoedema but also aim to lift it to aid drainage. For lower limb compression adjustable Velcro garments also exist. Good skin care is critical to prevent infection that can damage remaining lymphatic channels. Prophylactic antibiotics should be used following any episode of cellulitis, with penicillin V, erythromycin or clindamycin recommended, except in genital lymphoedema where prophylactic trimethoprim can be used [346].

Manual lymphatic drainage in the form of specialised massage techniques also helps to alleviate lymphoedema and encourages drainage. Following penile cancer treatments this is commonly used for stubborn mons and lower abdominal swelling and thickening of the scrotum and penile shaft.

Whilst regular exercise may temporarily increase lymphoedema due to the effect of gravity, it has an overall beneficial effect on lymphoedema by reducing abdominal fat (fat drains via lymphatic channels too) and using natural muscle pumps and changes in thoracic pressure to help lymphatic drainage. Strength training and stretching exercises to promote flexibility are also important.

Debulking surgery with scrotal reduction and penile shaft skin grafting can significantly improve issues related to significant genital lymphoedema. There is limited evidence for the benefit of other surgical interventions such as limb liposuction followed by compression and lymphatico-venous anastomosis in penile cancer although some evidence does exist for extremity lymphoedema due to various causes [347].

7.4 Centralisation of penile cancer services

Current large volume centres offer specialist nursing support, psychological support and specialised lymphoedema services to their patients. However, even in centralised healthcare systems, such as the UK, services vary and are not always available.

Centralisation of penile cancer services has a number of advantages in addition to delivering these important supportive services to patients (Table 7.2) [348]. These include provision of an environment where multi-disciplinary discussion of cases can occur along with specialist pathological review, and delivery of high volume penile-preserving and nodal surgery which can lead to innovation, such as closer surgical margins [151], more accurate DSNB and minimally-invasive surgery. In the UK, around 80% of penile cancers are treated with penile-preserving surgery. Centralisation can also reduce system delays [349] and result in better adherence to guidelines. In addition, patients should be able to access a larger team of specialists, including psychological and lymphoedema survivorship services. Centralisation of penile cancer services also creates opportunities for research and running clinical trials with a larger number of patients in a rare disease.

Disadvantages of centralisation include de-skilling of medical teams not involved with regularly looking after penile cancer and making patients travel long distances for treatment. This can be a significant financial burden, especially as many are in a lower socio-economic group. However, the recent increase in virtual healthcare and video consultation may reduce this burden, as does the provision of outreach clinics and services. In addition, educational sessions within cancer networks, can help keep local teams up-to-date, enabling them to help support the patient when back at home (Table 7.2).

In one hospital in the UK, 5-year CSS rates were observed to improve by up to 12% to 85% following centralisation, which is likely to be due to several factors, including the impact of early and complete pathological LN staging, regular multi-disciplinary patient reviews and use of adjuvant chemotherapy and chemo-radiotherapy in most patients where indicated [350].

Table 7.2: Advantages and disadvantages of centralisation

Advantages	Disadvantages
Multi-disciplinary team and holistic approach to penile cancer care	De-skilling of urologists and their teams
Opportunities for research, clinical trials and innovation	Distance patients need to travel
Improved survival	Financial burden of travel
High rates of penile-preserving surgery	Lack of local support for patients
High rates of surgical nodal staging	
Specialist lymphoedema services	
Specialist uro-radiology/nuclear medicine	
Specialist pathology reporting/review	
Psychological support	
Adherence to guidelines	
Clear referral pathway/reduced system delays	

7.5 Summary of evidence and guidelines for follow-up and quality of life

Summary of evidence	LE
Follow-up surveillance is important as early detection of recurrence may increase the likelihood of curative treatment.	3
Local or regional nodal recurrences usually occur within two years of primary treatment.	3
Penile cancer has a significant impact on QoL in many ways and there remain many unmet needs to address.	4
There is very little data on QoL after treatment for penile cancer. In particular, there is heterogeneity of the psychometric tools used to assess QoL outcomes and further research is needed to develop disease-specific PROMS for penile cancer.	3
Generally, penile-preserving surgery preserves erectile function, although glans sensation and orgasm can be affected. Overall, partial penectomy is associated with poorer sexual outcomes.	2b
Access to psychological support, counselling and psychosexual therapy are critical components of a holistic and multi-disciplinary patient support service.	4
Ideally, following nodal surgery, patients would be referred to specialist lymphoedema services for assessment and management before any significant lymphoedema occurs.	4
In one UK specialist penile cancer centre (referral population approximately 11 million), 5-year CSS rates were observed to improve by up to 12-85% following centralisation.	3

Recommendations	Strength rating
Deliver penile cancer care as part of an extended multi-disciplinary team comprising of urologists specialising in penile cancer, specialist nurses, pathologists, uro-radiologists, nuclear medicine specialists, medical and radiation oncologists, lymphoedema therapists, psychologists, counsellors, palliative care teams for early symptom control, reconstructive surgeons, vascular surgeons, sex therapists.	Strong
Follow-up men after penile cancer treatment, initially 3-monthly for two years then less frequently to assess for recurrent disease and to offer patient support services through the extended multi-disciplinary team. At discharge, recommend self-examination with easy access back to the clinic as local recurrence can occur late.	Strong
Discuss the psychological impact of penile cancer and its treatments with the patient and offer psychological support and counselling services.	Strong
Discuss the negative impact of treatments for the primary tumour on penile appearance, sensation, urinary and sexual function so that the patient is better prepared for the challenges he may face.	Strong
Discuss the potential impact of lymphoedema as a consequence of inguinal and pelvic lymph node treatment with the patient and assess patients for it at follow-up and refer to lymphoedema therapists early.	Strong

9. CONFLICT OF INTEREST

All members of the EAU-ASCO Penile Cancer Guidelines working group have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publicly accessible through the European Association of Urology website: http://uroweb.org/guideline/penile-cancer/.

This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

10. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU-ASCO Penile Cancer Guidelines. Edn. presented at the EAU Annual Congress Paris 2024. ISBN 978-94-92671-23-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, The Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aims and scope

The European Association of Urology (EAU) Urolithiasis Guidelines Panel has prepared these guidelines to help urologists assess evidence-based management of stones/calculi in the urinary tract and incorporate recommendations into clinical practice. This document covers most aspects of the disease, which is still a cause of significant morbidity despite technological and scientific advances. The Panel is aware of the geographical variations in healthcare provision. In addition, information on the management of bladder stones is now also included in these guidelines.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Urolithiasis Guidelines Panel consists of an international group of clinicians with expertise in this area. All experts involved in the production of this document have submitted potential conflict of interest which can be viewed on the EAU website Uroweb: http://uroweb.org/guideline/urolithiasis/.

1.3 Available publications

A quick reference document (Pocket guidelines) is available. This is an abridged version, which may require consultation together with the full-text versions. Several scientific publications are available [1-3]. All documents are accessible through the EAU website Uroweb: http://uroweb.org/guideline/urolithiasis/.

1.4 Publication history and summary of changes

*1.4.1 **Publication history***

The EAU Guidelines on Urolithiasis were first published in 2000. Standard procedure for EAU Guidelines includes an annual assessment of newly published literature in the field to guide future updates. This 2024 Urolithiasis Guidelines present a limited update of the 2023 publication.

*1.4.2 **Summary of changes***

The 2024 Urolithiasis Guidelines have undergone a major revision and restructuring of text, as well as a review of all recommendations.

2. METHODS

2.1 Data identification

Recommendation within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [4];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact and certainty of patient values and preferences on the intervention

Strong recommendations typically indicate a high degree of evidence quality and / or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [5].

Additional information can be found in the general Methodology section of this print, and online at the EAU website: https://uroweb.org/guidelines/urolithiasis/ publications-appendices. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review

The 2015 Urolithiasis Guidelines were subjected to peer review prior to publication. Chapter 6, detailing the treatment and follow-up of bladder stones was peer-reviewed in 2019.

3. GUIDELINES

3.1 Prevalence, aetiology, risk of recurrence

3.1.1 Introduction

Stone incidence depends on geographical, climatic, ethnic, dietary, and genetic factors. The recurrence risk is basically determined by the disease or disorder causing the stone formation. Accordingly, the prevalence rates for urinary stones vary from 1% to 20% [6]. In countries with a high standard of life such as Sweden, Canada or the USA, renal stone prevalence is notably high (> 10%). For some areas, an increase of more than 37% over the last 20 years has been reported [7-9]. There is emerging evidence linking nephrolithiasis to the risk of chronic kidney disease (CKD) [10].

Stones can be stratified into those caused by: infections, non-infectious causes, genetic defects [11, 12]; or adverse drug effects (drug stones) (Table 3.1). See also section 3.2.

Table 3.1: Stones classified by aetiology

Non-infection stones		
• Calcium oxalate	• Calcium phosphate	• Uric acid • Ammonium urate*
Infection stones		
• Magnesium ammonium phosphate	• Highly carbonated apatite	• Ammonium urate
Genetic causes		
• Cystine	• Xanthine	• 2,8-Dihydroxyadenine
Drug stones		

**In children in developing countries; in patients with anorexia or laxative-abuse.*

3.1.2 Stone composition

Stone composition is the basis for further diagnostic and management decisions. Stones are often formed from a mixture of substances. Table 3.2 lists the most clinically relevant substances and their mineral components.

Table 3.2: Stone composition

Chemical name	Mineral name [13]	Chemical formula
Calcium oxalate monohydrate	Whewellite	$CaC_2O_4.H_2O$
Calcium oxalate dihydrate	Weddelite	$CaC_2O_4.2H_2O$
Basic calcium phosphate	Apatite	$Ca_{10}(PO_4)_6.(OH)_2$
Calcium hydroxyl phosphate	Carbonate apatite	$Ca_5(PO_4)_3(OH)$
b-tricalcium phosphate	Whitlockite	$Ca_3(PO_4)_2$
Carbonate apatite phosphate	Dahllite	$Ca_5(PO_4)_3OH$
Calcium hydrogen phosphate dihydrate	Brushite	$CaHPO_4.2H_2O$
Calcium carbonate	Aragonite	$CaCO_3$
Octacalcium phosphate	-	$Ca_8H_2(PO_4)_6.5H_2O$
Uric acid	Uricite	$C_5H4N_4O_3$

Uric acid dihydrate	Uricite	$C_5H_4O_3.2H_20$
Ammonium urate	-	$NH_4C_5H_3N_4O_3$
Sodium acid urate monohydrate	-	$NaC_5H_3N_4O_3.H_2O$
Magnesium ammonium phosphate hexahydrate	Struvite	$MgNH_4PO_4.6H_2O$
Magnesium acid phosphate trihydrate	Newberyite	
Magnesium ammonium phosphate monohydrate	Dittmarite	
Cystine	-	
Xanthine	-	-
2,8-Dihydroxyadenine	-	-
Proteins	-	-
Cholesterol	-	-
Calcite	-	-
Potassium urate	-	-
Trimagnesium phosphate	-	-
Melamine	-	-
Matrix	-	-
Drug stones	Active compounds crystallising in urine	-
Foreign body calculi	-	-

*3.1.3 **Risk groups for stone formation***

Determination of the risk for stone formation is imperative for pharmacological treatment. Previous stone history (recurrence, regrowth, stone surgeries) is a fundamental element in determining risk for stone formation. About 50% of recurrent stone formers have just one-lifetime recurrence [9, 14]. A review of first-time stone formers calculated a recurrence rate of 26% in five years' time [15]. Highly recurrent disease is observed in slightly more than 10% of patients. Stone type and disease severity determine low- or high-risk stone formers (Table 3.3) [16-32].

However, the risk status of stone formers should be determined in a holistic way taking into consideration not only the probability of stone recurrence or regrowth, but also the risk of chronic kidney disease (CKD), end-stage kidney disease (ESKD), and metabolic bone disorder (MBD) [33, 34]. A comprehensive evaluation of stone risk in patients should also include the risk of developing CKD, ESKD, and MBD (Tables 3.4, 3.5, and 3.6) [33]. Urolithiasis can compromise renal function because of the renal stone (obstruction, infection), renal tissue damage due to the primary condition causing stone formation (some genetic diseases, nephrocalcinosis, enteric hyperoxaluria, etc.), or urological treatments for the condition [33]. Certain risk factors have been shown to be associated with such a risk in stone formers, as shown below.

Table 3.3: High-risk stone formers [16-32]

General factors
Early onset of urolithiasis (especially children and teenagers)
Familial stone formation
Recurrent stone formers
Short time since last stone episode
Brushite-containing stones ($CaHPO_4.2H_2O$)
Uric acid and urate-containing stones
Infection stones
Solitary kidney (the kidney itself does not particularly increase the risk of stone formation, but prevention of stone recurrence is of crucial importance to avoid acute renal failure)
Chronic Kidney Disease (CKD)

Diseases associated with stone formation
Hyperparathyroidism
Metabolic syndrome
Mineral Bone Disorder (MBD)
Nephrocalcinosis
Polycystic kidney disease (PKD)
Gastrointestinal diseases (i.e., enteric hyperoxaluria due to jejuno-ileal bypass, intestinal resection, Crohn's disease, malabsorptive conditions, urinary diversion, exocrine pancreatic insufficiency, and bariatric surgery).
Increased levels of vitamin D
Sarcoidosis
Spinal cord injury, neurogenic bladder
Genetically determined stone formation
Cystinuria (type A, B and AB)
Primary hyperoxaluria (PH)
Renal tubular acidosis (RTA) type I
2,8-Dihydroxyadeninuria
Xanthinuria
Lesch-Nyhan syndrome
Cystic fibrosis
Drug-induced stone formation (see Table 4.11)
Anatomical abnormalities associated with stone formation
Medullary sponge kidney (tubular ectasia)
Ureteropelvic junction (UPJ) obstruction
Calyceal diverticulum, calyceal cyst
Ureteral stricture
Vesico-uretero-renal reflux
Horseshoe kidney
Ureterocele
Environmental and professional factors
High ambient temperatures
Chronic lead and cadmium exposure

Table 3.4 Risk factors for CKD and ESKD in stone formerss

Risk factors for CKD/ESKD in stone formers
Female gender
Overweight
Frequent UTI
Struvite stones
Acquired single kidney
Neurogenic bladder
Previous obstructive nephropathy
Ileal conduit

Furthermore, some specific kinds of urolithiasis also carry a particular risk of developing CKD/ESKD as shown below.

Table 3.5 Risk factors for CKD and renal stones

Risk of chronic kidney disease and renal stones
• Possible risk of CKD
■ Xanthine stones
■ Indinavir stones
■ Distal renal tubular acidosis (incomplete)
■ Primary hyperparathyroidism
■ Eating disorders and laxative abuse
■ Medullary sponge kidney
• Moderate risk of CKD
■ Brushite stones
■ 2,8-Dihydroxyadenine stones
■ Sarcoidosis
■ Pyelo-ureteral or ureteral strictures
• High risk of CKD
■ Cystine stones
■ Struvite stones
■ Stones in a single kidney
■ Distal renal tubular acidosis (complete)
■ Secondary hyperoxaluria (bariatric surgery, inflammatory bowel disease, bowel resection and malabsorptive syndromes)
■ Other forms of nephrocalcinosis (often associated with genetic conditions with hypercalciuria)
■ Anatomical abnormalities of the kidney and urinary tract (for example, horseshoe kidney, ureterocele and vesicoureteral reflux)
■ Neurological bladder
• Very high risk of CKD
■ Primary hyperoxaluria
■ Autosomal dominant polycystic kidney

Table 3.6 Risk factors for metabolic bone disease and calcium renal stones

Risk of metabolic bone disease and calcium renal stones
• Distal renal tubular acidosis (complete or incomplete)
• Medullary sponge kidney
• Primary hyperparathyroidism
• Malabsorptive syndromes
• Fasting hypercalciuria
• Genetic disorders

3.2 Classification of stones

Urinary stones can be classified according to size, location, X-ray characteristics, aetiology of formation, composition, and risk of recurrence [2, 9, 32].

*3.2.1 **Stone size***

Stone size can be reported in a single, two or three dimensions. Currently, the guidelines still use the linear measurement of cumulative stone diameter to stratify stones in < 5 mm, 5-10 mm, 10-20 mm, and > 20 mm for use in the treatment algorithm.

*3.2.2 **Stone location***

Stones can be classified according to anatomical position: upper, middle, or lower calyx; renal pelvis; upper, middle, or distal ureter; and urinary bladder.

3.2.3 X-ray characteristics

Stones can be classified according to plain X-ray appearance [kidney-ureter-bladder (KUB) radiography] (Table 3.7), which varies according to mineral composition [35]. Non-contrast-enhanced computed tomography (NCCT) can be used to classify stones according to density, inner structure, and composition, which can affect treatment decisions (Section 3.3) [35, 36].

Table 3.7: X-ray characteristics

Radiopaque	Poor radiopacity	Radiolucent
Calcium oxalate dihydrate	Magnesium ammonium phosphate	Uric acid
Calcium oxalate monohydrate	Cystine	Ammonium urate
Calcium phosphate		Xanthine
		2,8-Dihydroxyadenine
		Drug-stones (Section 4.11)

3.3 Diagnostic evaluation

3.3.1 Diagnostic imaging

The most appropriate imaging modality will be determined by the clinical situation, which will differ depending on if a ureteral or a renal stone is suspected.

Standard evaluation includes a detailed medical history and physical examination. Patients with ureteral stones usually present with loin pain, vomiting, and sometimes fever, but may also be asymptomatic [37]. Immediate evaluation is indicated in patients with solitary kidney, fever or when there is doubt regarding a diagnosis of renal colic. Ultrasound (US) should be used as the primary diagnostic imaging tool, although pain relief, or any other emergency measures, should not be delayed by imaging assessments. Ultrasound is safe (no risk of radiation), reproducible and inexpensive. It can identify stones located in the calyces, pelvis, and pyeloureteric and vesico-ureteral junctions (US with filled bladder), as well as in patients with upper urinary tract (UUT) dilatation. Ultrasound has a sensitivity of 45% and specificity of 94% for ureteral stones and a sensitivity of 45% and specificity of 88% for renal stones [38, 39].

The sensitivity and specificity of KUB is 44-77% [40]. Kidney-ureter-bladder radiography [41] is helpful in differentiating between radiolucent and radiopaque stones and could be used for comparison during follow-up.

3.3.1.1 Evaluation of patients with acute flank pain/suspected ureteral stones

Non-contrast-enhanced computed tomography has become the standard for diagnosing acute flank pain and has replaced intravenous urography (IVU). Non-contrast-enhanced CT can determine stone location, burden, and density. When stones are absent, the cause of abdominal pain should be identified. In evaluating patients with suspected acute urolithiasis, NCCT is significantly more accurate than IVU or US [42, 43].

Non-contrast-enhanced CT can detect uric acid and xanthine stones, which are radiolucent on plain films, but not indinavir stones [44]. Non-contrast-enhanced CT can determine stone density, the inner structure of the stone, skin-to-stone distance, and surrounding anatomy; all of which affect the selection of treatment modality [45]. The advantage of non-contrast imaging must be balanced against the loss of information on renal function and urinary collecting system anatomy, as well as higher radiation dose [46-49].

Radiation risk can be reduced by low-dose CT, which may, however, be difficult to introduce in standard clinical practice [50-53]. In patients with a body mass index (BMI) < 30, low-dose CT has been shown to have a sensitivity of 86% for detecting ureteral stones < 3 mm and 100% for calculi > 3 mm [54]. A meta-analysis (MA) of prospective studies [55] has shown that low-dose CT diagnosed urolithiasis with a pooled sensitivity of 93.1% (95% CI: 91.5-94.4), and a specificity of 96.6% (95% CI: 95.1-97.7%). Dual-energy CT can differentiate uric acid containing stones from calcium-containing stones [36].

Summary of evidence	LE
Non-contrast-enhanced CT is used to confirm stone diagnosis in patients with acute flank pain, as it is superior to IVU.	1a
Computed tomography imaging enables 3D reconstruction of the collecting system, as well as measurement of stone density and skin-to-stone distance.	2a
Consider a contrast study if stone removal is planned and the anatomy of the renal collecting system needs to be assessed.	3

Recommendations	Strength rating
Immediate imaging is indicated with fever or solitary kidney, and when diagnosis is doubtful.	Strong
Use non-contrast-enhanced computed tomography to confirm stone diagnosis in patients with acute flank pain following initial ultrasound assessment.	Strong

*3.3.2 **Diagnostics - metabolism-related***

Besides imaging, each emergency patient with urolithiasis needs a succinct biochemical work-up of urine and blood test. At this point, no distinction is made between high- and low-risk patients for stone formation.

3.3.2.1 Basic laboratory analysis - non-emergency urolithiasis patients

Biochemical work-up is similar for all stone patients (see 3.3.2.3). However, if no intervention is planned, examination of sodium, potassium, C-reactive protein (CRP), and blood coagulation time can be omitted. Only patients at high risk for stone recurrence should undergo a more specific analytical programme [17]. Stone-specific metabolic evaluation is described in Chapter 4.

The easiest method for diagnosing stones is by analysis of a passed stone using a validated method as listed in section 3.3.2.3. Once the mineral composition is known, a potential metabolic disorder can be identified.

3.3.2.2 Analysis of stone composition

Stone analysis should be performed on all first-time stone formers.

In clinical practice, repeat stone analysis is needed in the case of:

- recurrence under pharmacological prevention;
- early recurrence after interventional therapy with complete stone clearance;
- late recurrence after a prolonged stone-free period [56, 57].

Patients should be instructed to filter their urine to retrieve a concrement for analysis. Stone passage and restoration of baseline renal function should be confirmed.

The preferred analytical procedures are infrared spectroscopy (IRS) or X-ray diffraction (XRD) [58, 59]. Equivalent results can be obtained by polarisation microscopy. Chemical analysis (wet chemistry) is generally deemed to be obsolete [58, 60].

3.3.2.3 Recommendations for laboratory examinations and stone analysis [17, 23, 61-63]

Recommendations	Strength rating
Urine	
Dipstick test of spot urine sample: • red cells; • white cells; • nitrites; • approximate urine pH; • urine microscopy and/or culture.	Weak
Blood	
Serum blood sample: • creatinine; • uric acid; • (ionised) calcium; • sodium; • potassium; • blood cell count; • C-reactive protein.	Strong
Perform a coagulation test (partial thromboplastin time and international normalised ratio) if intervention is likely or planned.	Strong
Perform stone analysis in first-time formers using a valid procedure (X-ray diffraction or infrared spectroscopy).	Strong

Repeat stone analysis in patients presenting with: • recurrent stones despite drug therapy; • early recurrence after complete stone clearance; • late recurrence after a long stone-free period because stone composition may change.	Strong

*3.3.3 **Diagnosis in special groups and conditions***

3.3.3.1 Diagnostic imaging during pregnancy

In pregnant women, radiation exposure may cause non-stochastic (teratogenesis) or stochastic (carcinogenesis, mutagenesis) effects. Teratogenic effects are cumulative with increasing doses and require a threshold dose (< 50 mGy are considered as safe) and depend on the gestation age (minimum risk prior to the 8th week and after the 23rd week). Carcinogenesis (dose even < 10 mGy present a risk) and mutagenesis (500-1000 mGy doses are required, far in excess of the doses in common radiographic studies) get worse with increasing dose but they do not require a dose threshold and are not dependent on the gestational age [64].

There is no imaging modality that should be routinely repeated in pregnant women. Scientific societies and organizations agree on the safety of the diagnostic evaluation when the US [65], X-ray imaging [66, 67], and MRI [68] are used as and when indicated [69-76]. A radiographic procedure should not be withheld from a pregnant woman if the procedure is clearly indicated and doing so will affect her medical care.

It is generally recommended that an investigation resulting in an absorbed dose to the foetus of greater than 0.5 mGy requires justification.

Ultrasound (when necessary, using changes in the renal resistive index and transvaginal/transabdominal US with a full bladder) has become the primary radiological diagnostic tool when evaluating pregnant patients suspected of renal colic. However, normal physiological changes in pregnancy can mimic ureteral obstruction [72-74].

Magnetic resonance imaging can be used, as a second-line option [70], to define the level of urinary tract obstruction, and to visualise stones as a filling defect [77]. The use of gadolinium is not routinely recommended in pregnancy to avoid toxic effects on the embryo [72].

For the detection of urolithiasis during pregnancy, low-dose CT is associated with a higher positive predictive value (95.8%), compared to MRI (80%) and US (77%). As per White *et al.*, low-dose CT offers improved diagnostic accuracy that can avoid negative interventions such as ureteroscopy [78]. Although low-dose CT protocols reduce radiation exposure, judicious use is currently recommended in pregnant women as a last-line option [72].

Summary of evidence	**LE**
Only low-level data exist for imaging in pregnant women supporting US and MRI.	3

Recommendations	**Strength rating**
Use ultrasound as the preferred method of imaging in pregnant women.	Strong
Use magnetic resonance imaging as a second-line imaging modality in pregnant women.	Strong
Use low-dose computed tomography as a last-line option in pregnant women.	Strong

3.3.3.2 Diagnostic imaging in children

Children with urinary stones have a high risk of recurrence; therefore, standard diagnostic procedures for high-risk patients apply, including a valid stone analysis (Section 3.1.3 and Chapter 4). The most common nonmetabolic disorders facilitating stone formation are vesicoureteral reflux (VUR), UPJ obstruction, neurogenic bladder, and other voiding difficulties [79].

When selecting diagnostic procedures to identify urolithiasis in children, it should be remembered that these patients might be uncooperative, require anaesthesia, and may be sensitive to ionising radiation. Again, the principle of ALARA (As Low As Reasonably Achievable) should be observed [80-84].

Ultrasound

Ultrasound is the primary imaging technique [85] in children. Its advantages are the absence of radiation and no need for anaesthesia. Imaging should include both the fluid-filled bladder with adjoining portion of the ureters, as well as the upper ureter [80]. Colour Doppler US shows differences in the ureteral jet [86] and resistive index of the arciform arteries of both kidneys, which are indicative of the grade of obstruction [87]. Nevertheless, the US may fail to identify ureteral stones and provides limited information on renal function [88].

Plain films (KUB radiography)
Kidney-ureter-bladder radiography can help to identify stones and their radiopacity and facilitate follow-up.

Intravenous urography
The radiation dose for IVU is comparable to that for voiding cystourethrography (0.33 mSV) [89]. However, the need for contrast medium injection is a major drawback.

Non-contrast-enhanced computed tomography
Low-dose CT protocols have been shown to significantly reduce radiation exposure [90-92]. Sedation or anaesthesia is rarely needed with modern high-speed CT equipment.

Magnetic resonance urography
Magnetic resonance urography (MRU) cannot be used to detect urinary stones. However, it might provide detailed anatomical information about the urinary collecting system, the location of an obstruction or stenosis in the ureter, and renal parenchymal morphology [93].

3.3.3.2.1 Summary of evidence and recommendations for diagnostic imaging in children

Summary of evidence	**LE**
Ultrasound is the first-line imaging modality in children when a stone is suspected; it should include the kidney, fluid-filled bladder, and the ureter next to the kidney and the (filled) bladder.	2b
A kidney-ureter-bladder radiography (or low-dose NCCT) is an alternative investigation if US will not provide the required information.	2b

Recommendations	**Strength rating**
Complete a metabolic evaluation based on stone analysis in all children.	Strong
Collect stone material for analysis to classify the stone type.	Strong
Perform ultrasound as first-line imaging modality in children when a stone is suspected; it should include the kidney, fluid-filled bladder, and the ureter.	Strong
Perform a kidney-ureter-bladder radiography (or low-dose non-contrast-enhanced computed tomography) if ultrasound will not provide the required information.	Strong

3.4 Disease Management

The treatment of urolithiasis is based on many parameters and is individualised for each patient. Parameters such as the size, number, location, and constitution of the stones are the cornerstones for deciding the treatment. In addition, the morphology, shape, volume, mobility, and hardness of the stone should be considered. Finally, the anatomy and compliance of the entire pelvic-calyceal system should be assessed for each patient. The design of therapeutic algorithms including all the above parameters is difficult mainly due to the great diversity of lithiasis disease per patient. Furthermore, there is a significant lack of comparative clinical studies to support development of algorithms using parameters other than stone size and composition.

3.4.1 Renal colic

Pain relief
Non-steroidal anti-inflammatory drugs (NSAIDs) (including metamizole dipyrone), and paracetamol are effective in patients with acute stone colic [94] and have better analgesic efficacy than opioids [95]. Ibuprofen compared to ketorolac is a more rapid-acting drug in controlling pain caused by renal colic with a similar side effect profile [96].

Pain relief from intramuscular (i.m.) diclofenac compared favourably with those from intravenous (i.v.) ibuprofen and i.v. ketorolac; however, no recommendation can be given due to the way in which the results have been reported [97]. The addition of antispasmodics to NSAIDs does not result in better pain control. Patients receiving NSAIDs are less likely to require further analgesia in the short term. It should be taken into consideration that the use of diclofenac and ibuprofen increased major coronary events [94, 95]. Oral diclofenac in the long-term increases the risk of cardiovascular events and upper GI bleeding [98]. Patients with significant risk factors for cardiovascular events should be treated with diclofenac only after careful consideration. As risks increase with dose and duration, the lowest effective dose should be used for the shortest duration [99]. Non-steroidal anti-inflammatory drugs may affect renal function in those patients with pre-existing decreased GFR.

In an RCT including 150 patients, Intradermal sterile water injection (ISWI) and diclofenac (i.m.) were shown equally effective for pain relief in acute renal colic. Intradermal sterile water injection may be an alternative to NSAIDs in pregnant patients or others where NSAIDs are contra-indicated [100].

Opioids, particularly pethidine, are associated with a high rate of vomiting compared to NSAIDs and carry a greater likelihood of further analgesia being needed [94, 101]. If an opioid is used, it is recommended that it is not pethidine. Combination of opioids and NSAIDs increase analgetic effect compared to opioids alone [102]. Acupuncture seems to be effective in renal colic alone or in combination with analgetic drugs, but there is limited data [103, 104].

Prevention of recurrent renal colic

Facilitation of passage of ureteral stones is discussed in Section 3.4.9. For patients with ureteral stones that are expected to pass spontaneously, NSAID tablets or suppositories (e.g., diclofenac sodium, 100-150 mg/day, 3-10 days) may help reduce inflammation and the risk of recurrent pain [105, 106]. Although NSAID can affect renal function in patients with already reduced function, it has no functional effect in patients with normal renal function [107].

The systematic review and MA by Hollingsworth *et al.,* [108] addressed pain reduction as a secondary outcome and concluded that medical expulsive therapy (MET) seems efficacious in reducing pain episodes of patients with ureteral stones.

If analgesia cannot be achieved medically, drainage, using stenting, percutaneous nephrostomy, or stone removal, is indicated [109].

3.4.1.1 Summary of evidence and recommendations for the management of renal colic

Summary of evidence	**LE**
Non-steroidal anti-inflammatory drugs are very effective in treating renal colic and are superior to opioids.	1b
For symptomatic ureteral stones, stone removal as first-line treatment is a feasible option in selected patients.	1b

Recommendations	**Strength rating**
Offer a non-steroidal anti-inflammatory as the first drug of choice; depending on cardiovascular risk factors and side effects.	Strong
Offer opiates (hydromorphine, pentazocine or tramadol) as a second choice.	Weak
Offer renal decompression or ureteroscopic stone removal in case of analgesic refractory colic pain.	Strong

*3.4.2 **Management of sepsis and/or anuria in obstructed kidney***

The obstructed kidney with all signs of urinary tract infection (UTI) and/or anuria is a urological emergency. Urgent decompression is often necessary to prevent further complications in infected hydronephrosis secondary to stone-induced, unilateral, or bilateral, renal obstruction.

Decompression

There are two options for urgent decompression of obstructed collecting systems [110]:

- placement of an indwelling ureteral stent
- percutaneous placement of a nephrostomy tube.

Several systematic reviews on the subject have been published, all of which emphasize that the available literature comparing different drainage modalities for obstructing stones with or without infection is scarce, based on small cohorts and of medium to very low quality [110]. There appears to be no difference in success rate or complication rate of both procedures and there is not a difference in time to defervescence in the population presenting with fever. Both meta-analyses identified patients receiving a nephrostomy tube to have a longer stay in the hospital. Based on the available data, a DJ stent has a more negative impact on the patients' quality of life in comparison with a nephrostomy tube, which can be explained mainly by the stent-related symptoms that these patients experience [111, 112].

Definitive stone removal should be delayed until the infection is cleared following a complete course of antimicrobial therapy. A small RCT showed the feasibility of immediate ureteroscopic stone removal combined

with an appropriate antibiotic regimen; however, at the cost of longer hospital stay and higher analgesic requirements [113].

Further measures
Along with urgent decompression of the obstructed and infected urinary collecting system, both urine- and blood samples should be sent for culture-antibiogram sensitivity testing and antibiotics should be initiated immediately [114, 115]. The regimen should be re-evaluated in the light of the culture-antibiogram results. Although clinically well accepted, the impact of a second antibiogram test on treatment outcome has not yet been evaluated [116]. Intensive care might become necessary.

3.4.2.1 Summary of evidence and recommendations for the management of sepsis and anuria

Summary of evidence	**LE**
For decompression of the renal collecting system, ureteral stents and percutaneous nephrostomy catheters are equally effective.	1b

Recommendations	**Strength rating**
Urgently decompress the collecting system in case of sepsis with obstructing stones, using percutaneous drainage or ureteral stenting.	Strong
Delay definitive treatment of the stone until sepsis is resolved.	Strong
Collect (again) urine for antibiogram test following decompression.	Strong
Start antibiotics immediately (+ intensive care, if necessary).	Strong
Re-evaluate antibiotic regimen following antibiogram findings.	Strong

*3.4.3 **Medical expulsive therapy***
Several drug classes including α-blockers, calcium channel inhibitors, and phosphodiesterase type 5 inhibitors (PDEI-5) are used for MET [117-120] A class effect of α-blockers in MET has been demonstrated in MAs although this is an off-label indication [121-123]. However, there is contradictory evidence between these studies and several well-designed, multicentre, placebo-controlled, double-blinded randomised studies showing limited, or no, benefit using α-blockers, besides some advantage for distal ureteral stones > 5 mm [124-128]. Based on studies with a limited number of patients [120, 121, 129, 130], no recommendation for the use of PDEI-5 or corticosteroids in combination with α-blockers in MET can be made. The panel concludes that MET using α-blockers seems efficacious in the treatment of patients with distal ureteral stones > 5 mm who are amenable to conservative management. Medical expulsive therapy in special situations is addressed in the relevant chapters.

3.4.3.1 Summary of evidence and recommendations for medical expulsive therapy

Summary of evidence	**LE**
Medical expulsive therapy seems to be efficacious for treating patients with ureteral stones who are amenable to conservative management. The greatest benefit might be among those with > 5 mm (distal) ureteral stones.	1a
Insufficient data exist to support the use of PDEI-5 or corticosteroids in combination with α-blockers as an accelerating adjunct.	2a
Alpha-blockers increase stone expulsion rates in distal ureteral stones > 5 mm.	1a
A class effect of α-blockers has been demonstrated.	1a

Recommendation	**Strength rating**
Offer α-blockers as medical expulsive therapy as one of the treatment options for (distal) ureteral stones > 5 mm.*	Strong

** Alpha-blockers are an off-label treatment*

*3.4.4 **Chemolysis***

Percutaneous irrigation chemolysis

Percutaneous chemolysis is rarely used nowadays, for practical reasons. Percutaneous irrigation chemolysis may be an option for infection stones and theoretically also for uric acid stones. For dissolution of struvite stones, Suby's G solution (10% hemiacidrin; pH 3.5-4) can be used. The method has been described in case series and literature reviews [131].

Oral chemolysis

Stones composed of uric acid, but not sodium or ammonium urate stones, can be dissolved by oral chemolysis. Prior stone analysis may provide information on stone composition. Urinary pH measurement and X-ray characteristics can provide information on the type of stone.

Oral chemolysis is based on alkalinisation of urine by application of alkaline citrate or sodium bicarbonate. The pH should be adjusted to 7.0-7.2. Chemolysis is more effective at a higher pH, which might, however, promote calcium phosphate stone formation. Patients will need to adjust the dosage of alkalising medication by self-monitoring the pH of their urine. A SR shows a complete or partial dissolution in 80.5%, discontinuation rate of 10.2% with 15.7% requiring further intervention [132].

In the case of uric acid obstruction of the collecting system, oral chemolysis in combination with urinary drainage is indicated. A combination of alkalinisation with tamsulosin can increase the frequency of spontaneous passage of distal ureteral uric acid stones as shown in one RCT for stones > 5 mm [133]. Additional SWL might help to improve the results but evidence is weak [134].

3.4.4.1 Summary of evidence and recommendations for chemolysis

Summary of evidence	**LE**
Irrigation chemolysis has been used in limited clinical settings to dissolve struvite stones.	3
Uric acid stones > 5mm can be dissolved based on oral alkalinisation of the urine above 7.0.	3
For obstructing uric acid stones, a combination of oral chemolysis with tamsulosin is more effective than each substance alone, particularly in stones > 8 mm.	1b

Recommendations (oral chemolysis of uric acid stones)	**Strength rating**
Inform the patient how to monitor urine-pH by dipstick and to modify the dosage of alkalising medication according to urine pH, as changes in urine pH are a direct consequence of such medication.	Strong
Carefully monitor patients during/after oral chemolysis of uric acid stones.	Strong
Combine oral chemolysis with tamsulosin in case of (larger) ureteral stones (if active intervention is not indicated).	Weak

*3.4.5 **Extracorporeal shock wave lithotripsy (SWL)***

The success of SWL depends on the efficacy of the lithotripter and the following factors:

- size, location (ureteral, pelvic, or calyceal), and composition (hardness) of the stones (Section 3.4.9.3);
- patient's habitus (Section 3.4.10.3);
- performance of SWL (best practice, see below).

Each of these factors significantly influences the retreatment rate and outcome of SWL.

Best clinical practice

Stenting

Routine use of internal stents before SWL does not improve stone-free rates (SFRs), nor lowers the number of auxiliary treatments. It may, however, reduce the formation of steinstrasse [135-138].

Pacemaker

Patients with a pacemaker can be treated with SWL, provided that appropriate technical precautions are taken. Patients with implanted cardioverter defibrillators must be managed with special care (firing mode temporarily reprogrammed during SWL treatment). However, this might not be necessary with new-generation lithotripters [139].

Shock wave rate

Lowering shock wave frequency from 120 to 60-90 shock waves/min improves SFRs [140-148]. Ultraslow

frequency of 30 shock waves/min may increase SFR [149]. Tissue damage increases with shock wave frequency [150-153].

Number of shock waves, energy setting, and repeat treatment sessions
The number of shock waves that can be delivered at each session depends on the type of lithotripter and shock wave power. There is no consensus on the maximum number of shock waves [154]. Starting SWL on a lower energy setting with stepwise power (and SWL sequence) ramping can achieve vasoconstriction during treatment [150], which prevents renal injury [155-157]. Animal studies [158] and a prospective randomised study [159] have shown better SFRs (96% vs. 72%) using stepwise power ramping, but no difference has been found for fragmentation or evidence of complications after SWL, irrespective of whether ramping was used [160, 161].

There are no conclusive data on the intervals required between repeated SWL sessions. However, clinical experience indicates that repeat sessions are feasible (within one day for ureteral stones) [162].

Improvement of acoustic coupling
Proper acoustic coupling between the cushion of the treatment head and the patient's skin is important. Defects (air pockets) in the coupling gel deflect 99% of shock waves [163]. Gentle swiping between the coupled therapy head and the patient skin helps remove air bubbles and improves the coupling [164]. Ultrasound gel is probably the most widely-used agent available as a lithotripsy coupling agent [165].

Procedural control
Results of treatment are operator-dependent, and experienced clinicians obtain better results. During the procedure, careful imaging control of localisation contributes to outcome quality [166].

Pain Control
Careful control of pain during treatment is necessary to limit pain-induced movements and excessive respiratory excursions [167-170].

Antibiotic prophylaxis
No standard antibiotic prophylaxis before SWL is recommended. However, prophylaxis is recommended in the case of internal stent placement ahead of anticipated treatments and in the presence of increased bacterial burden (e.g., indwelling catheter, nephrostomy tube, or infectious stones) [62, 171, 172].

Medical therapy after extracorporeal shock wave lithotripsy
Despite conflicting results, most RCTs and several MAs support MET after SWL for ureteral or renal stones as an adjunct to expedite expulsion and increase SFRs. Medical expulsion therapy might also reduce analgesic requirements [173].

Post-treatment management
Mechanical percussion and diuretic therapy can significantly improve SFRs and accelerate stone passage after SWL [174].

Complications of extracorporeal shock wave lithotripsy
Compared to percutaneous nephrolithotomy (PCNL) and ureteroscopy (URS), there are fewer overall complications with SWL [175] (Table 3.8). In a Meta-Analysis of 115 RCT´s 18.43% of Clavien I–II complications and 2.48% of Clavien III–IV complications occurred [175]. The relationship between SWL and hypertension or diabetes is unclear. Published data are contradictory; however, no evidence exists supporting the hypothesis that SWL may cause long-term adverse effects [176-182].

Table 3.8: Shock wave lithotripsy-related complications

Complications			**%**	**Reference**
Related to stone fragments	Steinstrasse		4	[183-185]
	Macroscopic haematuria		17.2%	[175]
	Pain		12.1%	[175]
	Regrowth of residual fragments		21 – 59	[186, 187]
	Auxiliary procedure		6.9%	[175]
	Renal colic		2 – 4	[188]

Infectious	Bacteriuria in non-infection stones		7.7 – 23	[186-189]
	Sepsis		0.15%	[175]
Tissue effect	Renal	Haematoma, symptomatic	0.21%	[175]
		Haematoma, asymptomatic	1.2%	[175]
	Cardiovascular	Dysrhythmia	11 – 59	[186, 188]
		Morbid cardiac events	Case reports	[186, 188]
	Gastrointestinal	Bowel perforation	Case reports	[190]
		Liver, spleen haematoma	Case reports	[190-193]

3.4.5.1 Summary of evidence and recommendations for Shock wave lithotripsy

Summary of evidence	**LE**
Stepwise power ramping prevents renal injury.	1b
Clinical experience has shown that repeat sessions are feasible (within one day for ureteral stones).	4
Optimal shock wave frequency is 1.0 to 1.5 Hz.	1a
Proper acoustic coupling between the cushion of the treatment head and the patient's skin is important.	2
Careful imaging control of localisation of stone contributes to outcome of treatment.	2a
Careful control of pain during treatment is necessary to limit pain-induced movements and excessive respiratory excursions.	1a
Antibiotic prophylaxis is recommended in the case of internal stent placement, infected stones, or bacteriuria.	1a

Recommendations	**Strength rating**
Ensure correct use of the coupling agent because this is crucial for effective shock wave transportation.	Strong
Maintain careful fluoroscopic and/or ultrasonographic monitoring during shock wave lithotripsy (SWL).	Strong
Use proper analgesia because it improves treatment results by limiting pain-induced movements and excessive respiratory excursions.	Strong
Prescribe antibiotics prior to SWL in the case of infected stones or bacteriuria.	Strong

3.4.6 ***Ureteroscopy (retrograde and antegrade)***

The current standard for rigid ureteroscopes is a tip diameter of < 8 French (F). Rigid URS can be used for the whole ureter [176]. However, technical improvements, as well as the availability of digital scopes, also favour the use of flexible ureteroscopes in the ureter [194].

Percutaneous antegrade removal of ureteral stones is a consideration in selected cases, i.e. large (> 15 mm), impacted proximal ureteral calculi in a dilated renal collecting system [195, 196], or when the ureter is not amenable to retrograde manipulation [197].

Ureteroscopy for renal stones: Retrograde Intrarenal Surgery (RIRS)

Technical improvements including endoscope miniaturisation, improved deflection mechanism, enhanced optical quality and tools, and introduction of disposables have led to an increased use of URS for both renal and ureteral stones. Major technological progress has been achieved for RIRS. A systematic review addressing renal stones > 2 cm showed a cumulative SFR of 91% with 1.45 procedures/patient; 4.5% of the complications were > Clavien 3 [198, 199]. Digital scopes demonstrate shorter operation times due to the improvement in image quality [200].

Stones that cannot be extracted directly must be disintegrated. If it is difficult to access stones within the lower renal pole that need disintegration it may help to displace them into a more accessible calyx [201].

Best clinical practice in ureteroscopy

Access to the upper urinary tract

Most interventions are performed under general anaesthesia, although local or spinal anaesthesia is possible [202]. Intravenous sedation is suitable for female patients with distal ureteral stones [203]. Smaller caliber (4.5/6 Fr) semi-rigid ureteroscope was associated with significantly higher SFR, lower rates of ureteric injury, and shorter hospital stay [204].

Antegrade URS is an option for large, impacted, proximal ureteral calculi [195, 205]. Reduction of flexible ureteroscope diameter may provide similar vision, deflection, and manoeuvrability to standard flexible ureteroscopes potentially with improved ureteric access [206]. Disposable ureteroscopes provide similar safety and clinical effectiveness to reusable scopes. Concerns regarding cost-effectiveness and environmental sustainability remain [204, 207-209].

Safety aspects

Fluoroscopic equipment must be available in the operating room. The Panel recommends placement of a safety wire, even though some groups have demonstrated that URS can be performed without it [210-214]. Balloon and plastic dilators should be available, if necessary.

Prior rigid URS can be helpful for optical dilatation followed by flexible URS, if necessary. If ureteral access is not possible, insertion of a JJ stent followed by URS after seven to fourteen days offers an alternative [215]. Bilateral URS during the same session is feasible resulting in equivalent-to-lower SFRs, but slightly higher overall complication rates (mostly minor, Clavien 1 and 2) [216, 217].

Difficult lower pole anatomy such as steep infundibulopelvic angle predisposes to failure during RIRS [218]. A reusable flexible ureteroscope can be more helpful in reaching a difficult lower pole calyx [219]. Prolonged operative times are linked to increased complication rates in ureteroscopy, and efforts must be made to keep it below 90 minutes [220].

Ureteral access sheaths

Hydrophilic-coated ureteral access sheaths, which are available in different calibres (inner diameter from 9 F upwards), can be inserted (via a guide wire) with the tip placed in the proximal ureter.

Ureteral access sheaths allow easy, multiple, access to the UUT and therefore significantly facilitate URS. The use of ureteral access sheaths improves vision by establishing a continuous outflow, decreases intrarenal pressure, and potentially reduces operating time [221, 222].

The insertion of ureteral access sheaths may lead to ureteral damage, the risk is lowest in pre-stented systems [223]. No data on long-term side effects are available [198, 223]. Whilst larger cohort series showed no difference in SFRs and ureteral damage (stricture rates of about 1.8%), they did show lower post-operative infectious complications [224, 225]. Increasing sheath size directly determines higher grades of ureteral injury rates but there is no difference in long-term stricture rates [226]. The use of a ureteral access sheath is safe and can be useful for large and multiple renal stones or if long procedural time is expected [227].

Stone extraction

The aim of URS is complete stone removal. “Dust and go” strategies should be limited to the treatment of large (renal) stones [228]. Stones can be extracted by endoscopic forceps or baskets. Only baskets made of nitinol can be used for flexible URS [229].

Intracorporeal lithotripsy

The most effective lithotripsy system is the holmium: yttrium-aluminum-garnet (Ho: YAG) laser, which is currently the optimum standard for URS and flexible nephroscopy (Section 3.4.6), because it is effective in all stone types [230, 231]. Compared to low-power lasers, high-power laser reduces procedural time although the reported difference in clinical outcomes was non-significant and based on a low level of evidence [232]. The only RCT to date shows no clinical difference regarding stone-free rate or operative time [233]. Although pulse-modulation in Ho: YAG lasers has demonstrated several in vitro benefits, a systematic review including 8 comparative studies and only one RCT showed no difference in stone-free rate, complication rate, or operative time [234]. The two available RCTs on the subject both found a shorter operative time, without conferring a difference in success rate [235, 236]. Thulium fiber laser (TFL) for stone disease has a promising role and offers good clinical outcomes, which seem to be comparable to Ho: YAG laser (holmium) laser [237-239]. With the limited reports of clinical use available to date, a meta-analysis could not demonstrate the superiority of TFL over Ho: YAG, although the operative time to achieve this stone-free rate seems to be shorter with the use of TFL [240]. More comparative clinical studies are however needed between these two modalities. When a laser is not available, pneumatic and US systems can be used with high disintegration efficacy in rigid URS [241, 242]. However, stone migration into the kidney is a common problem, which can be prevented by the placement

of special anti-migration tools proximal to the stone [243]. Medical expulsion therapy following Ho: YAG laser lithotripsy increases SFRs and reduces colic episodes [244].

Stenting before and after URS

Routine stenting is not necessary before URS. Despite a complete lack of RCTs on this subject, a meta-analysis has been performed, demonstrating that pre-stenting may improve the stone-free rate of ureteroscopic treatment of renal stones, but not of ureteral stones [245]. Although it may facilitate ureteroscopic management of stones and increase success in access sheath placement, intra-operative complications were not significantly different [245, 246]. One should also consider that pre-stenting also causes the patient to experience stent-related symptoms during the time the stent is indwelling, prior to a procedure.

Randomised prospective trials have found that routine stenting after uncomplicated URS (complete stone removal) is not necessary; stenting might be associated with higher postoperative morbidity and costs [247]. Smaller diameter ureteric stents may reduce urinary symptoms and patient-reported pain [248]. A ureteral catheter with a shorter indwelling time (one day) may also be used, with similar results [249].

Stents should be inserted in patients who are at increased risk of complications (e.g., ureteral trauma, residual fragments, bleeding, perforation, UTIs, or pregnancy), and in all doubtful cases, to avoid stressful emergencies. The ideal duration of stenting is not known. Most urologists favour one to two weeks after URS. Alpha-blockers reduce the morbidity of ureteral stents and increase tolerability [250].

Medical expulsive therapy before and after ureteroscopy

Medical expulsion therapy before URS might reduce the risk for intra-operative ureteral dilatation, protect against ureteral injury when using access sheaths and increase stone-free rates four weeks after URS [251, 252].

Medical expulsion therapy following Ho: YAG laser lithotripsy accelerates the spontaneous passage of fragments and reduces episodes of colic [244].

Complications of ureteroscopy

The overall complication rate after URS is 4-25% [253, 254]. Most complications are minor and do not require intervention. There is evidence suggesting a risk of post-operative urosepsis of up to 5% [255, 256]. Ureteral avulsion and strictures are rare (< 1%). Previous perforations, pre-operative positive urine cultures, comorbidities, and longer operation time are the most important risk factor for complications [220, 257, 258]. Infectious complications following URS can be minimised using prophylactic antibiotics, limiting stent dwell and procedural time, identification and treatment of UTI, and planning in patients with large stone burden and multiple comorbidities [259].

High intrarenal pressure (IRP) predisposes to URS complications, and measures should be used to reduce IRP. Currently, there are no accurate ways to measure the intra-operative IRP [260].

3.4.6.1 Summary of evidence and recommendations for retrograde URS, RIRS and antegrade ureteroscopy

Summary of evidence	**LE**
In uncomplicated URS, a post-procedure stent need not be inserted.	1a
In URS, pre-stenting has been shown to improve outcomes for renal stones.	1a
An α-blocker can reduce stent-related symptoms and colic episodes.	1a
The most effective lithotripsy system for flexible ureteroscopy is the Ho: YAG laser.	2a
Pneumatic and US systems can be used with high disintegration efficacy in rigid URS.	2a
Percutaneous antegrade removal of proximal ureter stones, or laparoscopic ureterolithotomy are feasible alternatives to retrograde ureteroscopy, in selected cases.	1b
Pre-treatment of patients undergoing URS with an α-blocker one week prior to the procedure reduces the need for active dilatation and increases the stone free rate.	1a

Recommendations	**Strength rating**
Use holmium: yttrium-aluminum-garnet (Ho: YAG) or Thulium fiber laser (TFL) laser lithotripsy for (flexible) ureteroscopy (URS).	Strong
Perform stone extraction only under direct endoscopic visualisation of the stone.	Strong

Do not insert a stent in uncomplicated cases.	Strong
Offer medical expulsive therapy for patients suffering from stent-related symptoms and after Ho: YAG laser lithotripsy to facilitate the passage of fragments.	Strong
Use percutaneous antegrade removal of ureteral stones as an alternative when shock wave lithotripsy (SWL) is not indicated or has failed, and when the upper urinary tract is not amenable to retrograde URS.	Strong
Use flexible URS (even for stones > 2 cm) in cases where percutaneous nephrolithotomy or SWL are not an option. However, in this case, there is a higher risk that a follow-up procedure and placement of a ureteral stent may be needed.	Strong

*3.4.7 **Percutaneous nephrolithotomy***

Percutaneous nephrolithotomy remains the standard procedure for large renal calculi. Different rigid and flexible endoscopes are available, and the selection is mainly based on the surgeon's own reference. Standard access tracts are 24-30 F. Smaller access sheaths, < 18 F, were initially introduced for paediatric use, but are now increasingly utilized in the adult population [261, 262].

Contraindications

Patients receiving anticoagulant therapy must be monitored carefully pre-and post-operatively. Anti-coagulant therapy must be discontinued before PCNL [263].

Other important considerations include:

- untreated UTI;
- tumour in the presumptive access tract area;
- potential malignant kidney tumour;
- pregnancy (Section 3.4.14.1).

Best clinical practice

Intracorporeal lithotripsy

Several methods for intracorporeal lithotripsy during PCNL are available. Ultrasonic, pneumatic, and combined systems are most commonly used for rigid nephroscopy, whilst the laser is increasingly used for miniaturised and flexible instruments [264].

Pre-operative imaging

Pre-procedural imaging evaluations are summarised in Section 3.3.1. In particular, US or CT of the kidney and the surrounding structures can provide information regarding interposed organs within the planned percutaneous path (e.g., spleen, liver, large bowel, pleura, and lung).

Positioning of the patient

Both prone and supine positions are equally safe. A meta-analysis including twelve studies and a total of 1,290 patients treated, showed a similar SFR but a lower operative time for supine PCNL [265]. The supine position allows simultaneous retrograde access to the collecting system, using a flexible ureteroscope [266]. The combination of PCNL and RIRS may be a good alternative for the treatment of complex renal stones compared to standard PCNL; however, the existing evidence is of low-quality [265, 267].

Puncture

Although fluoroscopy is still the most common intra-operative imaging method, the use of US as an additional or only means of puncture guidance provides advantages according to two meta-analyses including eight randomised controlled trials. Additional to the expected reduced radiation exposure with the use of ultrasound the meta-analyses also demonstrated a lower complication rate [268, 269]. Pre-operative CT or intra-operative US allows identification of the tissue between the skin and kidney and lowers the incidence of visceral injury. As an additional aid to increase puncture accuracy, the calyceal puncture may be done under direct visualisation using simultaneous flexible URS [270-272].

Dilatation

Dilatation of the percutaneous access tract can be achieved using a metallic telescopic, single (one-shot or serial) dilator, or balloon dilatator. During PCNL, safety and effectiveness are similar for different tract dilatation methods [273]. Although there are papers demonstrating that single-step dilation is equally effective as other methods and that US only can be used for the dilatation, the difference in outcomes is most likely related to surgeon experience rather than to the technology used [273, 274]. A meta-analysis of the most commonly used

tract dilation methods suggested that one-step dilation would allow for a shorter operative time and reduced complication rate, including haemoglobin loss and transfusion rate [275].

Choice of instruments

Several meta-analyses on mini-PCNL (12-22 F) vs. standard PCNL (> 22 F) have identified that both techniques allow for a similar SFR. Patients treated with mini-PCNL had reduced blood loss and transfusion rates, as well as a shorter hospital stay, without a significant difference in overall complication rates [262, 276-278]. However, it is important to note that the level of evidence was downgraded due to heterogeneity of data related to tract sizes used and types of stones treated. There is some evidence for using suction during PCNL to reduce intra-renal pressure and increase SFR [279].

Post-operative drainage

The decision on whether, or not, to place a nephrostomy tube or a double J stent at the conclusion of the PCNL procedure depends on several factors, including:

- presence of residual stones;
- likelihood of a second-look procedure;
- significant intra-operative blood loss/ bleeding from the percutaneous tract;
- urine extravasation;
- ureteral obstruction;
- potential persistent bacteriuria due to infected stones;
- solitary kidney;
- bleeding diathesis;
- planned percutaneous chemolitholysis.

Small-bore nephrostomies seem to have advantages in terms of postoperative pain [262, 280, 281]. Tubeless PCNL is performed without a nephrostomy tube and is associated with reduced post-operative pain and hospital stay [282]. When neither a nephrostomy tube nor a ureteral stent is introduced, the procedure is known as a totally tubeless PCNL [283]. In uncomplicated cases, the latter procedure results in a shorter hospital stay, with no disadvantages reported [284].

As reported in the above section on the drainage of an infected or obstructed system [110-112] (section 3.4.2), the quality of life may be slightly lower with a DJ stent in comparison to a short-term nephrostomy tube after PCNL. This should be weighed against the shorter hospital stay with a DJ stent [285].

Complications of percutaneous nephrolithotomy

A systematic review of almost 12,000 patients shows the incidence of complications associated with PCNL; fever 10.8%, transfusion 7%, thoracic complication 1.5%, sepsis 0.5%, organ injury 0.4%, embolisation 0.4%, urinoma 0.2%, and death 0.05% [286].

Perioperative fever can occur, even with a sterile pre-operative urinary culture and peri-operative antibiotic prophylaxis, because the renal stones themselves may be a source of infection. The evidence demonstrates that a stone culture or urine culture taken directly from the renal pelvis is more predictive of post-operative SIRS or sepsis. Whenever possible a urine culture from the renal pelvis and/or stone culture should be taken at the time of PCNL [287].

Intra-operative renal stone or renal pelvic urine culture may be more indicative of the causative organism for sepsis; therefore, helping to select the most suitable postoperative antibiotics [287-289]. Although this data is weak, there is limited retrospective data indicating that increased pressures during mPCNL may contribute to febrile complications [290-292]. This contrasts with the previously mentioned meta-analyses on mini vs standard PCNL that do not identify a difference in complication rate between the two procedures [262, 276-278]. Bleeding after PCNL may be treated by briefly clamping the nephrostomy tube. Super-selective embolic occlusion of the arterial branch may become necessary in the case of severe bleeding. Several meta-analyses have demonstrated that the use of tranexamic acid reduces bleeding complications and the transfusion rate of PCNL [293-295]. However, the transfusion rate in the control group of the meta-analyses was in the range of 10-12%.

Depending on the stone burden and the patient's anatomy, multiple tracts may be necessary to render the patient stone free in one session of PCNL. While this is a generally accepted practice, it should be highlighted that this comes with an increased risk of postoperative complications including pleural damage, infections, and the need for transfusion [296].

To reduce post-operative pain after PCNL, a peripheral nerve block can be performed at the intercostal nerve, paravertebral region, erector spinae, or quadratus lumborum. Such a block may significantly reduce the need for post-operative opioid analgesics [297, 298]. Current evidence shows that a quadratus lumborum block or

infiltration of a local anaesthetic around the nephrostomy tube may reduce post-operative pain and opioid consumption after PCNL [299, 300].

3.4.7.1 Summary of evidence and recommendations for endourology techniques for renal stone removal

Summary of evidence	LE
Imaging of the kidney with US or CT can provide information regarding inter-positioned organs within the planned percutaneous path (e.g., spleen, liver, large bowel, pleura, and lung).	3
Both prone and supine positions are equally safe with equivalent SFR.	1a
Percutaneous nephrolithotomy performed with small instruments tends to be associated with significantly lower blood loss, but the duration of procedure tended to be significantly longer. There are no significant differences in SFR or any other complications.	1a
In uncomplicated cases, a totally tubeless PCNL results in a shorter hospital stay, with no increase in complication rate.	1a
Peri-operative use of tranexamic acid may reduce bleeding complications and transfusion rates.	1a
Urine cultures taken directly from the renal pelvis, or a stone culture are more predictive of post-PCNL sepsis than a pre-operative midstream urine culture.	1a

Recommendations	Strength rating
Perform pre-procedural computed tomography (CT) imaging, including contrast medium when indicated or retrograde study when starting the procedure, to assess stone comprehensiveness and anatomy of the collecting system to ensure safe access to the renal stone.	Strong
Perform a tubeless (without nephrostomy tube) or totally tubeless (without nephrostomy tube and ureteral stent) percutaneous nephrolithotomy (PCNL) procedure, in uncomplicated cases.	Strong
Take a stone culture or urine culture directly from the renal pelvis at time of PCNL, if possible.	Strong

*3.4.8 **General recommendations and precautions for stone removal***

3.4.8.1 Antibiotic therapy

Urinary tract infections should always be treated if stone removal is planned. In patients with clinically significant infection and obstruction, drainage should be performed for several days before starting stone removal. A urine culture or urinary microscopy should be performed before treatment [301].

Peri-operative antibiotic prophylaxis

The available evidence for prevention of infection following URS and percutaneous stone removal, remains limited [302]. Administration of a single dose of prophylactic antibiotics prior to ureteroscopy was found to be sufficient [302-304]. In a review of a large database of patients undergoing PCNL, it was found that in patients with negative baseline urine culture, antibiotic prophylaxis significantly reduced the rate of postoperative fever and other complications [305]. Based on three meta-analyses, pooling data from small series with varying quality an extended course of pre-operative prophylactic antibiotics prior to PCNL compared to a single dose before anaesthesia significantly reduced post-operative sepsis and fever in patients with an a priori increased risk of infection [288, 306, 307]. In an RCT including only moderate to high-risk infection patients (patients with pre-operative stents/nephrostomy or positive urine culture), a seven-day course of pre-operative antibiotics reduced the risk of post-PCNL sepsis threefold in comparison to a two-day course [308]. In studies that did not specify the risk of the patient population, a single dose of antibiotic prophylaxis administered at induction was equivalent to an extended pre-operative course [307, 309]. In contrast to this, a prolonged course of post-operative antibiotics was not superior to a single dose pre-operatively [288, 307].

As national and regional antibiotic resistance patterns can differ significantly, the choice of antibiotic prophylaxis should be tailored to institutional or regional antimicrobial susceptibility [304].

Recommendations	Strength rating
Obtain a urine culture or perform urinary microscopy before any treatment is planned.	Strong
Exclude or treat urinary tract infections prior to stone removal.	Strong
Offer peri-operative antibiotic prophylaxis to all patients undergoing endourological treatment.	Strong

3.4.8.2 Antithrombotic therapy and stone treatment

Patients with a bleeding disorder, or receiving antithrombotic therapy, should be referred to an internist for appropriate therapeutic measures before deciding on stone management [310-314]. In patients with an uncorrected bleeding disorder, the following are at elevated risk of haemorrhage or perinephric haematoma (PNH) (high-risk procedures):

- SWL (hazard ratio of PNH up to 4.2 during anti-coagulant/anti-platelet medication) [315]
- PCNL;
- percutaneous nephrostomy;
- laparoscopic surgery;
- open surgery [310].

Shock wave lithotripsy is feasible and safe after correction of the underlying coagulopathy [316, 317]. In the case of an uncorrected bleeding disorder or continued antithrombotic therapy, URS, in contrast to SWL and PCNL, might offer an alternative approach since it is associated with less morbidity [318-320]. Despite the appropriate cessation of anti-platelet agents, following standardised protocols, prolonged haematuria in tube drainage after PCNL has been reported [321]. Only data on flexible URS are available which support the superiority of URS in the treatment of proximal ureteral stones [322, 323]. Although URS is safe in patients with bleeding disorders or anticoagulation, an individualised patient approach is necessary [320].

Table 3.9: Risk stratification for bleeding [312-314, 324]

Low-risk bleeding procedures	• Cystoscopy • Flexible cystoscopy • Ureteral catheterisation • Extraction of ureteral stent • Ureteroscopy
High-risk bleeding procedures	• Shock wave lithotripsy • Percutaneous nephrostomy • Percutaneous nephrolithotomy

Table 3.10: Suggested strategy for antithrombotic therapy in stone removal [312-314]
(In collaboration with a cardiologist/internist weigh the risks and benefits of discontinuation of therapy, vs. delaying elective surgical procedures).

Medication/Agent	Bleeding risk of planned procedure	Risk of thromboembolism		
		Low risk	Intermediate risk	High risk
Warfarin Dabigatran Rivaroxaban Apixaban	Low-risk procedure	May be continued	Bridging therapy	Bridging therapy
	High-risk procedure	May be temporarily discontinued at appropriate interval. Bridging therapy is strongly recommended.	Bridging therapy	Bridging therapy

Aspirin	Low-risk procedure	Continue	Continue	Elective surgery: postpone. Non-deferrable surgery: continue.
	High-risk procedure	Discontinue	Elective surgery: postpone. Non-deferrable surgery: continue, if it is possible.	Elective surgery: postpone. Non-deferrable surgery: continue.
Thienopyridine agents (P2Y12 receptor inhibitors)	Low-risk procedure	Discontinue five days before intervention. Resume within 24-72 hours with a loading dose.	Continue	Elective surgery: postpone. Non-deferrable surgery: continue.
	High-risk procedure	Discontinue five days before intervention and resume within 24-72 hours with a loading dose.	Elective surgery: postpone. Non-deferrable surgery: discontinue five days before procedure and resume within 24-72 hours with a loading dose. Bridging therapy -glycoprotein IIb/IIIa inhibitors if aspirin is discontinued.	Elective surgery: postpone. Non-deferrable surgery: discontinue five days before procedure and resume within 24-72 hours, with a loading dose. Bridging therapy -glycoprotein IIb/IIIa inhibitors.

3.4.8.2.1 Summary of evidence and recommendations for antithrombotic therapy and stone treatment

Summary of evidence	**LE**
Active surveillance is indicated in patients at high risk for thrombotic complications in the presence of an asymptomatic calyceal stone.	4
The temporary discontinuation, or bridging of antithrombotic therapy in high-risk patients, should be discussed with the internist.	3
Retrograde (flexible) URS stone removal is associated with less morbidity in patients when antithrombotic therapy cannot be discontinued.	2a

Recommendations	**Strength rating**
Offer active surveillance to patients at high risk of thrombotic complications in the presence of an asymptomatic calyceal stone.	Weak
Decide on temporary discontinuation, or bridging of antithrombotic therapy in high-risk patients, in consultation with the internist.	Strong
Retrograde (flexible) URS is the preferred intervention if stone removal is essential and antithrombotic therapy cannot be discontinued since it is associated with less morbidity.	Strong

3.4.8.3 Obesity

A high BMI can pose a higher anaesthetic risk and a lower success rate after SWL and PCNL and may influence the choice of treatment [325].

3.4.8.4 Stone composition

Stones composed of brushite, calcium oxalate monohydrate, or cystine are particularly hard, as well as homogeneous stones with a high density on NCCT [326, 327]. Percutaneous nephrolithotomy or RIRS and URS are alternatives for removal of large SWL-resistant stones.

Recommendations	Strength rating
Consider the stone composition before deciding on the method of removal, based on patient history, former stone analysis of the patient or Hounsfield unit on unenhanced computed tomography.	Strong
Attempt to dissolve radiolucent stones.	Strong

3.4.8.5 Contraindications of procedures

Contraindications of extracorporeal SWL

There are several contraindications to the use of extracorporeal SWL, including:

- pregnancy, due to the potential effects on the foetus [328];
- bleeding disorders, which should be compensated for at least 24 hours before and 48 hours after treatment [329];
- uncontrolled UTIs;
- severe skeletal malformations and severe obesity, which prevent targeting of the stone;
- arterial aneurysm in the vicinity of the stone [330];
- anatomical obstruction distal to the stone.

Contraindications of URS

Apart from general problems, for example with general anaesthesia or untreated UTIs, URS can be performed in all patients without any specific contraindications.

Contraindications of PCNL

Patients receiving anti-coagulant therapy must be monitored carefully pre- and post-operatively. Anti-coagulant therapy must be discontinued before PCNL [320]. Other important contraindications include:

- untreated UTI;
- tumour in the presumptive access tract area;
- potential malignant kidney tumour;
- pregnancy (Section 3.4.14.1).

General contraindication for endourological procedures

Endourological interventions do not adversely affect renal function although care must be taken in those with poor pre-operative renal function, diabetes and hypertension [331]. However, a meta-analysis, based on low quality evidence, suggests that patients with impaired renal function and stone disease, may in fact benefit from the procedure to preserve or increase their renal function [332].

3.4.9 ***Specific stone management of ureteral stones***

3.4.9.1 Conservative treatment/observation

There are only limited data regarding spontaneous stone passage according to stone size [333, 334].

Spontaneous stone passage was reported for 49-52% of upper ureteral stones, 58-70% of mid ureteral stones and 68-83% of distal ureteral stones. Considering stone size almost 75% of stones < 5 mm and 62% of stones ≥ 5 mm passed spontaneously, with an average time to stone expulsion about 17 days (range 6-29 days) [333, 335]. Considering both size and location, stones of <5mm in the distal ureteral have a 89% chance of spontaneous passage, while 71% of stones <5mm located in the upper ureter still pass spontaneously [333]. The Panel is aware of the fact that spontaneous stone expulsion decreases with increasing stone size and that there are differences between individual patients.

3.4.9.2 Pharmacological treatment, medical expulsive therapy

Medical expulsive therapy should only be used in informed patients if active stone removal is not indicated. Treatment should be discontinued if complications develop (infection, refractory pain, deterioration of renal function). In the case of known uric acid stones in the distal ureter, a combination of alkalinisation with tamsulosin can increase the frequency of spontaneous passage. For details see Sections 3.4.3 and 3.4.4.

3.4.9.3 Indications for treatment of ureteral stones

Indications for removal of ureteral stones are [176, 334, 336]:

- stones with a low likelihood of spontaneous passage;
- persistent pain despite adequate analgesic medication;
- persistent obstruction;
- renal insufficiency (renal failure, bilateral obstruction, or single kidney).

3.4.9.4 Selection of procedure for removal of ureteral stones

The selection of the procedure depends on many factors, including stone-related factors, such as size, location, and density, as well as patient-related factors, such as body habitus, urinary anatomy, bleeding disorders, and other potential comorbidities. These and their influence on the outcomes of each of the procedures should be considered when counselling patients.

As previously mentioned in this guideline, CT imaging can provide useful information that may influence the choice of treatment. A meta-analysis outlines that increasing stone density, stone burden, skin-to-stone distance, and hydronephrosis can negatively impact the success of the shockwave lithotripsy [337].

Overall, SFRs after URS or SWL for ureteral stones are comparable. However, larger stones achieve earlier stone-free status with URS.

A large multi-center non-inferiority trial compared URS to SWL for ureteral stones. When excluding patients that had spontaneously passed their stone prior to treatment, SWL could not be considered non-inferior to URS with only 12% of patients needing further intervention after URS in comparison to 26% in the SWL arm [253]. In contrast to the success of SWL, comparative data on the outcomes of URS depending on patients' BMI has shown URS to be as effective and safe in obese and morbidly obese patients as in non-obese patients [338].

The Panel performed a systematic review to assess the benefits and harms of URS compared to SWL [339]. Compared with SWL, URS was associated with a significantly greater SFR of up to four weeks, but the difference was not significant at three months in the included studies. Ureteroscopy was associated with fewer retreatments and the need for secondary procedures but with a higher need for adjunctive procedures, higher complication rates, and longer hospital stay. Counterbalancing for URS's higher SFRs, SWL is associated with lower morbidity. Success rates and complications of URS are not impacted by previous unsuccessful SWL [340]. Clavien-Dindo grade complications were if reported, less frequent in patients treated with SWL [175].

Apart from the treatment modality, the timing of treatment may also be of importance. Primary or emergent ureteroscopy appears to be a safe and feasible procedure for patients presenting with renal colic due to an obstructive ureteral stone [341], without however increasing the stone-free rate. These results however are based mainly on low level of evidence reports and should be interpreted with caution [341]. Similarly, SWL can be performed in the acute setting or electively allowing a trial of spontaneous passage. In contrast to acute URS, SWL in the acute setting does provide an increased stone-free rate and reduced need for auxiliary procedures [342].

For large proximal ureteral stones, a percutaneous antegrade approach may provide better stone-free results than a retrograde ureteroscopic approach [343].

Bleeding disorder

Ureteroscopy can be performed in patients with bleeding disorders, with a moderate increase in complications (see also Section 3.4.8.2) [320].

3.4.9.4.1 Summary of evidence and recommendations for selection of procedure for active removal of ureteral stones

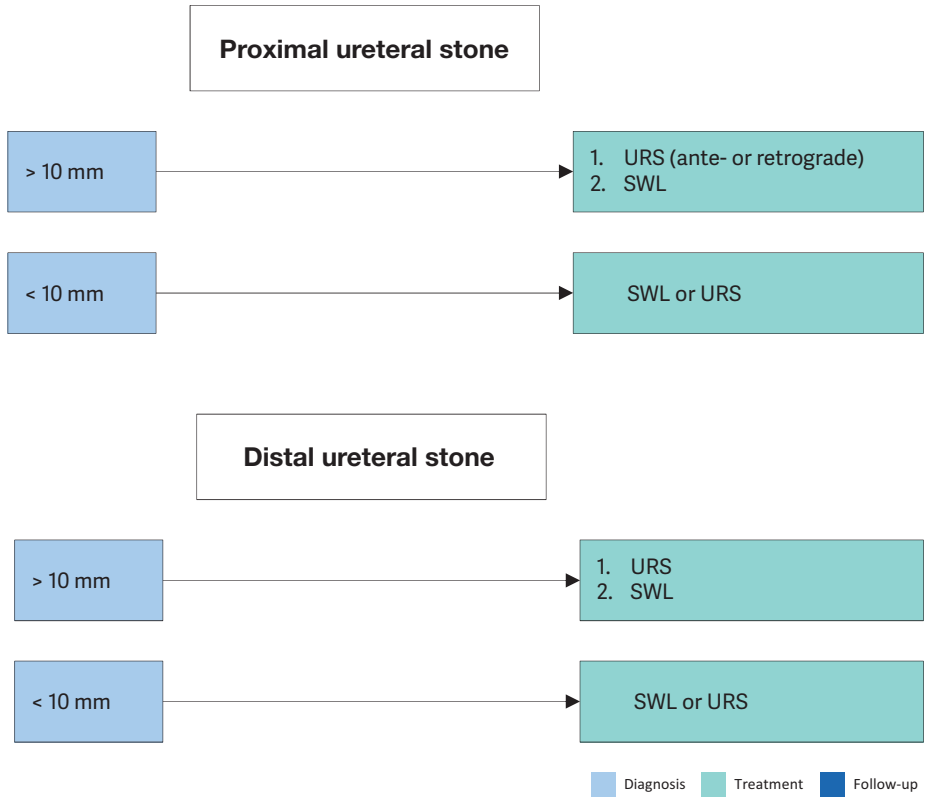
Summary of evidence	**LE**
Observation is feasible in informed patients who develop no complications (infection, refractory pain, deterioration of renal function).	2a
Medical expulsive therapy seems to be efficacious for treating patients with ureteral stones who are amenable to conservative management. The greatest benefit might be among those with > 5 mm (distal) stones.	1a
Compared with SWL, URS was associated with significantly greater SFRs up to four weeks, but the difference was not significant at three months in the included studies.	1a
Ureteroscopy was associated with fewer retreatments and need for secondary procedures, but with a higher need for adjunctive procedures, greater complication rates and longer hospital stay.	1a
In the case of severe obesity, URS is a more promising therapeutic option than SWL.	2b

Recommendations	Strength rating
If active removal is not indicated (Section 3.4.9.3) in patients with newly diagnosed small* ureteral stones, observe patient initially with periodic evaluation.	Strong
Offer α-blockers as medical expulsive therapy as one of the treatment options for (distal) ureteral stones > 5 mm**.	Strong
Inform patients that ureteroscopy (URS) has a better chance of achieving stone-free status with a single procedure.	Strong
Inform patients that URS has higher complication rates when compared to shock wave lithotripsy.	Strong
Use URS as first-line therapy for ureteral (and renal) stones in cases of severe obesity.	Strong

**See stratification data [176].*

*** Alpha-blockers are an off-label treatment for this indication*

Figure 3.1: Treatment algorithm for ureteral stones (if stone removal is indicated)



SWL = shock wave lithotripsy; URS = Ureteroscopy.

3.4.10 Specific stone management of renal stones

The natural history of small, non-obstructing asymptomatic calculi is not well defined, and the risk of progression is unclear. There is still no consensus on the follow-up duration, timing, and type of intervention. In an RCT patients with small asymptomatic renal stones, who were not treated actively, had a higher incidence of relapse [344].

3.4.10.1 Conservative treatment (observation)

Observation of renal stones, especially in calyces, depends on their natural history (Section 3.4.10.3). The recommendations provided are not supported by high-level literature [345]. There is a prospective trial supporting annual observation for asymptomatic inferior calyceal stones, < 10 mm. In case stone growth is detected, the follow-up interval should be lowered [346]. Intervention is advised for growing stones > 5 mm [347]. In a systematic review of patients with asymptomatic renal stones on active surveillance spontaneous stone passage rates varied from 3-29%, symptom development from 7-77%, stone growth from 5-66%, surgical intervention from 7-26% [345].

3.4.10.2 Pharmacological treatment of renal stones

Dissolution therapy seems to be an option for uric acid stones. See sections 3.4.4. and 3.4.8.4.

3.4.10.3 Indications for stone removal of renal stones

Indications for the removal of renal stones include:

- stone growth;
- stones in high-risk patients for stone formation;
- obstruction caused by stones;
- infection;
- symptomatic stones (e.g., pain or haematuria) [348];
- patient preference;
- comorbidity;
- the social situation of the patient (e.g., profession or traveling);

3.4.10.4 Selection of procedure for active removal of renal stones

For general recommendations and precautions see Section 3.4.8.

3.4.10.4.1 Stones in the renal pelvis or upper/middle calyces

Shock wave lithotripsy, PCNL and RIRS are available treatment modalities for renal calculi. While PCNL efficacy is hardly affected by the stone size, the SFRs after SWL or URS are inversely proportional to stone size [253, 349-355]. Although multiple treatments or sessions may be needed shock wave lithotripsy achieves good SFRs for stones up to 20 mm, except for those at the lower pole [351, 356, 357]. When SWL is considered, stones with density > 1,000 HU (and with high homogeneity) on non-contrast-enhanced CT are less likely to be disintegrated [43]. Endourology is considered an alternative because of the reduced need for repeated procedures and consequently a shorter time until stone-free status is achieved. For stones > 10 mm, mPCNL achieves a higher SFR than RIRS or SWL, but carries a higher risk of bleeding and is associated with a longer hospital stay; however, there is a high degree of heterogeneity among the included studies [353, 355]. Stones > 20 mm should be treated primarily by PCNL, because SWL often requires multiple treatments, and is associated with an increased risk of ureteral obstruction (colic or steinstrasse) with a need for adjunctive procedures (Figure 3.2) [358]. Retrograde renal surgery cannot be recommended as first-line treatment for stones > 20 mm in uncomplicated cases as SFRs decrease, and staged procedures will be required [359-361]. However, it may be a first-line option in patients where PCNL is not an option or contraindicated or in selected patients [362]. The combination of PCNL and RIRS may be a good alternative for the treatment of complex renal stones compared to standard PCNL; however, the level of the existing evidence is low [265].

3.4.10.4.2 Stones in the lower renal pole

The stone clearance rate after SWL seems to be lower for stones in the inferior calyx than for other intra-renal locations. Although the disintegration efficacy of SWL is not limited compared to other locations, the fragments often remain in the calyx and cause recurrent stone formation. The reported SFR of SWL for lower pole calculi is 25-95%. The preferential use of endoscopic procedures is supported by some current reports, even for stones < 1 cm [350, 352, 356, 358, 361, 363-370].

The following can impair successful stone treatment by SWL [371-377]:

- steep infundibular-pelvic angle;
- long calyx;
- long skin-to-stone distance;
- narrow infundibulum;
- shock wave-resistant stones (calcium oxalate monohydrate, brushite, or cystine).

Further anatomical parameters cannot yet be established. Supportive measures such as inversion, vibration or hydration may facilitate stone clearance (See 3.4.5 SWL) [174, 378, 379]. If there are negative predictors for SWL, PCNL and RIRS might be reasonable alternatives, even for smaller calculi [363]. Retrograde renal surgery seems to have comparable efficacy to SWL [350, 356, 358, 380]. Clinical experience has suggested a higher SFR of RIRS compared to SWL but at the expense of greater invasiveness. Depending on operator skills, stones up to 3 cm can be treated by RIRS [362, 381]. However, staged procedures are frequently required. Although mini-PCNL has the highest success rate for the treatment of lower pole stones up to 2 cm, it comes at the expense of a higher complication rate and longer hospital stay [355].

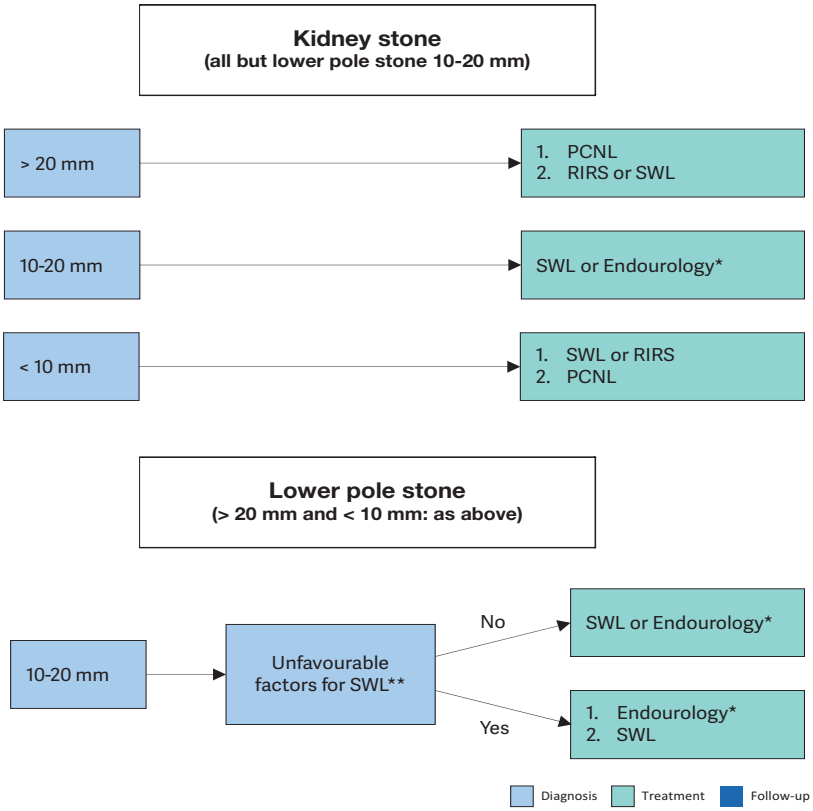
In complex stone cases, open or laparoscopic approaches are possible alternatives although they are infrequently used.

3.4.10.5 Summary of evidence and recommendations for the management of renal stones

Summary of evidence	LE
It is still debatable whether renal stones should be treated, or whether annual follow-up is sufficient for asymptomatic calyceal stones that have remained stable for six months.	4
Although the question of whether asymptomatic calyceal stones should be treated is still unanswered, stone growth, *de novo* obstruction, associated infection, and acute and/or chronic pain are indications for treatment.	3
Percutaneous nephrolithotomy is indicated in renal stones > 2 cm as primary option.	1a

Recommendations	Strength rating
Offer active treatment for renal stones in case of stone growth, *de novo* obstruction, associated infection, and acute and/or chronic pain.	Weak
Evaluate stone composition before deciding on the method of removal, based on patient history, former stone analysis of the patient or Hounsfield unit (HU) on unenhanced computed tomography.	Strong
Perform percutaneous nephrolithotomy (PCNL) as first-line treatment of larger stones > 2 cm.	Strong
Treat larger stones (> 2 cm) with flexible ureteroscopy or shock wave lithotripsy (SWL), in cases where PCNL is not an option. However, in such instances there is a higher risk that a follow-up procedure and placement of a ureteral stent may be needed.	Strong
Perform PCNL or retrograde intrarenal surgery for the lower pole, even for stones > 1 cm, as the efficacy of SWL is limited (depending on favourable and unfavourable factors for SWL).	Strong
Perform PCNL or retrograde intrarenal surgery for the lower pole, even for stones > 1 cm, as the efficacy of SWL is limited (depending on favourable and unfavourable factors for SWL).	Strong

Figure 3.2: Treatment algorithm for renal stones (if/when active treatment is indicated)



**The term 'Endourology' encompasses all PCNL and URS interventions.*
PCNL = percutaneous nephrolithotomy; RIRS = retrograde intrarenal surgery; SWL = shock wave lithotripsy; URS = ureteroscopy

3.4.11 *Laparoscopy and open surgery*

Advances in SWL and endourological surgery (URS and PCNL) have significantly decreased the indications for open or laparoscopic stone surgery [382-387]. There is a consensus that most complex stones, including partial and complete staghorn stones, should be approached primarily with PCNL. Additionally, a combined approach with PCNL and RIRS may also be an appropriate alternative. However, if percutaneous approaches are not likely to be successful, or if multiple endourological approaches have been performed unsuccessfully; open or laparoscopic surgery may be a valid treatment option [388-392].

Few studies have reported laparoscopic stone removal. These procedures are usually reserved for special cases. When expertise is available, laparoscopic ureterolithotomy can be performed for large proximal ureteral stones as an alternative to URS or SWL [393, 394]. These more invasive procedures have yielded high SFRs and lower auxiliary procedure rates [196, 205, 389]. A systematic review showed no difference in the post-operative phase for stented or unstented laparoscopic ureterolithotomy [389].

Laparoscopic pyelolithotomy could be offered for solitary stones > 2 cm located in the renal pelvis as an alternative to PCNL [390]. In addition, in selected cases with an extrarenal and dilated pelvis, RLP can be considered as an alternative management of staghorn calculi [395].

A few studies with limited numbers of patients have reported using robotic surgery in the treatment of urinary stones [391]. Open surgery should be considered as the last treatment option after all other possibilities have been explored.

Studies on laparoscopy should be interpreted with caution due to their low design and quality of evidence.

3.4.11.1 *Recommendation for laparoscopy and open surgery*

Recommendation	Strength rating
Offer laparoscopic or open surgical stone removal in rare cases in which shock wave lithotripsy, retrograde or antegrade ureteroscopy and percutaneous nephrolithotomy fail, or are unlikely to be successful.	Strong

3.4.12 *Steinstrasse*

Steinstrasse is an accumulation of stone fragments or stone gravel in the ureter and may interfere with the passage of urine [396]. Steinstrasse occurs in 4% of cases of SWL [175, 183], and the major factor in the development of steinstrasse formation is stone size [397].

A major problem of steinstrasse is ureteral obstruction, which may be silent in up to 23% of cases. A MA including eight RCTs (n = 876) suggested a benefit of stenting before SWL in terms of steinstrasse formation but did not result in a benefit on SFRs or less auxiliary treatments [136]. When steinstrasse is asymptomatic, conservative treatment is an initial option. Medical expulsion therapy increases stone expulsion and reduces the need for endoscopic intervention [398, 399]. Ureteroscopy and SWL are effective in the treatment of steinstrasse [185, 400]. In the event of UTI or fever, the urinary system should be decompressed, preferably by percutaneous nephrostomy [113, 401].

3.4.12.1 *Summary of evidence and recommendations for steinstrasse*

Summary of evidence	LE
Medical expulsion therapy increases the stone expulsion rate of steinstrasse.	1b
Ureteroscopy is effective for the treatment of steinstrasse.	3
Only low-level evidence is available, supporting SWL or URS for the treatment of steinstrasse.	4

Recommendations	Strength rating
Treat steinstrasse associated with urinary tract infection (UTI)/fever preferably with percutaneous nephrostomy.	Weak
Treat steinstrasse when large stone fragments are present with shock wave lithotripsy or ureteroscopy (in absence of signs of UTI).	Weak

*3.4.13 **Management of patients with residual stones***

Following initial treatment with SWL, URS or PCNL, residual fragments may remain and require additional intervention [347, 402-405]. Most of these studies indicate that initial imaging is performed on the first day or the first week after treatment. However, false positive results from dust or residual fragments, that will pass spontaneously without causing any stone-related event, might lead to over-treatment. Therefore, imaging at four weeks seems most appropriate [406-408]. Compared to US, KUB and IVU, NCCT scan has a higher sensitivity to detect small residual fragments after definitive treatment of ureteral or kidney stones [409, 410].

A SR/MA examining residual fragments following any treatment has demonstrated that around a third of patients with either dust or fragments </= 4 mm experience disease progression and re-intervention within three years, whilst a third have spontaneous passage within two years regardless of imaging modality follow-up. For fragments > 4 mm, there are fewer studies, but these suggest low spontaneous passage rates and high intervention rates [411].

Although NCCT has the highest sensitivity to detect residual fragments, this must be balanced to the exposure to ionising radiation when compared with KUB and US. Recurrence risk in patients with residual fragments after treatment of infection stones is higher than for other stones [412].

3.4.13.1 Recommendation for management of patients with residual stones

Recommendation	Strength rating
Treat residual fragments > 4 mm.	Weak

*3.4.14 **Management of specific patient groups***

3.4.14.1 Management of urinary stones and related problems during pregnancy

Clinical management of a pregnant patient with urolithiasis is complex and demands close collaboration between the patient, radiologist, obstetrician, and urologist [64]. For diagnostic imaging see Section 3.3.1. Patients with urolithiasis may be at increased risk of developing adverse maternal or neonatal outcomes [413].

Conservative approaches for symptomatic hydronephrosis as well as for ureteric calculi are the preferred initial management option in pregnant patients [414, 415].
If spontaneous passage does not occur, or if complications develop (e.g., intractable symptoms, severe hydronephrosis, spontaneous renal fornix rupture [416] or induction of premature labour), placement of a ureteral stent or a percutaneous nephrostomy tube is necessary as it is more effective than conservative treatment for symptom relief [417-419].

In the treatment of renal stones during pregnancy, when a stent is necessary, PCNL versus ureteral stent placement does not confer a significant difference in rates of adverse pregnancy events. However, ureteral stent placement was associated with a lower incidence of hospital admissions, emergency department visits, exchange procedures, and new UTIs or pyelonephritis [420].

Ureteroscopy has become a reasonable alternative in these situations [408, 421]. When compared to temporary ureteral JJ stenting until after delivery, ureteroscopy resulted in fewer needs for stent exchanges, less irritative LUTS and better patient satisfaction [422, 423].

Non-urgent ureteroscopy in pregnant women is best performed during the second trimester, by an experienced urologist. Counselling of the patient should include access to neonatal and obstetric services [72].

Although feasible, percutaneous removal of renal stones during pregnancy remains an individual decision and should be performed only in experienced centres [424]. Pregnancy remains an absolute contraindication for SWL.

3.4.14.1.1 Summary of evidence and recommendation for the management of urinary stones and related problems during pregnancy

Summary of evidence	LE
Stent insertion seems to be more effective than conservative treatment in the management of symptomatic moderate-to-severe hydronephrosis during pregnancy.	1a
Ureteroscopy is a reasonable alternative to avoid long-term stenting/drainage.	1b
There is a higher tendency for stent encrustation during pregnancy.	3

Recommendation	Strength rating
Treat all uncomplicated cases of urolithiasis in pregnancy conservatively (except when there are clinical indications for intervention).	Strong

3.4.14.2 Management of stones in patients with urinary diversion

Aetiology

Patients with urinary diversion are at high risk for stone formation in the renal collecting system and ureter or in the conduit or continent reservoir [425, 426]. Metabolic factors (hypercalciuria, hyperoxaluria and hypocitraturia), infection with urease-producing bacteria, foreign bodies, mucus secretion, and urinary stasis are responsible for stone formation [427] (section 3.1.3). One study has shown that the risk for recurrent upper tract stones in patients with urinary diversion subjected to PCNL was 63% at five years [428].

Management

Smaller upper-tract stones can be treated effectively with SWL [429, 430]. In most cases, endourological techniques are necessary to achieve stone-free status [431]. In individuals with long, tortuous conduits or with invisible ureter orifices, a retrograde endoscopic approach might be difficult or impossible [432].

For stones in the conduit, a trans-stomal approach can be used to remove all stone material (along with the foreign body) using standard techniques, including intracorporeal lithotripsy and flexible endoscopes. Trans-stomal manipulations in continent urinary diversion must be performed carefully to avoid disturbance of the continence mechanism [433].

Before considering any percutaneous approach in these cases, CT should be undertaken to assess the presence of overlying bowel, which could make this approach unsafe [434], and if present, a surgical approach should be considered.

Prevention

Recurrence risk is high in patients with urinary diversion [428]. Metabolic evaluation and close follow-up are necessary to obtain the risk parameters for effective long-term prevention. Preventive measures include medical management of metabolic abnormalities, appropriate therapy of urinary infections, and hyper-diuresis or regular irrigation of continent reservoirs [435].

3.4.14.2.1 Summary of evidence and recommendation for the management of stones in patients with urinary diversion

Summary of evidence	LE
The choice of access depends on the feasibility of orifice identification in the conduit or bowel reservoir. Whenever a retrograde approach is impossible, percutaneous access with antegrade ureteroscopy is the alternative.	4

Recommendation	Strength rating
Perform percutaneous lithotomy to remove large renal stones in patients with urinary diversion, as well as for ureteral stones that cannot be accessed via a retrograde approach, or that are not amenable to shock wave lithotripsy.	Strong

3.4.14.3 Management of stones in patients with neurogenic bladder

Aetiology, clinical presentation, and diagnosis

Patients with neurogenic bladder develop urinary calculi because of additional risk factors such as bacteriuria, hydronephrosis, VUR, renal scarring and lower urinary tract reconstruction [436, 437]. The most common causes are urinary stasis and infection (Section 3.1.3). Indwelling catheters and surgical interposition of bowel segments for treatment of bladder dysfunction both facilitate UTI. Although calculi can form at any level of the urinary tract, they occur more frequently in the bladder; especially if bladder augmentation has been performed [438, 439].

Diagnosis of stones may be difficult and delayed in the absence of clinical symptoms due to sensory impairment and vesicourethral dysfunction. Difficulties in self-catheterisation should lead to suspicion of bladder calculi. Imaging studies are needed (US, CT) to confirm the clinical diagnosis prior to surgical intervention.

Management

Management of calculi in patients with neurogenic bladder is similar to that described in Section 3.3. Any surgery in these patients must be performed under general anaesthesia because of the impossibility of using spinal anaesthesia. Bone deformities often complicate positioning on the operating table [440]. The risk of stone formation after augmentation cystoplasty in immobile patients with sensory impairment can be significantly reduced by irrigation protocols [435].

For efficient long-term stone prevention in patients with neurogenic bladder, correction of the metabolic disorder, appropriate infection control, and restoration of normal storing/voiding function of the bladder are needed.

3.4.14.3.1 Summary of evidence and recommendation for the management of stones in patients with neurogenic bladder

Summary of evidence	**LE**
Patients undergoing urinary diversion and/or suffering from neurogenic bladder dysfunction are at risk for recurrent stone formation.	3

3.4.14.4 Management of stones in patients with transplanted kidneys

Stones in transplanted kidneys can either be transplanted or present *de novo* allograft stones. Usually, they are detected by routine US examination, followed by NCCT in cases of unclear diagnosis [441].

Aetiology

Transplant patients depend on their solitary kidneys for renal function. Impairment causing urinary stasis/obstruction, therefore, requires immediate intervention or drainage of the transplanted kidney. Stones in kidney allografts have an incidence of 2% [441]. Risk factors for *de novo* stone formation in these patients are multi-fold:

- Immunosuppression increases the infection risk, resulting in recurrent UTIs.
- Hyper-filtration, excessively alkaline urine, renal tubular acidosis (RTA), and increased serum calcium caused by persistent tertiary hyperparathyroidism [442] are biochemical risk factors.

Management

Selecting the appropriate technique for stone removal in a transplanted kidney is difficult, although management principles are like those applied in other single renal units [443-445]. Additional factors such as transplant function, coagulative status, and anatomical alterations due to the iliac position of the organ, directly influence the surgical strategy.

For large or ureteral stones, careful percutaneous access and subsequent antegrade endoscopy are more favourable. The introduction of small flexible ureteroscopes and the holmium laser has made URS a valid treatment option for transplant calculi; however, one must be aware of potential injury to adjacent organs [444, 446, 447]. Retrograde access to transplanted kidneys can be difficult due to the anterior location of the ureteral anastomosis, and ureteral tortuosity [448-450]. Treatment of donor stones may be needed pre-transplant and increases the pool available for renal transplants. Post-transplant stone disease may also need treatment to maintain the allograft function. A systematic review evaluating the outcomes of pre- vs. post-transplant URS demonstrated a 100% SFR with an overall 7.5% complication rate, compared to a SFR of 60-100% with an overall complication rate of 12.9% for post-transplant URS; most complications were Clavien 1 [451]. A SR shows that SWL is also a safe and effective option for *de novo* stones after transplantation, with an overall SFR of 81% and a complication rate of 17.2% [452].

3.4.14.4.1 Summary of evidence and recommendation for the management of stones in patients with transplanted kidneys

Summary of evidence	LE
Conservative treatment for small asymptomatic stones is only possible under close surveillance and in absolutely compliant patients.	3
Shock wave lithotripsy for small calyceal stones is an option with minimal risk of complication, but localisation of the stone can be challenging.	3

Recommendation	Strength rating
Offer patients with transplanted kidneys any of the contemporary management options, including shock wave lithotripsy, flexible ureteroscopy and percutaneous nephrolithotomy.	Strong

3.4.14.5 Special problems in stone removal

Table 3.11: Special problems in stone removal [453]

Calyceal diverticulum stones	• SWL, PCNL [454] (if possible) or RIRS [454, 455]. • Can also be removed using laparoscopic retroperitoneal surgery [456, 457]. • Patients may become asymptomatic due to stone disintegration (SWL), whilst well-disintegrated stone material remains in the original position due to narrow calyceal neck.
Horseshoe kidneys	• Can be treated in line with the options described above [458-460]. • Passage of fragments after SWL might be poor. • Acceptable SFRs (up to 76%) with low major complication rates (2.4%) can be achieved with flexible ureteroscopy [458-460].
Stones in pelvic kidneys	• SWL, RIRS, PCNL or laparoscopic surgery [461].
Stones formed in a continent reservoir	• Each stone must be considered and treated individually.
Patients with obstruction of the UPJ	• When outflow abnormality requires correction, stones can be removed by PCNL together with percutaneous endopyelotomy or open/laparoscopic reconstructive surgery. • URS together with endopyelotomy with Ho:YAG laser [462].

3.4.15 ***Management of stones in children***

The true incidence of nephrolithiasis in children remains unclear due to the global lack of large epidemiological studies. Data derived from nationwide epidemiological studies, studies performed in different counties worldwide [463] and large-scale databases [464, 465] indicate that the incidence and prevalence of paediatric urinary stone disease have increased over the last few decades. Although boys are most commonly affected in the first decade of life [466] the greatest increase in incidence has been seen in older female adolescents [463].
Stone composition is similar in children as in adults, with a predominance of calcium oxalate stones. Compared to historical data, metabolic abnormalities responsible for stone formation are less commonly identified in children nowadays [467-469]. Hypocitraturia, low urine volume and hypercalciuria predominate [84, 467-469]. Age may affect the predominant metabolic abnormality with hypercalciuria and hypocitraturia being the most common disorder present in children < 10 and > 10 years old, respectively [469]. Genetic or systemic diseases (e.g., cystinuria or nephrocalcinosis) contributing to stone formation are relatively frequent in children accounting for less than 17% of the identifying causes [467, 470]. The role of diet remains unclear in children, although there is some evidence that children are drinking less water and taking greater daily amounts of sodium than is recommended [471-473].

For diagnostic procedures see Section 3.3.3.2, for acute decompression see Section 3.4.2. and for metabolic evaluation see Chapter 4.

3.4.15.1 Clinical presentation

Children with urinary stones can be asymptomatic or present with non-specific symptoms that necessitate a high index of suspicion for proper diagnosis. Symptoms are age-dependent with infants presenting with crying,

irritability and vomiting in 40% of cases [474] while in older children flank pain, micro or gross haematuria and recurrent UTIs are more common [475].

3.4.15.2 Conservative management

There is a lack of evidence on conservative management of paediatric stones with evidence for ureteric calculi coming from the placebo arms of medical expulsive trials, while evidence for renal stones comes from small cohort studies, either on primary stones [476, 477] or residual fragments remained after SWL, RIRS or PCNL [478]. Expectant management for single, asymptomatic lower-pole renal stones could be the initial approach with increased odds of stone passage, especially in patients with non-struvite, non-cystine stones < 7 mm, with no anatomic abnormalities [476]. Intervention may be needed for stones located elsewhere independently of their size [476-478].

3.4.15.3 Medical expulsive therapy in children

There are limited studies on MET as off-label expulsive therapy for children with ureteral stones up to 10 mm which show conflicting outcomes. Several systematic reviews and meta-analyses, including six RCTs and one conference abstract of an RCT, have been performed, all unanimously reporting that the use of alpha-blockers for distal ureteric stones increases the stone-free or stone expulsion rate [479-481]. The use of alpha-blockers also reduces the stone expulsion time and decreases pain episodes and analgesia demand with the disadvantage of more side-effects such as headache and nasal congestion [480, 481].

3.4.15.4 Extracorporeal shock wave lithotripsy

Shock wave lithotripsy is still the first-line treatment for most ureteral stones in children. However, it is less likely to be successful for stones > 10 mm in diameter, impacted stones, calcium oxalate monohydrate or cystine stones, or for stones in children with unfavourable anatomy and in whom localisation is difficult [482].

Studies on extracorporeal SWL in children suggest an overall SFR of 70-90%, retreatment rate of 4-50% and need for auxiliary procedures in 4-12.5% of cases [483-487]. A MA of fourteen studies reporting on 1,842 paediatric patients treated with SWL found significantly higher SFR for stones < 10 mm than for stones > 10 mm and higher retreatment rates as the stone size increased [482]. For best clinical practice see Section 3.4.5. A MA on slow SWL vs. rapid SWL for renal stones revealed very low-quality evidence about the effects of SWL on SFRs, serious adverse events or complications of treatment and secondary procedures for residual fragments [479]. Shock wave lithotripsy is well tolerated; however, good treatment outcomes are more likely to require the administration of general anaesthesia to children. With improvements in modern (second and third-generation) lithotripters, successful treatment using intravenous sedation, patient-controlled analgesia or no medication at all has been increasingly performed in a select population of older, co-operative children [488].

Based on the results of a MA which compared SWL to dissolution therapy for intra-renal stones, and SWL to ureteroscopy with holmium laser or pneumatic lithotripsy for renal and distal ureteric stones, no firm conclusions can be drawn about the effects of SWL on SFR, serious adverse events or complications of treatment and secondary procedures for residual fragments [479]. When SWL was compared to mini-percutaneous nephrolithotomy for lower pole renal stones 1-2 cm in size SWL resulted in lower SFRs (RR: 0.88, 95% CI: 0.80 - 0.97; moderate-quality evidence) and higher rates of secondary procedures (RR: 2.50, 95% CI: 1.01 - 6.20; low-quality evidence); however, SWL showed less severe adverse events (RR: 0.13, 95% CI: 0.02 - 0.98; low-quality evidence) [489].

3.4.15.5 Endourological procedures

Rigid/semi-rigid ureteroscopy

In recent years ureteroscopy is increasingly used in children with ureteral stones [490]. Ureteroscopy proved to be effective with SFR of 81-98% [491-493], retreatment rates of 6.3%-10% [494] and complication rates of 1.9-23% [491-493, 495]. Similar to adults, routine stenting is not necessary before URS. Pre-stenting may facilitate URS, increase SFR and decrease complication rates [496, 497].

Flexible ureteroscopy/retrograde intrarenal surgery

Retrograde intra-renal surgery with flexible ureteroscopes (FURS) has become an efficacious treatment modality for paediatric renal stones. Studies report SFRs of 76-100%, retreatment rates of 0-19% and complication rates of 0-28% [498-501]. Younger age, cystine composition [502], large stone diameter [501] and lack of pre-stenting predispose to FURS failure in children [496]. A large global study across eight centres shows an SFR of 75.5%; although complications were minor, they were higher in patients < 5 years of age [503].

Although high-level evidence is lacking to support a strong recommendation [479], FURS may be a particularly effective treatment option for lower calyceal stones in the presence of unfavourable factors for SWL [493, 499, 504].

For large and complex kidney stones RIRS has a significantly lower SFR compared to PCNL (71% vs. 95%), but is associated with less radiation exposure, lower complication rates, and a shorter hospital stay [505]. Similarly, retrospective data indicate that RIRS may achieve lower SFRs compared to micro percutaneous surgery in favour of shorter operative time, shorter fluoroscopy time, and less hospitalisation time [506, 507]. A published MA confirmed these results [508].

Percutaneous nephrolithotomy

Indications for PCNL in children are like those in adults and include renal stones > 2 cm, or smaller stones resistant to SWL and ureteroscopic treatment. Reported SFRs with paediatric PCNL are 71.4-95% after a single session [505-507, 509, 510] with an overall complication rate of 20% [511]. A high degree of hydronephrosis, increased number of tracts and operative time [512], and large tract size [510, 513-515] are associated with increased blood loss. Child age [514] and stone burden [510] predispose to the use of larger instruments during PCNL in children. The miniaturisation of equipment increases the opportunity to perform tubeless PCNL in appropriately selected children, which can reduce the length of hospital stay and post-operative pain [516, 517]. A systematic review on the role of mini-PCNL showed an initial and overall SFR of 87.9% and 97% respectively, with no conversions to standard PCNL, and a complication rate of 19%, with a mean transfusion rate of 3.3% [503].

Concerns have been raised regarding the possible adverse effects of PCNL on the renal parenchyma of the developing child. However, focal damage is only reported in 5% of cases [518]. Using pre- and post-PCNL dimercaptosuccinic acid (DMSA) scans, Cicekbilek *et al.* demonstrated that PCNL tracts between 12-24 Charrière in size did not cause significant harm to paediatric kidneys [509].

3.4.15.6 Open and laparoscopic/robot-assisted stone surgery

With the advances in SWL, PCNL and RIRS, very few cases of paediatric urolithiasis require open surgery. Data extracted from the National Inpatient Sample (NIS) databases for 2001-2014 showed that in the USA incisional procedures (mainly nephrolithotomy, pyelolithotomy and ureterotomy) were performed in 2.6% of hospitalised patients (52% aged 15-17 years) who required surgical intervention for urinary stones [519]. Laparoscopy for the management of paediatric renal and ureteric stones is a safe and effective procedure when specific indications are followed. Stone-free rates of 100% were reported when laparoscopic pyelolithotomy was applied for a ≥ 1 cm single stone located in an extra-renal pelvis [520], or when laparoscopic ureterolithotomy was applied to impacted ureteric stones ≥ 1.5 cm, or to ureteric stones that were refractory to SWL or URS [521]. There are extremely limited data available on the efficacy and complications of robot-assisted laparoscopic management of paediatric urolithiasis [522].

3.4.15.7 Special considerations on recurrence prevention

All paediatric stone formers need metabolic evaluation and recurrence prevention with respect to the detected stone type. Children are in the high-risk group for stone recurrence (See Chapter 4).

3.4.15.8 Summary of evidence and recommendations for the management of stones in children

Summary of evidence	**LE**
In children, MET could increase the rate of stone expulsion, reduce the stone expulsion time, and decrease pain episodes/analgesia demand, but it has a higher incidence of side effects.	1b
In children, the indications for SWL, URS and PCNL are similar to those in adults.	1b
Children with renal stones of a diameter up to 20 mm (~300 mm^2) are ideal candidates for SWL.	1b
Ureteroscopy has become the treatment of choice for larger distal ureteral stones in children.	1a
In children, the indications for PCNL are similar to those in adults.	1a
Mini-PCNL is safe and effective in children.	1b

Recommendations	**Strength rating**
Offer children with single ureteral stones less than 10 mm shock wave lithotripsy (SWL) if localisation is possible or ureteroscopy as first-line option.	Strong
Ureteroscopy is a feasible alternative for ureteral stones not amenable to SWL.	Strong
Offer children with renal stones with a diameter of up to 20 mm (~300 mm^2) SWL.	Strong
Offer children with renal pelvic or calyceal stones with a diameter > 20 mm (~300 mm^2) percutaneous nephrolithotomy.	Strong
Retrograde renal surgery is a feasible alternative for renal stones smaller than 20 mm in all locations.	Weak

3.5 Radiation exposure and protection during endourology

The diagnosis and treatment of nephrolithiasis are associated with high levels of ionising radiation exposure to patients [523, 524]. Currently, there are no studies estimating the lifetime radiation exposure of stone formers or the subsequent risk of malignancy development. The radiation exposure of endourologists has been extensively studied. Still, there are no studies assessing the risk of radiation-induced malignancies in urologists or operating theatre staff members [525-527].

Current evidence from atomic bomb patients [528, 529], retrospective epidemiological data on medical exposure [530, 531], and modelling studies [532, 533] suggest an age and dose-dependent risk of secondary malignancy from ionising radiation.

The International Commission on Radiological Protection (ICRP) recommends a maximum annual occupational exposure of 50mSv [534]. However, the risk of radiation-induced malignancy follows a stochastic model having no known safe threshold of exposure. Taking this into consideration as well as the length of a urologist's career the upper limit of 50mSv is still highly concerning.

Table 3.12 shows the EAU Urolithiasis guidelines panel recommended protection methods to reduce radiation exposure to patients, surgical, anaesthesiologic, and nursing staff.

Table 3.12 Radiation protection measures

Limit studies or intervention involving radiation exposure to those that are strictly medically necessary.
Implement a patient electronic record of medical imaging.
Make use of imaging studies with lower radiation doses (US, KUB, digital tomosynthesis, low-dose and ultra-low dose CT scan).
Create and follow a precise radiation exposure protection protocol in your department.
Act in accordance with the as low as reasonably achievable (ALARA) principle.
Measure and report fluoroscopy time to the operative surgeon (use dosimeters and perform monthly calculations).
Technical measures to reduce radiation exposure include: • Reducing fluoroscopy time; • Limiting time adjacent to patient; • Using low-dose radiation; Irradiating only to observe motion; • Intra-operative use of pulsed fluoroscopy; • Reduced fluoroscopy pulse rate; • Collimated fields; • Avoid digital image acquisition and rely on last image hold and instant replay technology.
Use radiation protection instruments (chest, pelvic and thyroid shields, lead or lead-free gloves, protective glasses, lead protection under the operating table between the x-ray source and the surgeon).
The radiation protection instruments must be cared for appropriately as any damage decreases effectiveness and increases exposure risk. They should be monitored and measured regularly to ensure integrity.
Proper surgeon and operating room setup should be observed (follow the inverse square law, use the x-ray source underneath the patient's body, decrease the x-ray source to patient distance, reduce magnification, avoid field overlap by not turning the C-arm in extreme angles, operate in the standing rather than the seated position).

The availability of fluoroscopy is mandatory for endourological procedures. There is an increasing interest in fluoroless and fluoroscopy-free operations in urology. Several RCTs have been published showing a good outcome in means of stone-free and complication rates [166, 270, 535-537]. These trials have been limited to non-complex cases and they were not sufficiently powered to show the non-inferiority of fluoroscopy in PCNL [270, 525] or the superiority of ultrasound in URS [213, 214].

4. METABOLIC EVALUATION AND RECURRENCE PREVENTION

4.1 General metabolic considerations for patient work-up

4.1.1 *Evaluation of patient risk*

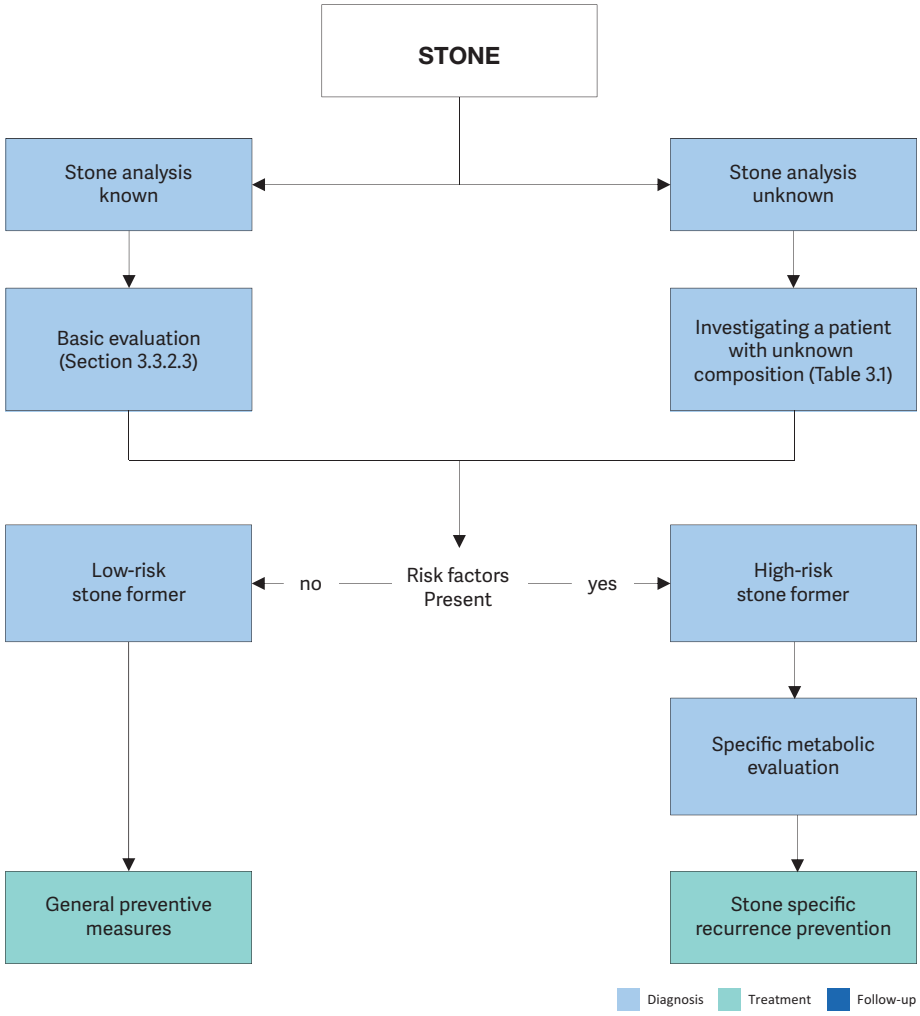
After stone passage, every patient should be assigned to a low- or high-risk group **(Table 3.3)** for stone formation (Figure 4.1).

Reliable stone analysis by infrared spectroscopy or X-ray diffraction and basic metabolic evaluation is mandatory for all stone formers.

Only high-risk stone formers require specific metabolic evaluation. Stone type is the deciding factor for further diagnostic tests. The different stone types include:

- calcium oxalate;
- calcium phosphate;
- uric acid;
- ammonium urate;
- struvite (and infection stones);
- cystine;
- xanthine;
- 2,8-Dihydroxyadenine;
- drug stones;
- stones of unknown composition.

Figure 4.1: Assignment of patients to low- or high-risk groups for stone formation



4.1.2 Urine sampling

Specific metabolic evaluation requires the collection of two consecutive 24-hour urine samples [63, 538, 539]. The collecting bottles should be prepared with 1 g thymol per liter or stored at < 8°C during collection to reduce bacterial proliferation [63]. Pre-analytical errors can be minimised by carrying out urinalysis immediately after collection. Alternatively, boric acid (10 g powder per urine container) can also be used, but this prevents the correct determination of pH [63]. The collecting method should be chosen in close cooperation with the laboratory. A pH < 5.5 in a 24-hour urine indicates hyper acidic urine (acidic arrest) [540-542]. In the course of alkalinising therapy for cystinuria and uric acid stones, urine pH should be assessed during the collection of freshly voided urine at different times throughout the day using sensitive pH dipsticks or a pH-meter [23, 63, 543]. A consensus statement stated that RTA is suspected if 24-hour urine pH is > 6.2 and fasting second-morning spot urine pH is > 5.8 [544, 545].

Spot urine samples are an alternative sampling method, particularly when 24-hour urine collection is difficult, for example, in non-toilet-trained children [546]. Spot urine studies normally link the excretion rates to the creatinine [547], but these are of limited use because the results may vary with collection time and patients' sex, body weight, and age.

4.1.3 Timing of specific metabolic work-up

For the initial specific metabolic work-up, the patient should stay on a self-determined diet under normal daily conditions and should ideally be stone-free for at least twenty days [548]. Follow-up studies are necessary for patients taking medication for recurrence prevention [549]. The first follow-up 24-hour urine measurement is suggested eight to twelve weeks after starting pharmacological prevention of stone recurrence. This enables diet and/or drug dosage to be adjusted if urinary risk factors have not normalised, with further 24-hour urine measurements, if necessary. Once urinary parameters have been normalised, it is sufficient to perform a 24-hour urine evaluation every twelve months. On this issue, the Panel realises that there is only very limited published evidence.

4.1.4 Reference ranges of laboratory values

Tables 4.1-4.4 provide the internationally accepted reference ranges for the different laboratory values in serum and urine.

Table 4.1: Normal laboratory values for blood parameters in adults [23, 549]

Blood parameter	Reference range	
Creatinine	50-100 µmol/L	
Sodium	135-145 mmol/L	
Potassium	3.5-5.5 mmol/L	
Calcium	2.0-2.5 mmol/L (total calcium)	
	1.12-1.32 mmol/L (ionised calcium)	
Uric acid	119-380 µmol/L	
Chloride	98-112 mmol/L	
Phosphate	0.81-1.29 mmol/L	
Blood gas analysis	pH	7.35-7.45
	pO_2	80-90 mmHg
	pCO_2	35-45 mmHg
	HCO_3	22-26 mmol/L
	BE	BE ± 2 mmol/L

BE = base excess (loss of buffer base to neutralise acid); HCO = bicarbonate; pCO = partial pressure of carbon dioxide; PO = partial pressure of oxygen.

4.1.5 Risk indices and additional diagnostic tools

Several risk indices have been developed to describe the crystallisation risk for calcium oxalate or calcium phosphate in the urine [550-553]. However, clinical validation of these risk indices for recurrence prediction or therapy improvement is ongoing.

Table 4.2: Laboratory values for urinary parameters in adults

Urinary Parameters	Reference ranges and limits for medical attention
pH	Consistently fasting morning spot urine pH > 5.8 and > 6.2 in 24-hr collection (suspicious of renal tubular acidosis) [544, 545]
	Consistently > 7.0 (suspicious of infection)
	Consistently < 5.5 in morning urine and in 24-hr collection (suspicious of acidic arrest) [540, 554]
Specific weight	Specific weight > 1.010
Creatinine	7-13 mmol/day (females), 13-18 mmol/day (males)
Calcium	> 5.0 mmol/day (see Fig. 4.2)
	> 8.0 mmol/day (see Fig. 4.2)
Oxalate	> 0.5 mmol/day (suspicious of enteric hyperoxaluria)
	>1.0 mmol/day (suspicious of primary hyperoxaluria)
Uric acid	> 4.0 mmol/day (females), 5 mmol/day (males)
Citrate	< male < 1.7 mmol/day, female < 1.9 mmol/day
Magnesium	< 3.0 mmol/day
Inorganic phosphate	> 35 mmol/day
Ammonium	> 50 mmol/day
Cystine	> 0.8 mmol/day

Table 4.3: Normal values for spot urine samples: creatinine ratios (solute/creatinine) in children [555]

Parameter/Patient age	Ratio of solute to creatinine	Units
Calcium	**mol/mol**	**mg/mg**
< 12 months	< 2.0	0.81
1-3 years	< 1.5	0.53
1-5 years	< 1.1	0.39
5-7 years	< 0.8	0.28
> 7 years	< 0.6	0.21
Oxalate	**mol/mol**	**mg/mg**
0-6 months	< 325-360	288-260
7-24 months	< 132-174	110-139
2-5 years	< 98-101	80
5-14 years	< 70-82	60-65
> 16 years	< 40	32
Citrate	**mol/mol**	**g/g**
0-5 years	> 0.25	0.42
> 5 years	> 0.15	0.25
Magnesium*	**mol/mol**	**g/g**
	> 0.63	> 0.13
Uric acid		
> 2 years	< 0.56 mg/dL (33 µmol/L) per GFR (ratio x plasma creatinine)	

** There is low-level evidence regarding the importance of magnesium.*

Table 4.4: Solute excretion in 24-hour urine samples in children [556, 557]*

Calcium/24	Citrate/24 hour		Cystine/24 hour		Oxalate/24 hour		Urate/24 hour	
All age groups	Boys	Girls	< 10 years	> 10 years	All age groups	< 1 year	1-5 years	> 5 years
< 0.1 mmol/kg/ 24 h	> 1.9 mmol/ 1.73 m2/24 h	> 1.6 mmol/ 1.73 m2/24 h	< 55 µmol/ 1.73 m2/24 h	< 200 µmol/ 1.73 m2/24 h	< 0.5 mmol/ 1.73 m2/24 h	< 70 µmol/ kg/24 h	< 65 mµmol/ kg/24 h	< 55 µmol/ kg/24 h
< 4 mg/kg/24 h	> 365 mg/ 1.73 m2/24 h	> 310 mg/ 1.73 m2/24 h	< 13 mg/ 1.73 m2/24 h	< 48 mg/ 1.73 m2/24 h	< 45 mg / 1.73 m2/24 h	< 13 mg/ kg/24 h	< 11 mg/ kg/24 h	< 9.3 mg/ kg/24 h

**24 h urine parameters are diet and gender-dependent and may vary geographically.*

4.2 General considerations for recurrence prevention

All stone formers, independent of their individual risk, should follow the preventive measures in Table 4.5. The main focus is the normalisation of dietary habits and lifestyle risks. Stone formers at high risk need specific prophylaxis for recurrence, which is usually pharmacological treatment based on stone analysis and urinary risk profile.

Table 4.5: General Preventive Measures

Fluid intake (drinking advice)	Fluid amount: 2.5-3.0 L/day
	Water is the preferred fluid
	Diuresis: 2.0-2.5 L/day
	Specific weight of urine: < 1,010 g/day
Nutritional advice for a balanced diet	Balanced diet*
	Rich in vegetables and fibre
	Normal calcium content: 1-1.2 g/day
	Limited NaCl content: 4-5 g/day
	Limited animal protein content: 0.8-1.0 g/kg/day
Lifestyle advise to normalise general risk factors	Retain a normal BMI level
	Adequate physical activity
	Balancing of excessive fluid loss
	Reduce the intake of alcohol containing fluids
	Reduce the intake of sodas and calorie-containing fluids

Caution: Protein requirements are age dependent; therefore, protein restriction in childhood should be handled carefully.

** Avoid excessive consumption of vitamin supplements.*

*4.2.1 **Fluid intake***

An inverse relationship between high fluid intake and stone formation has been repeatedly demonstrated [556-560]. The beneficial effect of fruit juices is mainly determined by the presence of citrate or bicarbonate [561]. Citrus fruit juices seem to protect against stone disease either by increasing urinary citrate levels or by having an alkalinising effect on it [562]. However, if potassium is present, both pH and citrate are increased [563, 564]. One large moderate-quality RCT randomly assigned men with more than one past renal stone of any type and soft drink consumption of at least 160 mL/day to reduced soft drink intake or no treatment. Although the intervention significantly reduced the risk for symptomatic recurrent stones (RR: 0.83; CI: 0.71-0.98), the level of evidence for this outcome is low because the results were from only one trial [565]. An analysis of 3 Channing's cohorts (194,095 participants) over a median follow-up of more than eight years has shown that consumption of sugar-sweetened soda and punch is associated with a higher risk of stone formation, whereas consumption of coffee, tea, beer, wine, and orange juice is associated with a lower risk [566], whereas consumption of tea and coffee does not seem to increase the risk of stones disease [567]. However, the intake of fluids should be considered within a holistic approach to health. Some of them contain calories or alcohol that may be detrimental to health. Therefore, water should be the preferred fluid.

Diet

A common-sense approach to diet should be taken, that is, a mixed, balanced diet with contributions from all food groups, without any excesses [557, 568, 569]. Sufficient calcium intake is needed especially in vegetarian and vegan diets [570].

Fruit, vegetables and fibre: Fruit and vegetable intake should be encouraged because of the beneficial effects of fiber, although the role of the latter in preventing stone recurrences is debatable [571-574]. The alkaline content of a vegetarian diet also increases urinary pH. In addition, fruits and vegetables have a high-water content and can significantly contribute to fluid intake.

Oxalate: Excessive intake of oxalate-rich products should be limited or avoided to prevent high oxalate load [575], particularly in patients who have high oxalate excretion.

Vitamin C: Although vitamin C is a precursor of oxalate, its role as a risk factor in calcium oxalate stone formation remains controversial [576]. However, it seems wise to advise calcium oxalate stone formers to avoid excessive intake.

Animal protein: Animal protein should not be consumed in excess [577, 578] and limited to 0.8-1.0 g/kg body weight. Excessive consumption of animal protein has several effects that favour stone formation, including hypocitraturia, low urine pH, hyperoxaluria, and hyperuricosuria.

Calcium intake: Calcium should not be restricted, unless there are strong reasons for doing so, due to the inverse relationship between dietary calcium and stone formation [572, 579]. The daily requirement for calcium is 1,000 to 1,200 mg [23]. Calcium supplements are not recommended except in enteric hyperoxaluria when additional calcium should be taken with meals to bind intestinal oxalate [557, 575, 577, 580]. Older adults who do not have a history of renal stones but who take calcium supplements should ensure adequate fluid intake since it may prevent increases in urine calcium concentration, and thereby reduce or eliminate any increased risk of renal stones formation associated with calcium supplement use [581].

Sodium: Daily sodium (NaCl) intake should not exceed 4-5g [23]. High intake adversely affects urine composition:

- Calcium excretion is increased by reduced tubular re-absorption;
- urinary citrate is reduced due to loss of bicarbonate;
- increased risk of sodium urate crystal formation.

Calcium stone formation can be reduced by restricting sodium and animal protein [577, 578]. A positive correlation between sodium consumption and the risk of first-time stone formation has been confirmed only in women [579]. There have been no prospective clinical trials on the role of sodium restriction as an independent variable in reducing the risk of stone formation.

Urate: Intake of purine-rich food should be restricted in patients with hyperuricosuric calcium oxalate [582, 583] and uric acid stones. Intake should not exceed 500 mg/day [23].

*4.2.2 **Lifestyle***

Lifestyle factors may influence the risk of stone formation, for example, those causing obesity [584], diabetes mellitus [585], and metabolic syndrome [586].

*4.2.3 **Summary of evidence and recommendation for recurrence prevention***

Summary of evidence	**LE**
Increasing water intake reduces the risk of stone recurrence.	1a

Recommendation	**Strength rating**
Advise patients that a generous intake of fluids, preferably water, is to be maintained, allowing for a 24-hour urine volume > 2.5 L.	Strong

4.3 Stone-specific metabolic evaluation and pharmacological recurrence prevention

4.3.1 Introduction

Pharmacological treatment is necessary in patients at high risk for stone formation or for associated systemic conditions. The ideal drug should halt stone formation, have no side effects, and be easy to administer. Each of these aspects is important to achieve good compliance. Table 4.6 highlights the most important characteristics of commonly used medication.

Table 4.6: Pharmacological substances used for stone prevention - characteristics, specifics, and dosage.

Agent	Rationale	Dose	Specifics and side effects	Stone type	Ref
Alkaline citrates	Alkalinisation Hypocitraturia Inhibition of calcium oxalate crystallisation	3.25-9.75 g/d (10-30 mmol/d) Children: 0.1-0.15 g/kg/d	Daily dose for alkalinisation depends on urine pH.	Calcium oxalate Uric acid Cystine	[587-592]
Allopurinol	Hyperuricosuria Hyperuricaemia	100-300 mg/d Children: 1-3 mg/kg/d	100 mg in isolated hyperuricosuria. Renal insufficiency demands dose correction. Contraindicated in acute gout pregnancy, and breastfeeding. Allergies from trivial to very severe forms, xanthine stone formation.	Calcium oxalate Uric acid Ammonium urate 2,8-Dihydroxyadenine	[557, 593-596]
Calcium	Enteric hyperoxaluria	Up to 2,000 mg/d depending on oxalate excretion	Intake 30 min before meals.	Calcium oxalate	[577, 579, 580, 597]
Captopril	Cystinuria Active decrease of urinary cystine levels	75-150 mg	Second-line option in case of significant side effects of tiopronin.	Cystine	[598, 599]
Febuxostat	Hyperuricosuria Hyperuricaemia	80-120 mg/d	Contraindicated in acute gout, pregnancy and breastfeeding. Xanthine stone formation.	Calcium oxalate Uric acid	[600, 601]
L-Methionine	Acidification	600-1,500 mg/d	Hypercalciuria, bone demineralisation, systemic acidosis. No long-term therapy.	Infection stones Ammonium urate Calcium phosphate	[587, 602]
Magnesium	Isolated Hypomagnesuria Enteric hyperoxaluria	200-400 mg/d Children: 6 mg/kg/d	Renal insufficiency demands dose correction. Diarrhoea, chronic alkali losses, hypocitraturia.	Calcium oxalate	[603, 604] (Low level of evidence)
Sodium bicarbonate	Alkalinisation Hypocitraturia	4.5 g/d	Daily dose for alkalinisation depends on urine pH	Calcium oxalate Uric acid, Cystine	[605]

Pyridoxine	Primary hyperoxaluria	Initial dose 5 mg/kg/d Max. 20 mg/kg/d	Sensory peripheral neuropathy	Calcium oxalate	[606]
Thiazide (Hydro-chlorothiazide*)	Hypercalciuria	25-50 mg/d Children: 0.5-1 mg/kg/d	Risk for hypotension diabetes, hyperuricaemia, hypokalaemia, hypocitraturia.	Calcium oxalate Calcium phosphate	[583, 587-596, 598-616]
Tiopronin	Cystinuria Increase in solubility of levels	Initial dose 800 mg/d Avg. 2,000 mg/d** Children: Initial dose in patients > 20kg is 15 mg/kg/day. Avoid dosages > 50mg/kg/day	Risk for proteinuria.	Cystine	[617-620]

** Patients on hydrochlorothiazide should be advised to get their skin checked on a regular basis as they have a higher risk of developing a non-melanoma skin cancer (NMSC) and some forms of melanoma. In patients with a history of skin cancer, the indication for treatment with hydrochlorothiazide should be thoroughly reviewed [621-623].*

*** No information is available on maximum dose and patients may be initiated on a very low dose if they have previously had reactions to tiopronin or penicillamine. For all patients, dosage should be titrated according to the frequency of stone episodes, side effects, and renal function under expert supervision with close monitoring.*

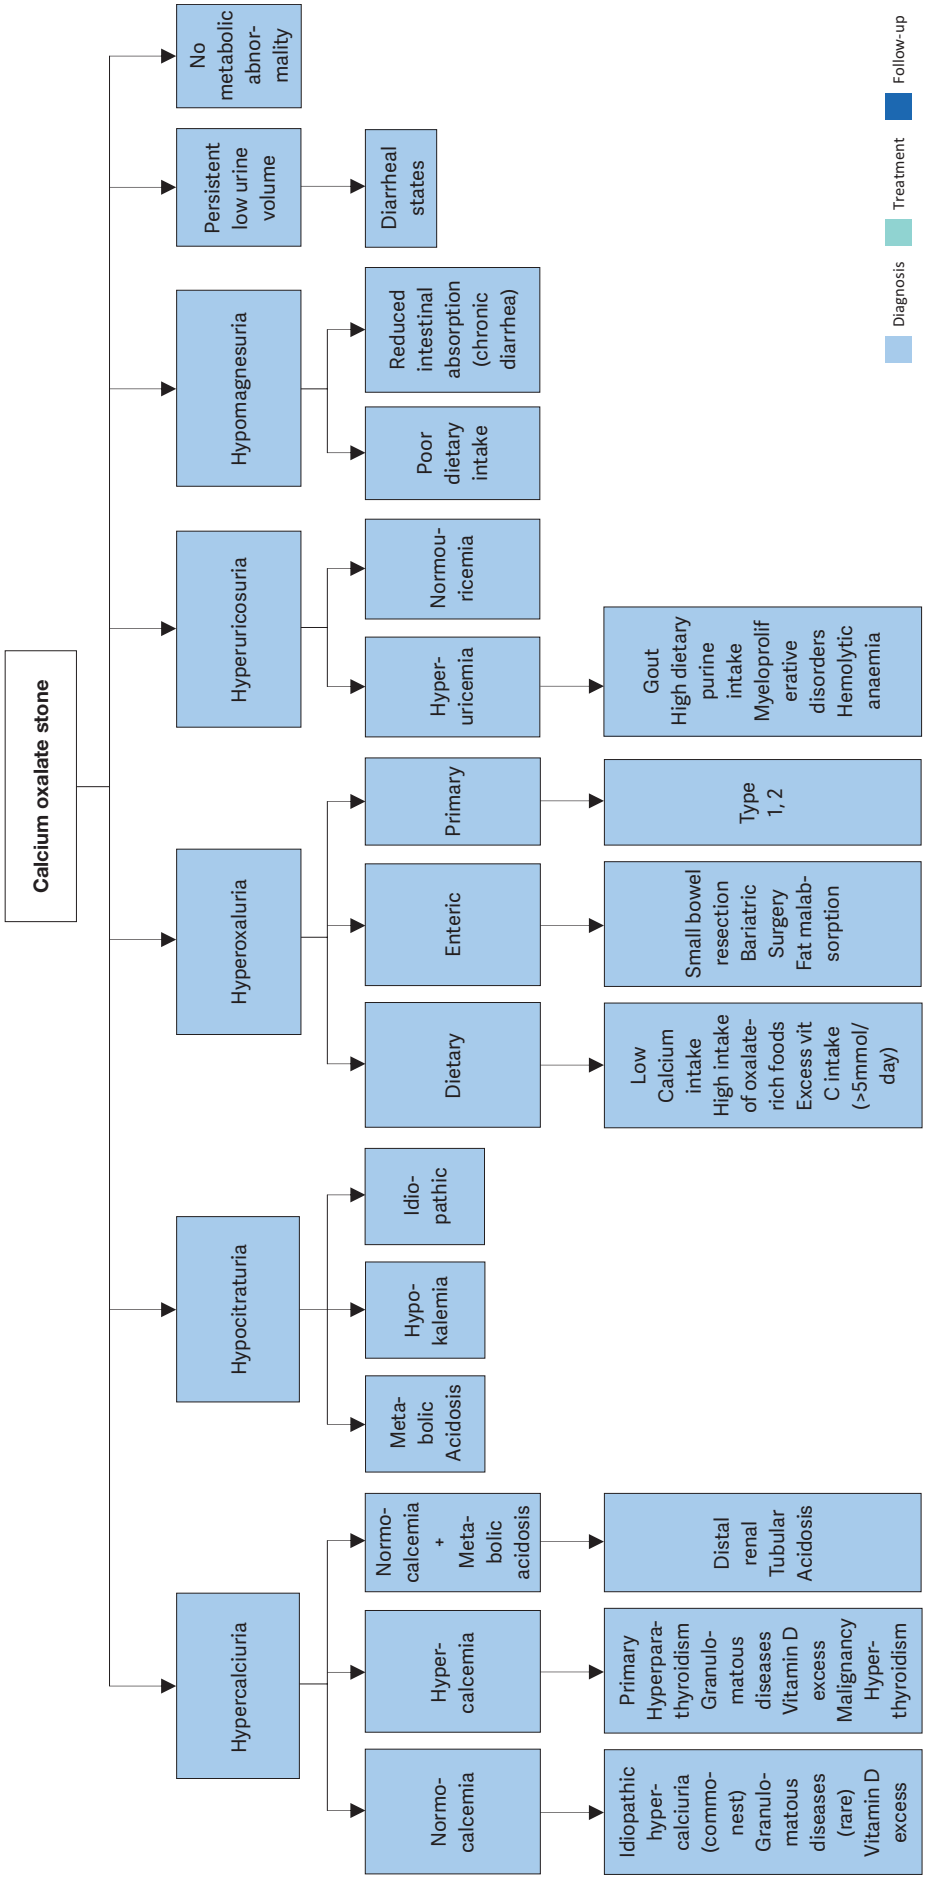
4.4 Calcium oxalate stones

The criteria for identification of calcium oxalate stone formers with a high risk of recurrences and comorbidities are listed in section 3.1.3.

*4.4.1 **Diagnosis***

Blood analysis requires measurement of creatinine, sodium, potassium, chloride, ionised calcium (or total calcium + albumin), phosphate, uric acid; and, in the case of increased calcium levels, parathyroid hormone (PTH) and vitamin D. Urinalysis requires measurement of urine volume, urine pH, specific weight, calcium, oxalate, uric acid, citrate, sodium, and magnesium. Figure 4.2 summarises the diagnostic steps for calcium oxalate stones.

Figure 4.2 Diagnostic algorithm for Calcium Oxalate stones

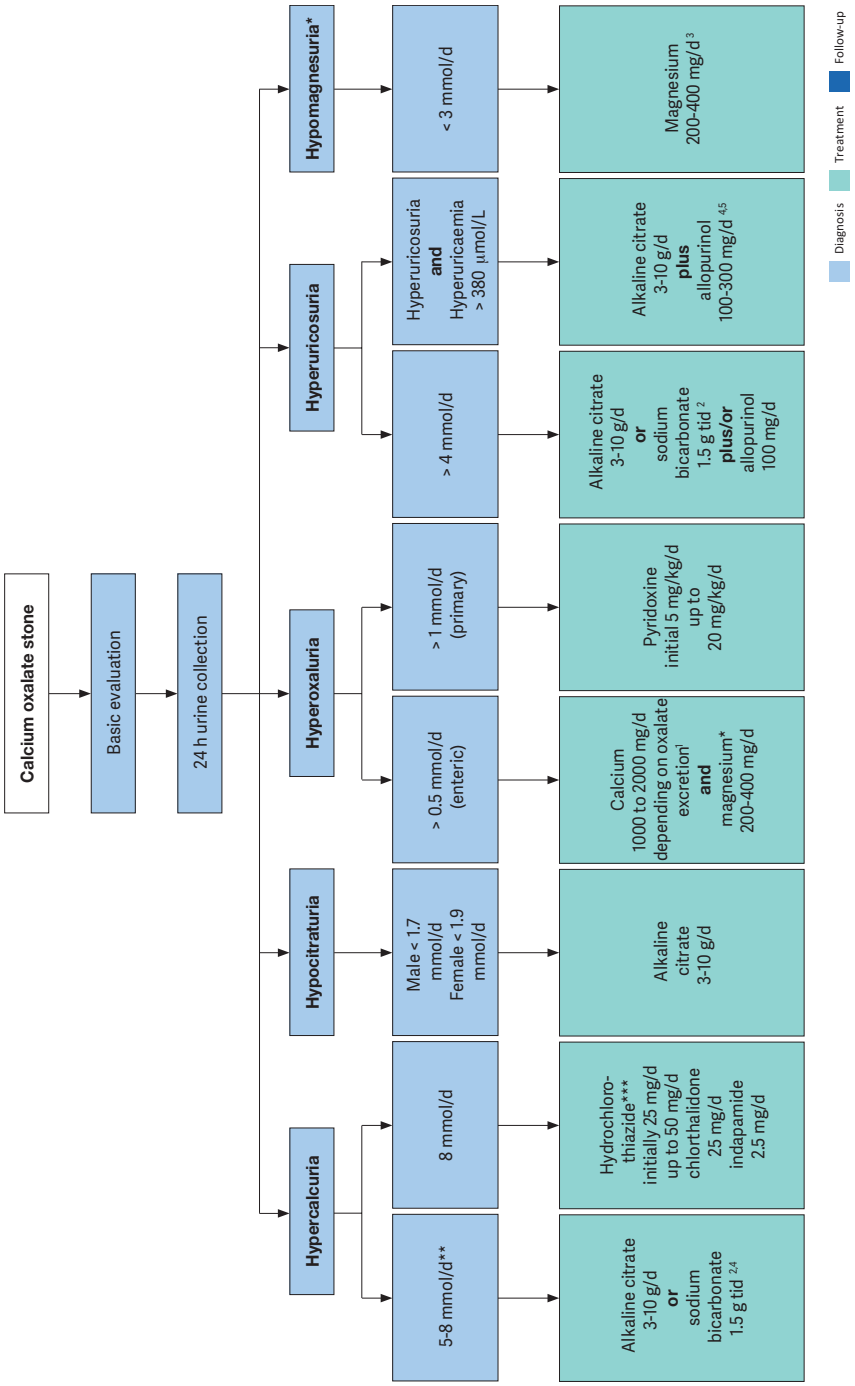


*4.4.2 **Interpretation of results and aetiology***

The most common metabolic abnormalities associated with calcium stone formation are hypercalciuria, which affects 30-60% of adult stone formers, and hyperoxaluria (26-67%), followed by hyperuricosuria (15-46%), hypomagnesuria (7-23%), and hypocitraturia (5-29%). However, ranges tend to differ based on ethnicity [624].

- Elevated levels of ionised calcium in serum (or total calcium and albumin) require assessment of intact PTH to confirm or exclude suspected hyperparathyroidism (HPT).
- Consistently low pH (< 5.5) or 24-hour urine pH < 5.5 may promote co-crystallisation of uric acid and calcium oxalate.
- Similarly, increased uric acid excretion (> 4 mmol/day in adults or > 12 mg/kg/day in children) can act as a promoter.
- A pH > 6.2 in a 24-hour urine collection may indicate RTA provided UTI has been excluded. An ammonium chloride loading test confirms distal RTA (Section 4.6.5).
- Hypercalciuria may be associated with normocalcemia (idiopathic hypercalciuria, or granulomatous diseases) or hypercalcemia (hyperparathyroidism, granulomatous diseases, vitamin D excess, or malignancy).
- Hypocitraturia (male < 1.7 mmol/d, female < 1.9 mmol/d) may be idiopathic or secondary to metabolic acidosis or hypokalaemia.
- Oxalate excretion > 0.5 mmol/day in adults confirms hyperoxaluria (see Table 4.3 for the values in children).
    - primary hyperoxaluria (oxalate excretion mostly > 1 mmol/day), appears in three genetically determined forms;
    - secondary hyperoxaluria (oxalate excretion > 0.5 mmol/day, usually < 1 mmol/day), occurs due to intestinal hyperabsorption of oxalate or extreme dietary oxalate intake;
    - mild hyperoxaluria (oxalate excretion 0.45-0.85 mmol/day), commonly found in idiopathic calcium oxalate stone formers.
- Hypomagnesuria (< 3.0 mmol/day) may be related to poor dietary intake or to reduced intestinal absorption (chronic diarrhoea).

Figure 4.3: Therapeutic algorithm for calcium oxalate stones



1 *Be aware of excess calcium excretion.*

2 *tid = three times/day (24h).*

3 *No magnesium therapy for patients with renal insufficiency.*

4 *There is no evidence that combination therapy (thiazide + citrate) or (thiazide + allopurinol) is superior to thiazide therapy alone [588, 625].*

5 *Febuxostat 80 mg/d.*

* *Low evidence (see text)*

** *Calciuria is a continuous variable and treatment may be adjusted to clinical need even when below the threshold indicated.*

*** *Patients on hydrochlorothiazide should be advised to get their skin checked on a regular basis as they have a higher risk of developing NMSC and some forms of melanoma. In patients with a history of skin cancer, the indication for treatment with hydrochlorothiazide should be thoroughly reviewed [621-623].*

4.4.3 Specific treatment

General preventive measures are recommended for fluid intake and diet. Hyperoxaluric stone formers should consume foods with low oxalate content, whereas hyperuricosuric stone formers benefit from daily dietary reduction of purine. Figure 4.3 summarises the pharmacological treatment of calcium oxalate stones [557, 564, 587-590, 593, 594, 596, 600, 603-605, 609-616, 624, 626-629]. There is only low-level evidence for the efficacy of preventing stone recurrence based on pre-treatment stone composition examination and biochemistry measures, or on-treatment biochemistry measures [557]. One RCT concluded that treatment with hydrochlorothiazide (HCTZ) does not differ substantially from placebo in the prevention of stone recurrence of kidney stones in patients at high risk for recurrence [630]. However, the study was not powered to show any difference of HCTZ over placebo [631]. In fact, the study's main objective based on the author's protocol [631], was to investigate the existence of a dose-response relationship, i.e., a linear trend for three different doses of HCTZ (12.5, 25 mg, and 50 mg/day) on stone recurrence, and this was shown. In addition, the hypercalciuria levels in the population enrolled in the study were significantly lower than the threshold the EAU guidelines recommend being administered to patients (Figure 4.3).

4.4.4 Summary of evidence and recommendations for pharmacological treatments for patients with specific abnormalities in urine composition (based on 24-hour urine samples)

Summary of evidence	LE
Alkaline citrates can reduce stone formation.	1a
Thiazides reduces calciuria.	1a
Oxalate restriction is beneficial if hyperoxaluria is present.	2b
Alkaline citrates can reduce stone formation in enteric hyperoxaluria.	4
Calcium supplement can reduce stone formation in enteric hyperoxaluria.	2
A diet reduced in fat and oxalate can be beneficial in reducing stone formation.	3
Alkaline citrates and sodium bicarbonate can be used if hypocitraturia is present.	1b
Allopurinol is first-line treatment of hyperuricosuria.	1a
Febuxostat is second-line treatment of hyperuricosuria.	1b
Avoid excessive intake of animal protein in hyperuricosuria.	1b
Restricted intake of salt is beneficial if there is high urinary sodium excretion.	1b

Recommendations	Strength rating
Prescribe thiazide or alkaline citrates or both in case of hypercalciuria*.	Strong
Advise oxalate restriction if hyperoxaluria is present.	Weak
Offer alkaline citrates in enteric hyperoxaluria.	Weak
Offer calcium supplement in enteric hyperoxaluria.	Strong
Advise reduced dietary fat and oxalate in enteric hyperoxaluria.	Weak
Prescribe alkaline citrates or sodium bicarbonate in case of hypocitraturia.	Strong
Prescribe allopurinol in case of hyperuricosuria.	Strong
Offer febuxostat as second-line treatment of hyperuricosuria.	Strong
Avoid excessive intake of animal protein in hyperuricosuria.	Strong
Advise restricted intake of salt if there is high urinary sodium excretion.	Strong

** Patients on hydrochlorothiazide should be advised to get their skin checked on a regular basis as they have a higher risk of developing an NMSC and some forms of melanoma. In patients with a history of skin cancer, the indication for treatment with hydrochlorothiazide should be thoroughly reviewed [621-623].*

4.5 Calcium phosphate stones [557, 587, 596, 609, 610, 614, 632]

Some calcium phosphate stone formers are at high risk of recurrence. Further information on identifying high-risk patients is provided in section 3.1.3.

Calcium phosphate mainly appears in two completely different minerals: carbonate apatite and brushite. Carbonate apatite crystallisation occurs at a pH > 6.8 and may be associated with infection. Brushite crystallises at an optimum pH of 6.5-6.8 at high urinary concentrations of calcium (> 8 mmol/day) and phosphate (> 35 mmol/day). Its occurrence is not related to UTI. Possible causes of calcium phosphate stones include HPT, RTA, and UTI; each of which requires different therapy.

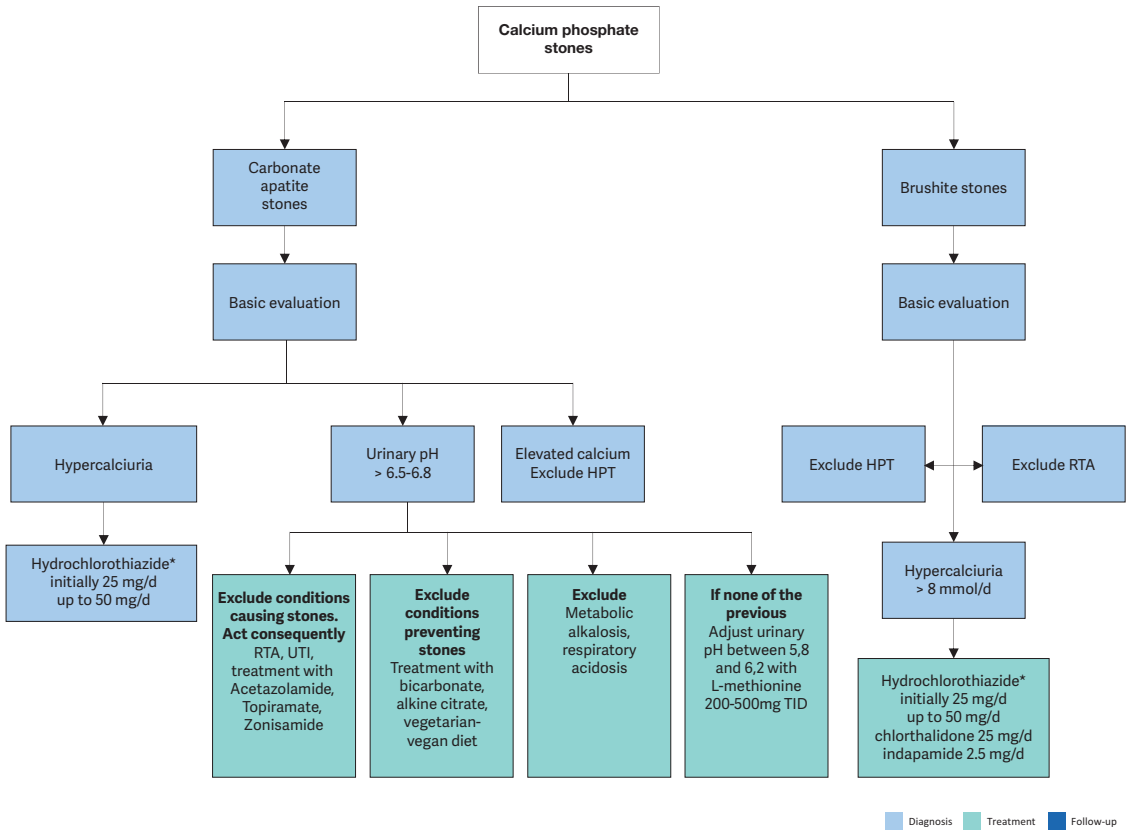
*4.5.1 **Diagnosis***

Diagnosis requires blood analysis for creatinine, sodium, potassium, chloride, ionised calcium (or total calcium + albumin), phosphate, and PTH (in the case of increased calcium levels). Urinalysis includes measurement of volume, urine pH, specific weight, calcium, phosphate, and citrate.

*4.5.2 **Interpretation of results and aetiology***

General preventive measures are recommended for fluid intake and diet. The diagnostic and therapeutic algorithm for calcium phosphate stones is shown in Figure 4.4.

Figure 4.4: Diagnostic and therapeutic algorithm for calcium phosphate stones



HPT = hyperparathyroidism; RTA = renal tubular acidosis; UTI = urinary tract infection.

** Patients on hydrochlorothiazide should be advised to get their skin checked on a regular basis as they have a higher risk of developing NMSC and some forms of melanoma. In patients with a history of skin cancer, the indication for treatment with hydrochlorothiazide should be thoroughly reviewed [621-623].*

*4.5.3 **Pharmacological therapy*** [557, 587, 596, 609, 610, 614, 632]

Hyperparathyroidism and RTA are common causes of calcium phosphate stone formation. Most patients with primary HPT require surgery. Renal tubular acidosis can be corrected pharmacologically including with bicarbonate or alkaline citrate therapy. If primary HPT and RTA have been excluded, pharmacotherapy for calcium phosphate calculi depends on the effective reduction of urinary calcium levels using thiazides. For infection-associated calcium phosphate stones, it is important to consider the guidance given for infection stones.

4.5.4 Summary of evidence and recommendation for the management of calcium phosphate Stones

Summary of evidence	LE
Thiazide decreases calciuria.	1a

Recommendation	Strength rating
Prescribe thiazide in case of hypercalciuria > 8 mmol/24 hours.	Strong

4.6 Disorders and diseases related to calcium stones

*4.6.1 **Hyperparathyroidism** [633-636]*

Primary HPT is responsible for an estimated 5% of all calcium stone formation. Renal stones occur in approximately 20% of patients with primary HPT. Elevated levels of PTH significantly increase calcium turnover, leading to hypercalcemia, hypercalciuria, and bone disease. Serum calcium may be mildly elevated and serum PTH may be within the upper normal limits, therefore, repeated measurements may be needed; preferably with the patient fasting. Stones of HPT patients may contain both calcium oxalate and calcium phosphate. Nephrocalcinosis and CKD may also occur.

If HPT is suspected, neck exploration should be performed to confirm the diagnosis. If surgery is contraindicated, primary HPT can be treated with cinacalcet.

*4.6.2 **Granulomatous Diseases** [637]*

Granulomatous diseases, such as sarcoidosis, may be complicated by hypercalcemia and hypercalciuria secondary to increased calcitriol production. The latter is independent of PTH control, leading to increased calcium absorption in the gastrointestinal tract and suppression of PTH. Treatment focuses on the activity of the granulomatous diseases and may require steroids, hydroxychloroquine, or ketoconazole. Treatment should be reserved for a specialist.

*4.6.3 **Primary Hyperoxaluria** [606]*

Patients with primary hyperoxaluria (PH) should be referred to a specialised center, as successful management requires an experienced interdisciplinary team. The main therapeutic aim is to reduce endogenous oxalate production, which is increased in patients with PH. In approximately one-third of patients with PH type I, pyridoxine therapy normalises or significantly reduces urinary oxalate excretion. The goal of adequate urine dilution is achieved by adjusting fluid intake to 3.5-4.0 L/day in adults (children 1.5 L/m^2 body surface area) and following a circadian drinking regimen.

Therapeutic options for preventing calcium oxalate crystallisation include hyper-diuresis, alkaline citrates, magnesium, and Lumasiran, an RNAi agent, a new treatment for reducing the synthesis of oxalate of PH type 1 [638].

Treatment regimens are:

- pyridoxine in PH type I: 5-20 mg/kg/day according to urinary oxalate excretion and patient tolerance;
- alkaline citrate: 3.25-9.75 g/day in adults, 0.1-0.15 mq/kg/day in children;
- magnesium: 200-400 mg/day (no magnesium in the case of renal insufficiency).
- Lumasiran: Subcutaneous injection with dose and timing adjusted according to body weight and duration of treatment:
    - Initial Dose: Bodyweight < 10 kg: 6 mg/kg; Bodyweight 10-20 kg: 6 mg/kg; Bodyweight > 20 kg: 3 mg/kg; once per month for three months subcutaneous injection.
    - Maintenance starting one month after initial doses: Bodyweight < 10 kg: 3 mg/kg 1-mal monthly; Bodyweight 10-20 kg: 6 mg/kg every three months, Bodyweight > 20 kg: 3 mg/kg [639]

4.6.3.1 Summary of evidence and recommendation for the management of primary hyperoxaluria

Summary of evidence	LE
Pyridoxine can reduce the urinary oxalate excretion in primary hyperoxaluria type 1.	3
Lumasiran can reduce the urinary oxalate excretion in primary hyperoxaluria type 1.	1b

Recommendation	Strength rating
Prescribe pyridoxine for primary hyperoxaluria type 1.	Strong
Prescribe Lumasiran for primary hyperoxaluria type 1 if not responsive to pyridoxine.	Strong

*4.6.4 **Enteric hyperoxaluria** [575, 580, 640-642]*

Enteric hyperoxaluria is a particularly problematic condition in patients with intestinal malabsorption of fat. This abnormality is associated with a high risk of stone formation and is seen after intestinal resection and malabsorptive bariatric surgery, as well as in Crohn's disease and pancreas insufficiency. In addition to hyperoxaluria, these patients usually present with hypocitraturia due to loss of alkali. Urine pH is usually low, as are urinary calcium and urine volume. All these abnormalities contribute to high levels of supersaturation with calcium oxalate, crystalluria, stone formation, and less frequently to nephrocalcinosis and CKD. Specific preventive measures are:

- restricted intake of oxalate-rich foods [575];
- restricted fat intake [575];
- calcium supplementation at mealtimes to enable calcium oxalate complex formation in the intestine [580, 640-642];
- sufficient fluid intake to balance the intestinal loss of water caused by diarrhoea;
- alkaline citrates to raise urinary pH and citrate.

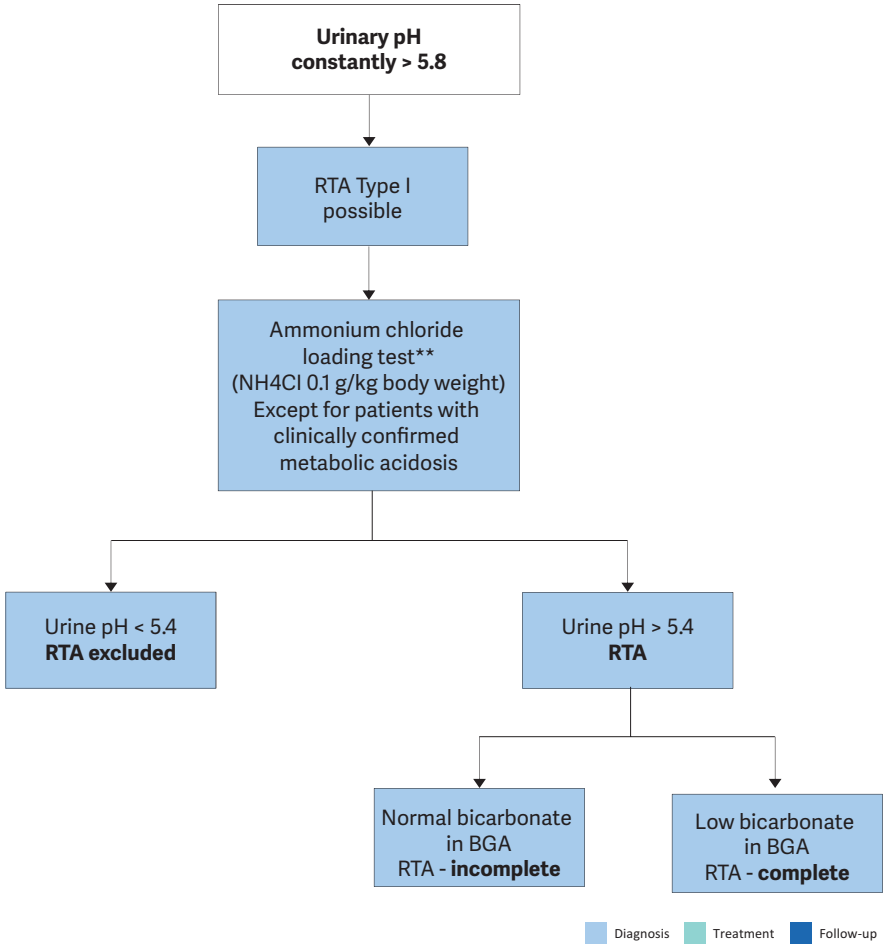
Summary of evidence	LE
Alkaline citrates can be beneficial to replace citrate loss and raise urine pH.	3
Calcium supplements with meals enable calcium oxalate complex formation in the intestine.	2b
Reduction in dietary fat and oxalate can be beneficial in intestinal malabsorption.	3

Recommendations	Strength rating
Prescribe alkaline citrates for enteric hyperoxaluria.	Weak
Advise patients to take calcium supplements with meals.	Strong
Advise patients to follow a diet with a low fat and oxalate content.	Weak

*4.6.5 **Renal tubular acidosis** [557, 596, 643, 644]*

Renal tubular acidosis is caused by severe impairment of proton (type I) or bicarbonate handling (type II) along the nephron. Kidney stone formation occurs in patients with distal RTA type I. Figure 4.5 outlines the diagnosis of RTA type I. Table 4.7 shows acquired and inherited causes of RTA.

Figure 4.5: Diagnosis of renal tubular acidosis



BGA = blood gas analysis; RTA = renal tubular acidosis.
*** An alternative ammonium chloride loading test using 1-day NH4Cl load with 0.05 g/kg body weight might provide similar results and may be better tolerated by the patient [645]. A second alternative in these cases could be the furosemide/fludrocortisone acidification test [646].*

Renal tubular acidosis can be acquired or inherited. Reasons for acquired RTA can be chronic obstructive uropathy, recurrent pyelonephritis, acute tubular necrosis, renal transplantation, analgesic nephropathy, sarcoidosis, Sjögren syndrome and other autoimmune diseases, medullary sponge kidney, liver cirrhosis, sickle cell anaemia, idiopathic hypercalciuria, and primary parathyroidism; it may also be drug-induced (e.g., amphotericin B, foscarnet, lithium, zonisamide, and other carbonic anhydrase inhibitors).

Table 4.7: Inherited causes of renal tubular acidosis

Type - inheritance	Gene/gene product/function	Phenotype
Autosomal dominant	SLC4A1/AE1/Cl-bicarbonate exchanger	Hypercalciuria, hypokalaemia, rickets/osteomalacia
Autosomal recessive with hearing loss	ATP6V1B1/B1 sub-unit of vacuolar H-ATPase/proton secretion	Hypercalciuria, hypokalaemia, rickets/osteomalacia
Autosomal recessive	ATP6V0A4/A4 sub-unit of vacuolar H-ATPase/proton secretion	Hypercalciuria, hypokalaemia, rickets/osteomalacia

Very rarely biallelic causative variants in FOXI1 and WDR72 genes have also been identified. The main therapeutic aim of RTA treatment is restoring a normal acid-base equilibrium. Despite the alkaline pH of urine in RTA, alkalinisation using alkaline citrates or sodium bicarbonate is important for normalising the metabolic changes (intracellular acidosis) responsible for stone formation (Table 4.8) and bone demineralisation. The alkali load reduces tubular re-absorption of citrate, which in turn normalises citrate excretion. Therapeutic success can be monitored by venous blood gas analysis (base excess: ± 2.0 mmol/L) in complete RTA. If

excessive calcium excretion (> 8 mmol/day) persists after re-establishing acid-base equilibrium, thiazides may lower urinary calcium excretion.

Table 4.8: Pharmacological treatment of renal tubular acidosis

Biochemical risk factor	Indication for pharmacological therapy	Medication
Hypercalciuria	Calcium excretion > 8 mmol/day	Hydrochlorothiazide*, - in adults: 25 mg/day initially, up to 50 mg/day - in children: 0.5-1 mg/kg/day Alternatives in adults: Chlorthalidone 25 mg/d Indapamide 2.5 mg/d
Inadequate urine pH	Citrate excretion male < 1.7 mmol/day, female < 1.9 mmol/day	Alkaline citrate, 3.25-9.75 g/day divided in three doses *OR* Sodium bicarbonate, 1.5 g, three times daily

** Patients on hydrochlorothiazide should be advised to get their skin checked on a regular basis as they have a higher risk of developing NMSC and some forms of melanoma. In patients with a history of skin cancer, the indication treatment with hydrochlorothiazide should be thoroughly reviewed [621-623].*

4.6.5.1 Summary of evidence and recommendations for the management of tubular acidosis

Summary of evidence	LE
Alkaline citrates can be beneficial in distal renal tubular acidosis.	2b
Thiazides are beneficial for hypercalciuria.	1a

Recommendations	Strength rating
Prescribe alkaline citrates for distal renal tubular acidosis.	Strong
Address normalization of bicarbonatremia and citraturia with alkaline citrate	Strong
Prescribe thiazides for hypercalciuria.	Strong

*4.6.6 **Nephrocalcinosis** [647]*

Nephrocalcinosis (NC) refers to increased calcium crystal deposition within the renal cortex or medulla and occurs alone or in combination with renal stones. There are various metabolic causes. The main causes are HPT, primary and enteric hyperoxalurias, genetic and acquired RTA, medullary sponge kidney, vitamin D metabolic disorders, sarcoidosis, idiopathic hypercalciuria and hypocitraturia, and genetic disorders, including Dent's disease and Bartter's syndrome. The many causes of NC mean there is no single standard therapy. Therapeutic attention must focus on the underlying metabolic or genetic disease, on the frequent association with CKD while minimising the biochemical risk factors.

4.6.6.1 Diagnosis

Diagnosis requires the following blood analysis: PTH (in the case of increased calcium levels), vitamin D and metabolites, vitamin A, sodium, potassium, magnesium, chloride, and bicarbonate. Urinalysis should investigate urine pH profile at different times of the day daily urine volume, specific weight of urine, and levels of calcium, oxalate, phosphate, uric acid, magnesium, and citrate [545].

4.7 Uric acid and ammonium urate stones

All uric acid and ammonium urate stone formers are considered to be at high risk of recurrence [23]. Uric acid nephrolithiasis is responsible for approximately 10% of renal stones [648] and is associated with hyperuricosuria or low urinary pH. Hyperuricosuria may be a result of dietary excess, endogenous overproduction (enzyme defects), myeloproliferative disorders, chemotherapy drugs, gout or catabolism [542]. Low urinary pH may be caused by decreased urinary ammonium excretion (insulin resistance, gout, Autosomal dominant polycystic kidney disease [ADPKD]), increased endogenous acid production (insulin resistance, metabolic syndrome, or exercise-induced lactic acidosis), increased acid intake (high animal protein intake), or increased base loss (diarrhoea) [542].

Ammonium urate stones are extremely rare, comprising < 1% of all types of urinary stones. They are associated with UTI, malabsorption (inflammatory bowel disease and ileostomy diversion or laxative abuse), phosphate deficiency, hypokalemia, and malnutrition. Suggestions on uric acid and ammonium urate nephrolithiasis are based on level 3 and 4 evidence. Chronic kidney disease is frequently observed.

*4.7.1 **Diagnosis***

Figure 4.6 shows the diagnostic algorithm for uric acid stones and figure 4.7 shows the therapeutic algorithm for uric acid and ammonium urate stones. Blood analysis requires measurement of creatinine and uric acid levels. Urinalysis requires measurement of urine volume, urine pH, specific weight of urine, and uric acid level. Urine culture is needed in the case of ammonium urate stones.

*4.7.2 **Interpretation of results***

Uric acid and ammonium urate stones form under completely different biochemical conditions. Low urine pH promotes uric acid crystallisation.

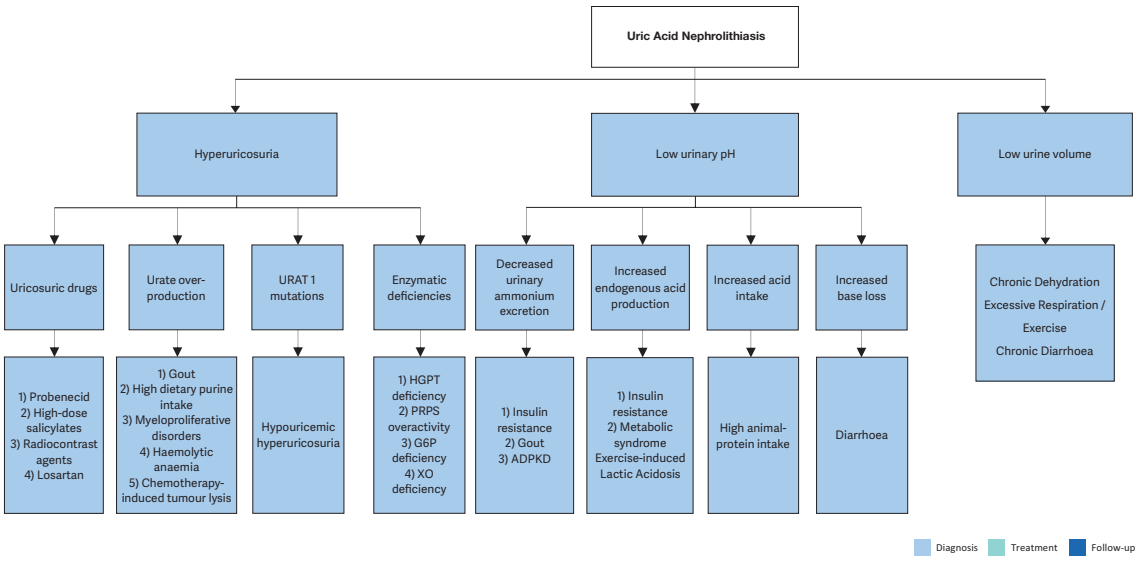
Hyperuricosuria is defined as uric acid excretion > 4 mmol/day and day and > 5 mmol/day in adult females and males, respectively, or > 0.12 mmol/kg/day in children. Hyperuricaemia may be present, but there is only weak evidence for its association with stone formation [649].

Hyperuricosuric calcium oxalate stone formation can be distinguished from uric acid stone formation by urinary pH, which is usually > 5.5 in calcium oxalate stone formation and < 5.5 in uric acid stone formation and occasional absence of hyperuricosuria in patients with pure uric acid stones [650, 651]. Ammonium urate crystals form in urine at pH > 6.5, high uric acid concentration in urine when ammonium is present [652, 653].

*4.7.3 **Specific treatment***

General preventive measures are recommended for fluid intake and diet. Hyperuricosuric stone formers benefit from purine reduction in their daily diet. Figure 4.6 describes pharmacological treatment [23, 648, 650-660]. For uric acid stones, allopurinol may change the stone composition distribution in patients with gout to a pattern similar to that in stone formers without gout [661].

Figure 4.6: Diagnostic algorithm for uric acid stones



ADPKD = autosomal dominant polycystic kidney disease; G6P = glucose-6 phosphate dehydrogenase; HGPT = hypoxanthine guanine phosphoribosyl transferase; PRPS = phosphoribosyl-pyrophosphate synthetase superactivity; XO = xanthine oxidase.

4.7.4 Summary of evidence and recommendations for the management of uric acid- and ammonium urate stones

Summary of evidence	LE
Alkaline citrates can be beneficial to alkalinise the urine in uric acid stone formers.	3
Allopurinol can be beneficial in hyperuricosuric urate stone formers.	1b

Recommendations	Strength rating
Prescribe alkaline citrates to alkalinise the urine in uric acid stone formers.	Strong
Prescribe allopurinol in hyperuricosuric urate stone formers.	Strong

4.8 Struvite and infection stones

All infection-stone formers are deemed at high risk of recurrence. Struvite stones represent 2-15% of the stones sent for analysis. Stones that contain struvite may originate *de novo* or grow on pre-existing stones, which are infected with urea-splitting bacteria [662]. There are several factors predisposing patients to struvite stone formation (Table 4.9) [663]. Several studies have reported that urinary metabolic alterations can be disclosed in 36-81% of patients with mixed struvite stones [664-669].

*4.8.1 **Diagnosis***

Blood analysis requires measurement of creatinine, and urinalysis requires repeat urine pH measurements and urine culture. In cases of mixed struvite stones, the search for metabolic abnormalities in 24-hour urine after stone removal and infection control is suggested.

*4.8.2 **Interpretation***

Infection stones contain the following minerals: struvite and/or carbonate apatite and/or ammonium urate. Urine culture typically provides evidence for urease-producing bacteria, which increase ammonia ions and develop alkaline urine (Table 4.10). Carbonate apatite starts to crystallise at a urine pH level of 6.8. Struvite only precipitates at pH > 7.2 [670, 671]. A mixed struvite stone, i.e., containing a high percentage of calcium oxalate and carbonate apatite, suggests the over-infection of a "metabolic" calcium oxalate or calcium phosphate stone [669]. Proteus mirabilis accounts for more than half of all urease positive UTIs [672, 673].

*4.8.3 **Specific treatment***

General preventive measures are recommended for fluid intake and diet. Specific measures include complete surgical stone removal [663], short- or long-term antibiotic treatment [674], and urinary acidification using methionine [602] or ammonium chloride [675]. For persistent infections/colonisation, acetohydroxamic acid may be an option [676, 677] (Figure 4.8); however, it is not licensed/available in all European countries.

Eradication of infection after complete stone removal is desirable. The evidence regarding the duration of post-operative antibiotic administration is inconclusive.

Summary of evidence	LE
Removing the stone material as completely as possible with surgery can reduce ongoing infection.	3
Antibiotics are beneficial after complete stone removal.	3
Ammonium chloride, 1 g, two or three times daily, can ensure urinary acidification to prevent recurrent infection.	3
Methionine, 200-500 mg, one to three times daily, can be used as an alternative to ammonium chloride, to ensure urinary acidification.	3
Treatment of underlying metabolic abnormalities reduces recurrence of mixed struvite stones.	3
Urease inhibitors in case of severe infection are occasionally used (if licensed).	1b

Recommendations	Strength rating
Surgically remove the stone material as completely as possible.	Strong
Prescribe antibiotics in case of persistent bacteriuria.	Strong
Prescribe ammonium chloride, 1 g, two or three times daily to ensure urinary acidification.	Weak
Prescribe methionine, 200-500 mg, one to three times daily, as an alternative, to ensure urinary acidification.	Weak

4.9 Cystine stones

Cystine stones account for 1-2% of all urinary stones in adults and 6-8% of the stones reported in paediatric studies [678, 679]. All cystine stone formers are deemed at high risk of recurrence and CKD [680, 681].

*4.9.1 **Diagnosis***

Blood analysis includes measurement of creatinine, and urinalysis includes measurement of urine volume, pH profile, specific weight, and cystine. Since the disease may be asymptomatic, siblings of cystinuric patients should be investigated for cystinuria [682].

Interpretation

- Cystine is poorly soluble in urine and crystallises spontaneously within the physiological urinary pH range.
- Cystine solubility depends strongly on urine pH: at pH 6.0, the limit of solubility is 1.33 mmol/L.

- Routine analysis of cystine is not suitable for therapeutic monitoring.
- Regardless of the phenotype or genotype of the cystinuric patient, the clinical manifestations are the same [683].
- There is no role for genotyping patients in the routine management of cystinuria [684, 685].
- Reductive therapy targets the disulphide binding in the cystine molecule. For therapy monitoring, it is important to differentiate between cystine, cysteine, and drug-cysteine complexes. However, available methods to monitor cystinuria treatment which may be able to differentiate between the different complexes formed by therapy are cumbersome [686, 687] non accurate, including high-performance liquid chromatography (HPLC) [63].
- Quantitative 24-hour urinary cystine excretion confirms the diagnosis in the absence of stone analysis.
- Levels above 0.125 mmol/day (30 mg/day) are considered abnormal [688, 689].

*4.9.2 **Specific treatment***

General preventative measures for fluid intake and diet are recommended. A diet low in methionine may theoretically reduce urinary excretion of cystine; however, patients are unlikely to comply sufficiently with such a diet. A restricted intake of sodium is more easily achieved and is more effective in reducing urinary cystine. Patients are usually advised to avoid sodium consumption > 2 g/day (5 g NaCl) [690]. A high level of diuresis is of fundamental importance, aiming for a 24-hour urine volume of > 3 L [683, 690-692]. A considerable fluid intake evenly distributed throughout the day is necessary.

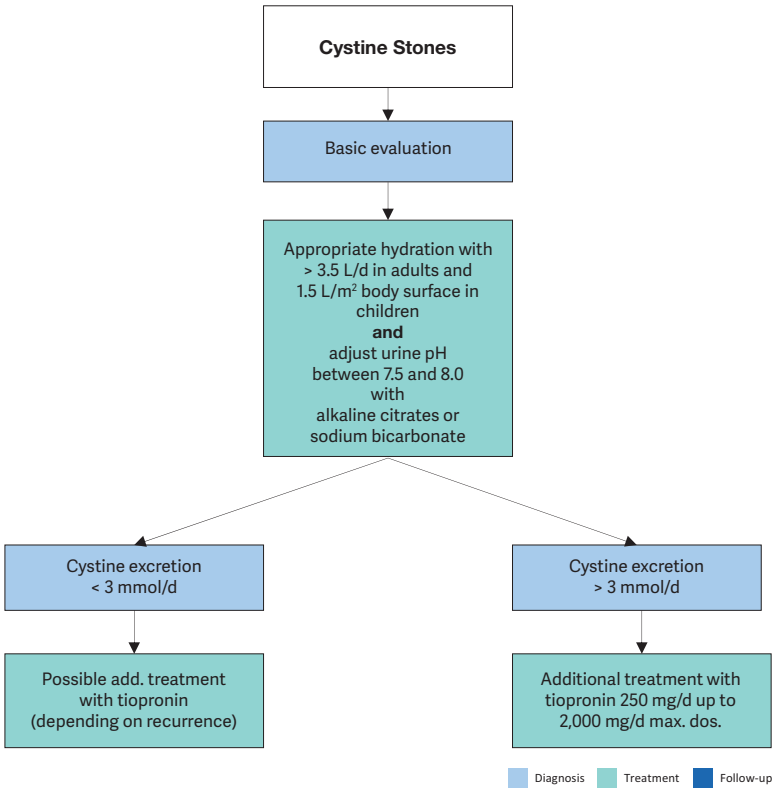
4.9.2.1 Pharmacological treatment of cystine stones

The main therapeutic option for avoiding cystine crystallisation is to maintain urine pH > 7.5, to improve cysteine solubility, and ensure appropriate hydration with a minimum of >3 L/day in adults, or 1.5 L/m2 body surface area in children [683, 690-692]. Home monitoring of the urine pH is suggested because of the possibility of self-adjusting alkaline treatment keeping the urine pH within range [63].

Free cystine concentration can be decreased by reductive substances, which act by splitting the disulphide binding of cystine.

Tiopronin is currently the best choice for cystine reduction. However, side effects often lead to treatment termination, for example when nephrotic syndrome develops or when there is poor compliance, especially with long-term use. After carefully considering the risk of early tachyphylaxis, putting into place a dose-escape phenomenon for long-term use, and recurrence risk, tiopronin is recommended at cystine levels > 3.0 mmol/day (720 mg/day) or in the case of recurring stone formation, notwithstanding other preventive measures [683, 690-692]. Spot measurement of urine protein should be performed at baseline and during follow-up.

Figure 4.9: Metabolic management of cystine stones [693]



4.9.3 Summary of evidence and recommendations for the management of cystine stones

Summary of evidence	LE
Increasing fluid intake so that 24-hour urine volume exceeds 3 L is used to dilute the cystine.	3
Alkaline citrates 3-10 mmol two or three times daily can be used to achieve pH > 7.5.	3
Tiopronin, 250-2,000 mg/day can be used to reduce stone formation in patients with cysteine excretion, > 3 mmol/day, or when other measures are insufficient.	3

Recommendations	Strength rating
Therapeutic measures	
Urine dilution Advise patients to increase their fluid intake so that 24-hour urine volume exceeds 3 L.	Strong
Alkalinisation Prescribe potassium citrate 3-10 mmol two or three times daily, to achieve pH > 7.5	Strong
Complex formation with cystine For patients with cystine excretion, > 3 mmol/day, or when other measures are insufficient: prescribe in addition to other measures tiopronin, 250-2,000 mg/day.	Strong

4.10 2,8-Dihydroxyandenine stones and xanthine stones

All 2,8-Dihydroxyadenine and xanthine stone formers are at high risk of recurrence. Both stone types are rare. Diagnosis and specific prevention are similar to those for uric acid stones [23].

4.10.1 2,8-Dihydroxyadenine stones

A genetically determined defect of adenine phosphoribosyl transferase causes high urinary excretion of poorly soluble 2,8-Dihydroxyadenine [694]. High-dose allopurinol or febuxostat are important options but should be given with regular monitoring [695].

4.10.2 Xanthine stones

Patients who form xanthine stones usually show decreased levels of serum uric acid. There is no available pharmacological intervention.

4.10.3 Fluid intake and diet

Recommendations for general preventive measures apply. Pharmacological intervention is difficult; therefore, high fluid intake ensures optimal specific weight levels of urine < 1.010 (urine specific gravity). A purine-reduced diet decreases the risk of spontaneous crystallisation in urine.

4.11 Drug-induced stones

Drug stones are induced by pharmacological treatment [587, 696] (Table 4.11). Two types exist:

- stones formed by crystallised compounds of the drug;
- stones formed due to unfavourable changes in urine composition under drug therapy.

Table 4.11: Compounds that cause drug stones.

Active compounds crystallising in urine	Substances impairing urine composition
• Allopurinol/oxypurinol • Amoxicillin/ampicillin • Ceftriaxone • Quinolones • Ephedrine • Indinavir and other HIV-protease inhibitors • Magnesium trisilicate • Sulphonamides • Triamterene	• Acetazolamide • Aluminium magnesium hydroxide • Ascorbic acid • Calcium • Laxatives • Losartan • Methoxyflurane • Orlistat • Vitamin D • Topiramate • Zonisamide

4.12 Matrix Stones

Pure matrix stones are extremely rare with less than 70 cases described in the literature. They are more prevalent in females. The main risk factors are recurrent UTIs, especially due to *P. mirabilis* or *E. coli*, previous surgery for stone disease, chronic renal failure, and haemodialysis. Complete endourological removal, frequently via the percutaneous approach, is critical. Given the rarity of matrix calculi a specific prophylactic regimen to minimise recurrence cannot be recommended. Eliminating infections and prophylactic use of antibiotics are most commonly proposed [697].

4.13 Unknown stone composition [16]

An accurate medical history is the first step towards identifying risk factors as summarised in sections 3.1.3 and 4.13.1 and Fig. 4.1.

Diagnostic imaging begins with a US examination of both kidneys to establish whether the patient is stone-free. Stone detection by the US should be followed by KUB and unenhanced multislice CT in adults to differentiate between calcium-containing and non-calcium stones.

Blood analysis may demonstrate severe metabolic and organic disorders, such as renal insufficiency, HPT or other hypercalcaemic states and hyperuricaemia. In children with GFR lower than 30 ml/min, oxalaemia should also be checked.

Urinalysis is performed routinely with a dipstick test as described above. A urine culture is required if there are signs of infection. Urine pH < 5.5 in 24-hour urine collection indicates hyper-acidic urine, which could promote uric acid crystallisation. Urine pH > 6.2 in 24-hour urine collection may indicate RTA if UTI is excluded [642, 644].

Microscopy of urinary sediment can help to discover rare stone types because crystals of 2,8-dihydroxyadenine, cystine, and xanthine are pathognomonic for the corresponding disease. In cases in which the presence of cystine is doubtful, a cyanide nitroprusside colorimetric qualitative test can be used to detect the presence of cystine in urine, with a sensitivity of 72% and specificity of 95%. False-positive results are possible in patients with Fanconi's syndrome or homocystinuria or in those taking various drugs, including ampicillin or sulfa-containing medication [698, 699].

Following this programme, the most probable stone type can be assumed, and specific patient evaluation can follow. Further metabolic investigations will depend on the presence of risk factors (see section 3.1.3) and on the results of previous investigations. However, if any expulsed stone material is available, it should be analysed for diagnostic confirmation or correction.

*4.13.1 **Recommendations for investigations for the assessment of patients with stones of unknown composition** [17, 23, 62, 587]*

Recommendations		**Strength rating**
Investigation	**Rationale for investigation**	
Take a medical history	• Stone history (former stone events, family history) • Dietary habits • Medication chart	Strong
Perform diagnostic imaging	• Ultrasound in the case of a suspected stone • Un-enhanced helical computed tomography • Determination of Hounsfield units provides information about the possible stone composition	Strong
Perform a blood analysis	• Creatinine • Calcium (ionised calcium or total calcium + albumin) • Uric acid	Strong
Perform a urinalysis	• pH measurement • Dipstick test: leukocytes, erythrocytes, nitrites • Protein, specific weight • Urine cultures • Microscopy of urinary sediment (morning urine) • Cyanide nitroprusside test (cystine exclusion) Further examinations depend on the results of the investigations listed above.	Strong

5. FOLLOW-UP OF URINARY STONES

There is no consensus in the urological literature on whether, when, how, and how often stone patients should be followed up after definitive treatment (extracorporeal shock wave lithotripsy, ureteroscopy, percutaneous nephrolithotripsy, medical chemoprophylaxis). This is mainly attributed to the high heterogeneity of stone disease among patients and to the lack of comparative studies regarding follow-up versus no follow-up.

The EAU Urolithiasis Guidelines Panel performed a systematic review questioning the benefits and harms of scheduled imaging and metabolic follow-up for patients who underwent definitive treatment for upper urinary tract stone disease [411]. Based on the results a consensus was reached regarding the frequency of the follow-up for stone-free patients (the general population and the high-risk patients), patients with residual fragments ≤ 4 mm, and patients with residual fragments > 4 mm (Figures 5.1 and 5.2).

Stone-free patients could be discharged after two years (radiopaque stones) or after three years (radiolucent stones) as 80% of them will remain stone-free thereafter. Increasing the safety margin for remaining stone-free up to 90%, the patients should be followed up to five years. Most stone-free patients in the general population remained stone-free during the first year, while < 40% of patients with metabolic abnormalities not on medication remained stone-free after three years of follow-up. Therefore, a more extensive follow-up is proposed for patients with metabolic abnormalities.

Patients with fragments ≤ 4 mm showed a spontaneous expulsion rate of 17.9-46.5% during the first year. At 49 months of follow-up disease progression rate was 9-34%, the intervention rate 17-29%, and the spontaneous passage rate 21-34%.

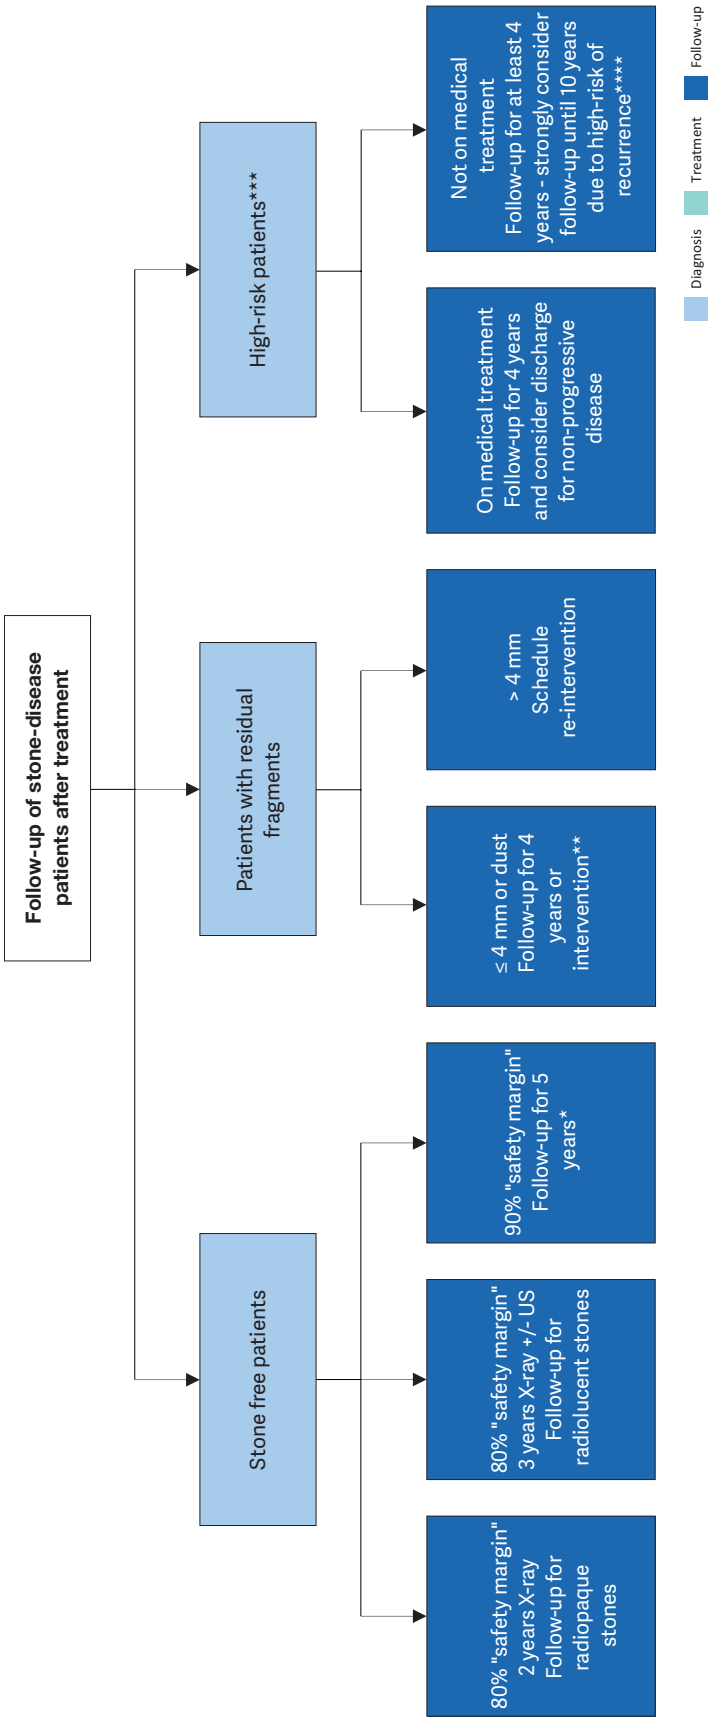
Patients with residual stone fragments > 4 mm had only 9% of spontaneous expulsion at three years. These patients should be offered further definitive treatment since intervention rates are high (24-100%). For those on follow-up close surveillance is needed.

Insufficient data exist for high-risk patients, but current literature dictates that patients who are adherent to targeted medical treatment seem to experience less stone growth or re-growth of residual fragments and may be discharged after 36-48 months of non-progressive disease on imaging (Figure 5.1).

Proposed imaging consists of plain X-ray KUB and/or US, based on stone characteristics and clinicians' preferences. Computed tomography scan should be reserved for symptomatic disease or pre-operative imaging, to avoid extensive radiation exposure [411].

The information on stone composition can be used to counsel patients to set expectations and help plan the need for follow up and medical stone management [700].

Figure 5.1: Follow-up duration of Urinary stone patients after treatment.



** Not enough data about subgroup analysis of radiolucent and radiopaque stones.*
***According to patient preference or symptomatic disease.*

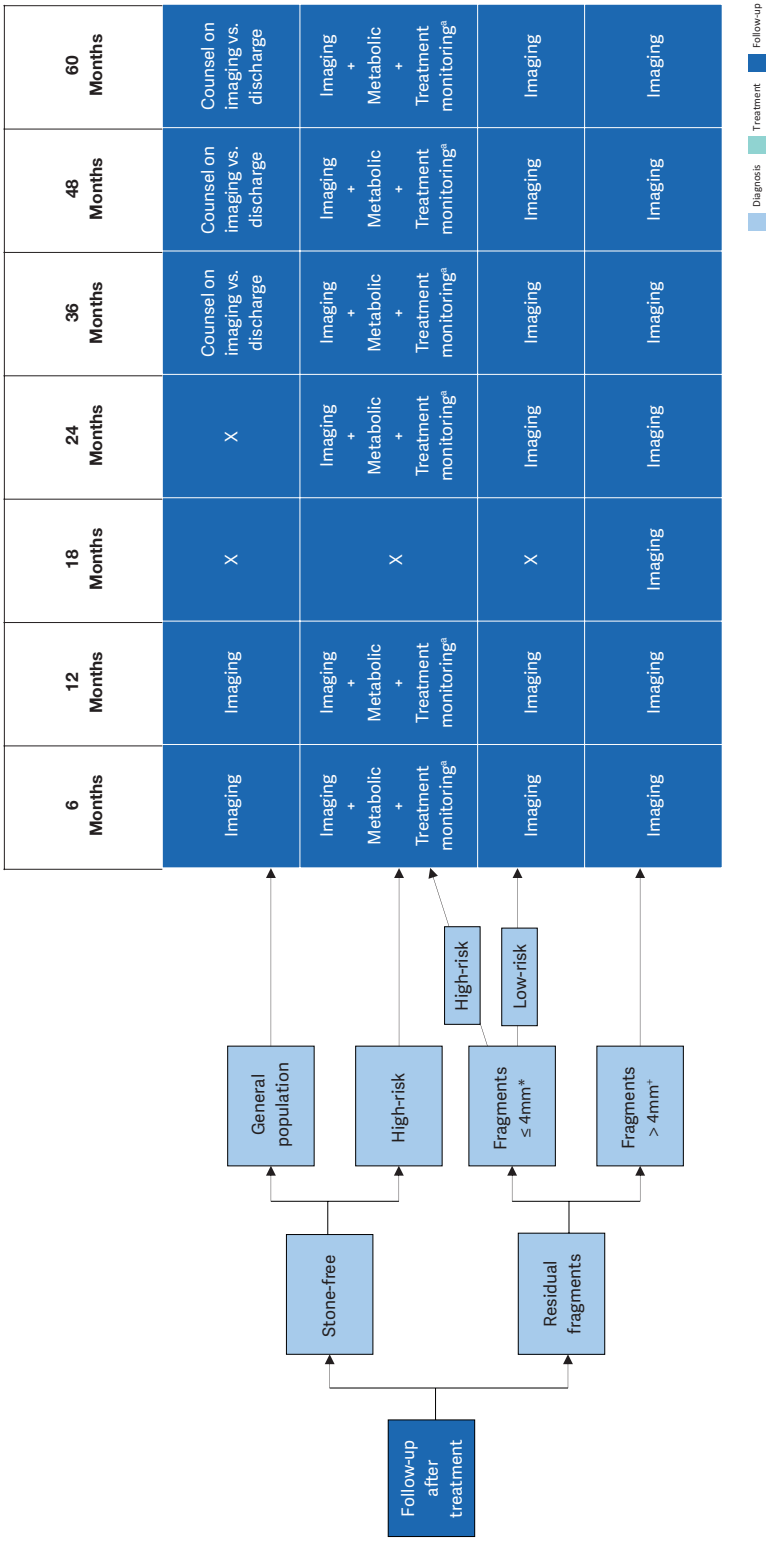
Figure 5.2: Consensus on follow-up frequency and imaging modality to use after treatment



Stone free = No stone fragments on postoperative imaging (i.e. no stone fragments on CT/KUB/US).
High-Risk = Known biochemical abnormality (i.e.: hypercalciuria, hypocitraturia, hyperuricosuria, RTA, or high-risk stone type such as struvite [See table 3.6]).
Imaging = plain film KUB &/or kidney ultrasonography (KUS) based on clinicians' preference and stone characteristics. Consider CT if the patient is symptomatic or if intervention is planned.

** Clinicians may choose the imaging-only pathway in patients with fragments ≤ 2 mm.*
a Treatment monitoring for side effects, intolerance, and compliance.
+ Panel recommends reintervention however close follow up may be considered for some patients at high risk for reintervention based on clinicians' preference.

6. BLADDER STONES

6.1 Prevalence, aetiology, and risk factors of bladder stones

Bladder stones constitute only approximately 5% of all urinary tract stones [701] yet are responsible for 8% of urolithiasis-related mortalities in developed nations [702]. The incidence is higher in developing countries [703]. The prevalence of bladder stones is higher in males, with a reported male-to-female ratio between 10:1 and 4:1 [704, 705]. The age distribution is bimodal: incidence peaks at three years in children in developing countries [704, 706], and 60 years in adulthood [705].

The aetiology of bladder stones is typically multi-factorial [705]. Bladder stones can be classified as primary, secondary, or migratory [707].

Primary or endemic bladder stones occur in the absence of other urinary tract pathology, typically seen in children in areas with poor hydration, recurrent diarrhoea, and a diet deficient in animal protein [708].

Secondary bladder stones occur in the presence of other urinary tract abnormalities, which include bladder outlet obstruction (BOO), neurogenic bladder dysfunction, chronic bacteriuria, foreign bodies (including catheters), bladder diverticula, and bladder augmentation or urinary diversion. In adults, BOO is the most common predisposing factor for bladder stone formation and accounts for 45-79% of vesical calculi [705, 709-712].

Migratory bladder stones are those that have passed from the upper urinary tract where they formed and may then serve as a nidus for bladder stone growth. Patients with bladder calculi are more likely to have a history of upper tract stones and risk factors for their formation [713].

A wide range of metabolic urinary abnormalities can pre-dispose to calculi anywhere in the urinary tract, which is covered in more detail in Section 4. Metabolic Evaluation and Recurrence Prevention. There is a paucity of studies on the specific metabolic abnormalities that predispose to bladder stones.

Bladder stones will form in 3-4.7% of men undergoing surgery for benign prostatic obstruction (BPO) [714, 715], 19-39% and 36-67% of motor-incomplete and motor-complete spinal cord injury patients, respectively [716], and 2.2% of patients with long-term catheters [717]. Two research groups have identified that a larger intravesical protrusion of the prostrate is an independent risk factor for bladder stone formation in patients with BPH undergoing TURP [718, 719]. Kim and colleagues additionally found older age and a lower Qmax to be predictive of bladder stones [718].

In men with chronic urinary retention secondary to BPO, the 24-hour urine of 27 men with bladder stones had a higher uric acid supersaturation (2.2 vs. 0.6 mmol/L, $p < 0.01$), lower magnesium (106 vs. 167 mmol/L, $p = 0.01$) and lower pH (5.9 vs. 6.4, $p = 0.02$) than the 21 men without bladder stones [713]. It is therefore likely that patients with these conditions who form bladder stones also have an abnormal urine composition which predisposes them to bladder stone formation.

The metabolic abnormalities which predispose patients to form secondary bladder stones are poorly understood. Stone analysis of 86 men with a BPO-related bladder stone demonstrated that 42% had calcium-based stones (oxalate, phosphate), 33% had magnesium ammonium phosphate, 10% had mixed stones and 14% had urate stones [705]. Similar findings were reported in more recent studies [720-722] and it is therefore likely that multiple metabolic factors predispose patients to secondary bladder stone formation.

Low urine volume (poor hydration) is the most consistently demonstrable abnormality [723-725].

As an outlet obstruction is more often absent in children than in adults, the aetiology is most likely quite different in this population. Twenty-four-hour urine analysis in children with endemic bladder stones is reported in two studies. Of 57 children in Pakistan, 89.5% had hypocitraturia, 49% had a low urine volume, 44% had hyperoxaluria and 42% had hypocalciuria [723]. Of 61 children in India, stone formers had higher urine calcium and uromucoid concentrations than controls [724]. One study from Thailand compared 24-hour urine analyses from children from a rural area with a high prevalence of bladder stones with those from an urban area: rural children had lower urine volumes and, despite equal calcium, oxalate, and uric acid concentrations, crystalluria with uric acid and calcium oxalate crystals was more prevalent in rural children [725].

Table 6.1 Bladder stones classified by aetiology.

Type of bladder stone	Primary	Secondary	Migratory
Cause/Associations	Occur in the absence of other urinary tract pathology, typically in children in areas with poor hydration, recurrent diarrhoea, and a diet deficient in animal protein	BOO (e.g., BPO, urethral stricture)	Form in the upper urinary tract, then passed into the bladder where they may be a nidus for stone growth
		Neurogenic bladder dysfunction	
		Chronic bacteriuria	
		Foreign bodies (including catheters)	
		Bladder diverticula	
		Bladder augmentation	
		Urinary diversion	

BOO = Bladder Outlet Obstruction; BPO = Benign Prostatic Obstruction.

6.2 Presentation

The symptoms are most associated with bladder stones are urinary frequency, haematuria (which is typically terminal) and dysuria or suprapubic pain, which are worst towards the end of micturition. Sudden movement and exercise may exacerbate these symptoms. Detrusor over-activity is found in over two-thirds of adult male patients with vesical calculi and is significantly more common in patients with larger stones (> 4 cm). However, recurrent UTIs may be the only symptom [710, 711].

In children, symptoms may also include pulling of the penis, difficulties in micturition, urinary retention, enuresis, and rectal prolapse (resulting from straining due to bladder spasms). Bladder stones may also be an incidental finding in 10% of cases [708, 726].

6.3 Diagnostic evaluation

6.3.1 Diagnostic investigations for bladder stones

Plain X-ray of KUB has a reported sensitivity of 21%-78% for cystoscopically detected bladder stones in adults [710, 727]. Larger (> 2.0 cm) stones are more likely to be radiopaque [727]. However, plain X-ray provides information on radio-opacity which may guide treatment and follow-up (see Section 3.2.3 X-ray characteristics, for further information).

Ultrasound has a reported sensitivity and specificity of 20-83% and 98-100%, respectively for the detection of bladder stones in adults [728, 729]. Computed tomography and cystoscopy have a higher sensitivity for detecting bladder stones than US or X-ray in adults [728, 729]. No study compares cystoscopy and CT for the diagnosis of bladder stones. Cystoscopy has the advantage of detecting other potential causes for a patient's symptoms (e.g., bladder cancer), whilst CT can also assess upper tract urolithiasis (see also section 3.2.3 X-ray characteristics) [730].

There is a paucity of evidence for the investigation of bladder stones, particularly in children [83, 731]. See also Section 3.3 Diagnostic evaluation, for further information on diagnostic imaging for urolithiasis. The principle of ALARA should be applied, especially in children [732].

6.3.2 Diagnosing the cause of bladder stones

The cause of the bladder stone should be considered prior to bladder stone treatment as eliminating the underlying cause will reduce recurrence rates [733]. The following should be performed where possible prior to (or at the time of) bladder stone treatment:

- physical examination of external genitalia, and peripheral nervous system (including digital rectal examination, peri-anal tone, and sensation in men);
- uroflowmetry and post-void residual urine assessment;
- urine dipstick to include pH ± culture;
- metabolic assessment (see also section 3.3.2.3) including: serum (creatinine, (ionised) calcium, uric acid, sodium, potassium, blood cell count);
- urine pH;
- stone analysis: in first-time formers using a valid procedure (X-ray diffraction or infrared spectroscopy).

The following investigations should also be considered for selected patients:

- upper tract imaging (in patients with a history of urolithiasis or loin pain);
- cysto-urethroscopy or urethrogram.

6.4 Disease Management

*6.4.1 **Conservative treatment and Indications for active stone removal***

Migratory bladder stones in adults may typically be left untreated, especially asymptomatic small stones. Rates of spontaneous stone passage are unknown, but data on ureteric stones suggest stones < 1 cm are likely to pass in the absence of BOO, bladder dysfunction, or long-term catheterisation (see section 3.4.9 Specific stone management of ureteral stones).

Primary and secondary bladder stones are usually symptomatic and are unlikely to pass spontaneously: active treatment of such stones is therefore indicated.

*6.4.2 **Medical management of bladder stones***

There is a paucity of evidence on chemolitholysis of bladder stones. However, guidance on the medical management of urinary tract stones in section 3.4.9 Specific stone management of ureteral stones, can be applied to urinary stones in all locations. Uric acid stones can be dissolved by oral urinary alkalinisation when a PH > 6.5 is consistently achieved, typically using alkaline citrate or sodium bicarbonate. Regular monitoring is required during therapy (see section 3.4.4 Chemolysis). Irrigation chemolysis is also possible using a catheter; however, this is time-consuming may cause chemical cystitis and is therefore not commonly employed [734, 735].

*6.4.3 **Bladder stone interventions***

Minimally invasive techniques for the removal of bladder stones have been widely adopted to reduce the risk of complications and shorten hospital stay and convalescence. Bladder stones can be treated with open, laparoscopic, robotic-assisted laparoscopic, endoscopic (transurethral or percutaneous) surgery or ESWL [736].

6.4.3.1 Suprapubic cystolithotomy

Open suprapubic cystolithotomy is very effective but is associated with a need for catheterisation and longer hospital stay in both adults and children compared to all other stone removal modalities [736]. In children, a non-randomised study found that, if the bladder was closed meticulously in two layers, “tubeless” (drain-less and catheter-less) cystolithotomy was associated with a significantly shorter length of hospital stay compared with traditional cystolithotomy, without significant differences regarding late or intra-operative complications provided that children with prior UTI, recurrent stones, or with previous surgery for anorectal malformation (or other relevant surgery) were excluded [737].

6.4.3.2 Transurethral cystolithotripsy

In both adults and children, transurethral cystolithotripsy provides high SFRs and appears to be safe, with a very low risk of unplanned procedures and major post-operative and late complications [736].

6.4.3.2.1 Transurethral cystolithotripsy in adults

In adults, a meta-analysis of four RCTs including 409 patients demonstrated that transurethral cystolithotripsy has a shorter hospital stay and convalescence with less pain, but equivalent SFR and complications compared to percutaneous cystolithotripsy [736]. Transurethral cystolithotripsy with a nephroscope was quicker than percutaneous cystolithotripsy in three RCTs, although transurethral cystolithotripsy with a cystoscope was slower than percutaneous cystolithotripsy [736].

Rates of urethral strictures following transurethral procedures were not robustly reported: studies report rates between 2.9% and 19.6% during a follow up period of 12 – 24 months [720, 736, 738].

One small RCT demonstrated a shorter duration of catheterisation, hospital stay and procedure with transurethral cystolithotripsy than open cystolithotomy with similar SFR [736]. Meta-analysis of five RCTs found significantly shorter procedure duration for transurethral cystolithotripsy using a nephroscope vs. cystoscope with similar SFRs, hospital stay, convalescence, pain, and complications [739]. Two retrospective studies (n=188) reported that using a resectoscope or nephroscope was associated with a shorter procedure duration ($p < 0.05$) than a cystoscope for transurethral cystolithotripsy [740, 741]. This suggests that transurethral cystolithotripsy is quicker when using a continuous flow instrument.

6.4.3.2.1.1 Lithotripsy modalities used during transurethral cystolithotripsy in adults.
When considering lithotripsy modalities for transurethral cystolithotripsy, the Panel's systematic review found very low-quality evidence from five non-randomised studies (n=385) which found no difference in SFR between modalities (mechanical, laser, pneumatic, ultrasonic, electrohydraulic lithotripsy [EHL] or washout alone) [736]. Unplanned procedures and major postoperative complications were low-rate events and were not significantly different between lithotripsy modalities, although one non-randomised study (NRS) suggested these might be higher with EHL or mechanical lithotripsy than pneumatic or ultrasonic lithotripsy [742]. All outcomes had very low-quality evidence (GRADE) [736]. High-powered lasers seem to reduce lithotripsy time. Laser lithotripsy was faster than pneumatic lithotripsy (MD 16.6 minutes; CI: 23.51-9.69, p < 0.0001) in one NRS (n=62); however, a laser was used with a resectoscope and the pneumatic device with a cystoscope [743]. The same conclusion was stated in a meta-analysis of ten RCTs with high heterogeneity and small sample sizes in some of the included RCTs [744]. Continuous vs. intermittent irrigating instruments may affect the operation time more significantly than the choice of lithotripsy device [736].

6.4.3.2.1.2 Transurethral cystolithotripsy in children
In children, three NRS suggest that transurethral cystolithotripsy has a shorter hospital stay and catheterisation time than open cystolithotomy, but similar stone-free and complication rates [745]. One small quasi-RCT found a shorter procedure time using laser vs. pneumatic lithotripsy for < 1.5 cm bladder stones with no difference in SFR or other outcomes [746]. Another RCT (n=73) found shorter procedure time using pneumatic vs. laser therapy for bladder stones ≤ 1.5 cm with similar SFRs and higher (minor) complication rates for pneumatic lithotripsy [747].

6.4.3.3 Percutaneous cystolithotripsy
6.4.3.3.1 Percutaneous cystolithotripsy in adults:
One NRS found a shorter duration of procedure and catheterisation and less blood loss for percutaneous, compared with open surgery in adult male patients with urethral strictures; all patients in both groups were rendered stone-free [722].

Meta-analysis of four RCTs comparing transurethral and percutaneous cystolithotripsy found a shorter hospital stay for transurethral cystolithotripsy over percutaneous surgery. Transurethral cystolithotripsy was quicker when using a nephroscope. There were no significant differences in SFRs, major postoperative complications, or re-treatment [736].

6.4.3.3.2 Percutaneous cystolithotripsy in children:
In children, three NRS suggest that percutaneous cystolithotripsy has a shorter hospital stay and catheterisation time, but a longer procedure duration and more peri-operative complications than open cystolithotripsy; SFRs were similar [726, 736, 745, 748].

A systematic review identified four non-randomised studies comparing percutaneous and transurethral cystolithotripsy and found similar SFRs, but that transurethral surgery offers shorter duration of catheterisation and hospital stay [726, 745] in contrast, a transurethral approach may need a longer operative time and shows a higher post-operative stricture rate [748]. One small NRS found a non-significant increased risk of unplanned procedures (within 30 days of primary procedure) and major postoperative complications for percutaneous operations compared with transurethral procedures; however, age and stone size determined which intervention children underwent and all patients were rendered stone-free [726]. One RCT compared 48 boys < 14 years undergoing transurethral lithotripsy vs. 49 boys undergoing percutaneous lithotripsy with comparable success and complication rates; however, PCCL had a shorter operative time and less need for stone disintegration [749].

6.4.3.4 Extracorporeal shock wave lithotripsy
Extracorporeal SWL is the least invasive therapeutic procedure [736].

6.4.3.4.1 Shock wave lithotripsy in adults
In adults, one RCT compared SWL with transurethral cystolithotripsy in 100 patients with ≤ 2 cm bladder stones presenting with acute urinary retention. Stone-free rate after one SWL session favoured transurethral cystolithotripsy (86% vs. 98%, p = 0.03); however, following up to three sessions of SWL, there was no significant difference in SFR (94% vs. 98%, p = 0.3) [736, 750].

Two NRS compared transurethral cystolithotripsy vs. SWL and found no significant difference in SFR (97.0% vs. 93.9%, p=0.99, 97.7% vs. 89.7% p=0.07) despite larger stones in transurethral cystolithotripsy patients (4.2 vs. 2.5 cm, p=0.014; and 3.6 vs. 2.6 cm [p value not reported]) [751, 752].

Length of hospital stay appeared to favour SWL in all three studies (0 vs. 1 day, 4.8 vs. 0 days, p=0.02, 0.8 vs. 2.4 days, respectively) [750-752]. No significant differences in major post-operative or intra-operative complications were reported in any study [750-752].

One NRS compared SWL vs. open cystolithotomy in just 43 patients. Stone sizes were not comparable (2.5 vs. 7.4 cm, p < 0.001). Stone-free rates were not significantly different (93.9% vs. 100%, p=0.50). Length of stay favored SWL. There was no significant difference in intra-operative or major post-operative complications [751].

6.4.3.4.2 Shock wave lithotripsy in children

One large NRS found lower SFR for SWL than both transurethral cystolithotripsy and open cystolithotomy, despite treating smaller stones with SWL. However, the length of hospital stays favoured SWL over open cystolithotomy, although this appeared to be comparable between SWL and transurethral cystolithotripsy [753].

6.4.3.5 Laparoscopic cystolithotomy

Laparoscopic cystolithotomy has been described in adults and is typically performed in combination with simple prostatectomy using either traditional laparoscopy or with robotic assistance [754, 755]. A SR found no studies comparing laparoscopic surgery with other procedures [736].

6.4.4 Treatment for bladder stones secondary to bladder outlet obstruction in adult men

Bladder stones in men aged over 40 years may be caused by BPO, the management of which should also be considered. Bladder stones were traditionally an indication for a surgical intervention for BPO: a doctrine that has been questioned by studies. One prospective study reports urodynamics (cystometrogram) findings in 46 men aged > 60 years before and after bladder stone treatment [711]. Only 51% of men had BOO while 10% had detrusor under-activity. Eighteen percent of men had a completely normal urodynamic study and 68% had detrusor over-activity. There was no significant difference between pre- and post-bladder stone removal urodynamic findings [711].

One NRS compared 64 men undergoing transurethral cystolithotripsy with either transurethral resection of the prostate (TURP) or medical management for BPO (α-blocker with or without 5-alpha reductase inhibitor). After 28 months of follow-up, no men on medication had had a recurrence, but 34% underwent TURP: a high post-void residual urine volume predicted the need for subsequent TURP [756]. Another observational study of 23 men undergoing cystolithotripsy and commencing medical management for BPO found 22% developed a BPO-related complication, including 17% who had recurrent stones [733]. One RCT comparing cystolithotripsy with concomitant TURP to cystolithotripsy with medical management of bladder outlet obstruction with Tamsulosin and finasteride demonstrated that both groups had a significantly improved QMax, IPSS, and PVR at follow-up, although the TURP group had a longer procedure and catheterisation time [757]. Large prostates and a high PVR (> 190 ml) were predictive of needing a TURP over time in the medical management cohort, although this was based on only a small number of patients.

Large studies support the safety of performing BPO and bladder stone procedures during the same operation with no difference in major complications compared to a BPO procedure alone [758-760]. An observational study on 2,271 patients undergoing TURP found no difference in complications except UTIs, which occurred slightly more frequently in patients with simultaneously treated bladder stones: 0% vs. 0.6%, p=0.044 [758]. An observational study of 321 men undergoing Holmium laser enucleation of the prostate (HoLEP) found a higher rate of early post-operative incontinence (26.8% vs. 12.5%, p=0.03) in men having concomitant transurethral cystolithotripsy, but no difference in long-term continence rates [760]. Another larger multicenter observational study of 963 patients undergoing HoLEP found no significant differences in the frequency of complications in patients with (n=54 [5.6%]) or without concomitant transurethral cystolithotripsy [761].

6.4.5 Special situations

6.4.5.1 Neurogenic bladder and stone formation

A study of 2,825 spinal cord injury patients over eight years found a 3.3% incidence of bladder stones: 2% with CISC, 6.6% with an indwelling urethral catheter, 11% with a suprapubic catheter, and 1.1% in patients voiding using reflex micturition [766]. However, another study of 457 spinal cord injury patients for six months found no difference in bladder stones between urethral and suprapubic catheterisation [765]. Spinal cord injury patients with an indwelling urethral catheter are six times more likely to develop bladder stones than patients with normal micturition [764, 766].

The risk of stone recurrence after complete removal in spinal cord injury patients is 16% per year [765]. An RCT of 78 spinal cord injury patients who perform CISC found a significant reduction in bladder stone formation when twice weekly manual bladder irrigations were performed for six months (49% vs. 0%, p = < 0.0001), as well as less symptomatic UTIs (41% vs. 8%; p = 0.001) [767]. However, this study excluded patients who developed autonomic dysreflexia during bladder irrigations. The irrigation volume used was not reported.

6.4.5.2 Bladder Augmentation

The incidence of vesical calculus formation after bladder augmentation is 2-44% in adults [768-777], and 4-53% in children [777-791]. Following cystoplasty, stones form after 24-31 months in adults [769, 771, 776], and after 25-68 months in children [782, 785, 786, 790, 792-794]. The reported cumulative incidence of bladder stone formation after ten years is 28-36% and after twenty years is 41% [777, 795].

Risk factors for bladder stone formation after augmentation include excess mucus production, incomplete bladder emptying, non-compliance with CIC or bladder irrigations, bacteriuria or urinary tract infections (due to urease-producing bacteria), foreign bodies (including staples, mesh, non-absorbable sutures), drainage by vesico-entero-cystostomy (Mitrofanoff or Monti) [435, 769, 772, 774, 775, 782, 786, 789, 795] and voiding by CISC compared with those voiding spontaneously [773]. Gastric segment augmentation confers a lower risk of bladder stones than ileal or colonic segment cystoplasty [778, 782, 786, 789].

In previous stone formers, the rate of recurrence is 15-44% in adults [769-771, 773, 776], and 19-56% in children [435, 777, 778, 782, 784-787, 789, 794]. The risk of recurrence is greatest during the first two years, at about 12% per patient per year, with the risk decreasing with time [794].

Daily, or three-times-weekly bladder irrigations reduce the incidence of bladder stones following bladder augmentation or continent urinary diversion [435, 772]. A randomised study found that daily bladder irrigation with 240 mL of saline reduced stone recurrences (p< 0.0002, p=0.0152) and symptomatic UTIs (p < 0.0001, p < 0.0001) compared to 60mL or 120mL [772]. The frequency of bladder irrigations required is unclear.

6.4.5.3 Urinary diversion

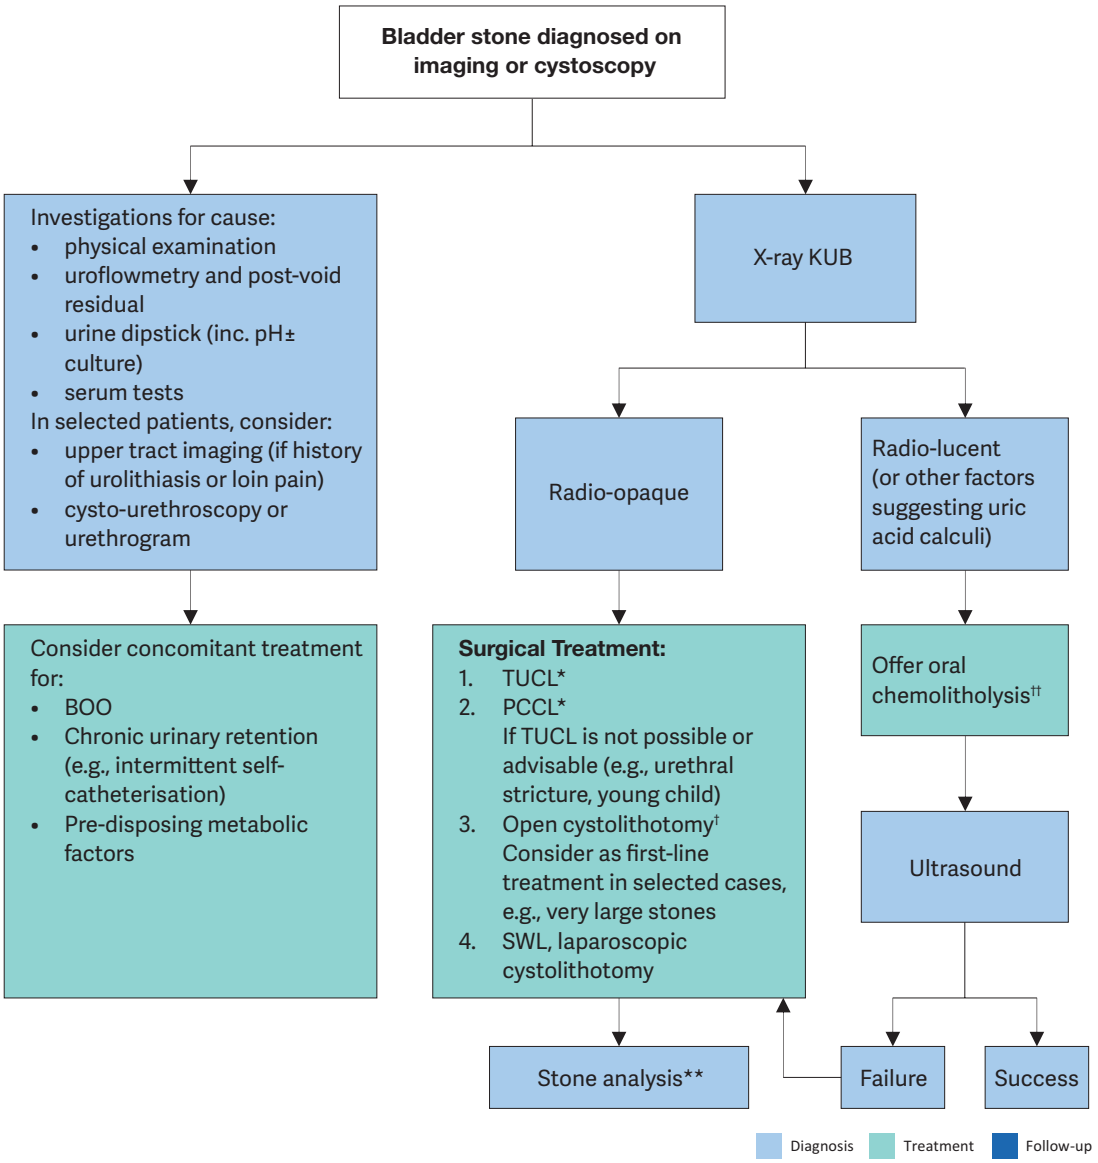
The incidence of stone formation after urinary diversion with an ileal or colon conduit is 0-3% [796, 797]. The incidence of stone formation is 0-34% in orthotopic ileal neobladders (Hautmann, hemi-Kock, Studer, T-pouch or w-neobladder) [433, 773, 797-805], and 4-6% in orthotopic sigmoid neobladders (Reddy) [802, 806]. The risk of pouch stone formation is 4-43% in adults with an ileocaecal continent cutaneous urinary diversion (Indiana, modified Indiana, Kock, or Mainz I) [425, 773, 796, 797, 805, 807]. The average interval from construction of the urinary diversion to stone detection is 71-99 months [801, 808]. In children, the incidence of neobladder stone formation is 30% after Mainz II diversion (rectosigmoid reservoir) [779], and 27% after Kock ileal reservoir construction [791].

6.4.5.4 Treatment of stones in patients with bladder augmentation or urinary diversion

Stones may be removed by open or endoscopic surgery in patients with bladder augmentation or diversion [784]. However, often access cannot be obtained through a continent vesico-entero-cystostomy without damaging the continence apparatus; hence a percutaneous or open approach is typically preferred [784].

No studies comparing outcomes following procedures for stones in reconstructed or augmented bladders were found. Two observational studies indicate that percutaneous lithotomy can be safely performed with US or CT guidance in patients with reconstructed or augmented bladders [809, 810] and is proposed to offer similar advantages over open surgery to those for percutaneous native bladder surgery. Stone recurrence after successful removal has been reported to be 10-42% [809, 810], but appears to be unrelated to the modality used for stone removal [776, 782, 786, 787, 789, 794].

Figure 6.1 Management of Bladder stones



** Lithotripsy modality at surgeon's discretion (e.g., mechanical, laser, pneumatic, ultrasonic).*
† Prefer "tubeless" procedure (without placing a catheter or drain) for children with primary bladder stones and no prior infection, surgery, or bladder dysfunction where open cystolithotomy is indicated.
*** Stone analysis should be sent for all first-time stone formers and in patients who develop a recurrence under pharmacological prevention, early recurrence after interventional therapy with complete stone clearance or late recurrence after a prolonged stone-free period (see main Urolithiasis guideline).*
†† Use an alkaline citrate or sodium bicarbonate with frequent urine pH monitoring and dose titration to achieve a consistent pH > 6.5.

BOO = Bladder Outlet Obstruction, TUCL = Trans-urethral cystolithotripsy, PCCL = Percutaneous cystolithotripsy, SWL = Shock-wave Lithotripsy.

6.5 Bladder stones follow-up

There are no studies examining the merits of differing follow-up modalities or frequencies following conservative, medical, or operative treatment of bladder stones in adults or children. Identification and prevention of the cause of bladder stone formation will be crucial to prevent recurrence (see section 6.3.2 Diagnosing the cause of bladder stones).

In adults, there is a paucity of evidence on dietary modification or medical treatment for the prevention of bladder stone recurrence. Recommendations in the EAU Guideline on Urolithiasis, based on evidence from upper tract stones, constitute the best available recommendations, especially for migratory bladder stones (see Section 4 Metabolic Evaluation and Recurrence Prevention).

Where it is possible to address the cause of secondary bladder stones (e.g., treatment of BPO), it is unclear whether metabolic intervention would offer any significant additional benefit in preventing stone recurrence. However, especially where the secondary cause cannot be addressed (e.g., indwelling catheter, neuropathic bladder, bladder augmentation, or urinary diversion); metabolic interventions are likely to reduce bladder stone recurrence rates.

Regular bladder irrigation reduces the chances of bladder stone recurrence in adults and children with bladder augmentation or continent cutaneous urinary diversion and adults with spinal cord injury who perform CISC (see section 6.4.5 Special Situations) [767, 772, 797].

In children with primary (endemic) bladder stones maintenance of hydration, avoidance of diarrhoea, and a mixed cereal diet with milk and Vitamins A and B supplements, with the addition of eggs, meat, and boiled cows' milk after one year of age are recommended to prevent a recurrence [723].

Finally, there are contradictory reports on a possible association between bladder calculi and the future development of bladder cancer [811-813]. The need for follow-up with regular cystoscopy therefore remains controversial.

6.6 Summary of evidence and recommendations for the treatment of bladder stones

Summary of evidence	LE
The incidence of bladder stones peaks at three years in children (endemic/primary stones in developing countries) and 60 years in adults.	2c
In adults, BOO is the most common pre-disposing factor for bladder stone formation.	2c
Of men undergoing surgery for BPO, 3-4.7% form bladder stones.	2b
Primary (endemic) bladder stones typically occur in children in areas with poor hydration, recurrent diarrhoea, and a diet deficient in animal protein. The following measures are proposed to reduce their incidence: maintenance of hydration, avoidance of diarrhoea, and a mixed cereal diet with milk and Vitamins A and B supplements; with the addition of eggs, meat, and boiled cows' milk after one year of age.	5
Endoscopic bladder stone treatments (trans-urethral or percutaneous) are associated with comparable SFRs, but a shorter length of hospital stay, duration of procedure and duration of catheterisation compared to open cystolithotomy in adults.	1a
Stone-free rates are lower in patients treated with SWL than those treated with open or endoscopic procedures in both adults and children.	2a
Transurethral cystolithotripsy is associated with a shorter length of hospital stay, less pain and a shorter convalescence period than percutaneous cystolithotripsy in adults.	1b
Transurethral cystolithotripsy with a nephroscope is quicker than when using a cystoscope with no difference in SFR in adults.	1a
Mechanical, pneumatic and laser appear equivalent lithotripsy modalities for use in endoscopic bladder stone treatments in adults and children.	2a
Open cystolithotomy without a retropubic drain or urethral catheter ("tubeless") is associated with a shorter length of hospital stay than traditional cystolithotomy and can be performed safely in children with primary stones and no prior bladder surgery or infections.	2b
Bladder stone removal with concomitant treatment for BOO is associated with no significant difference in major post-operative complications when compared to BOO treatment alone in adults. However, concomitant bladder stone treatment does increase the rates of short-term post-operative incontinence and UTI.	2b
The incidence of bladder stone formation in spinal cord injury patients is 19-67% over time. The absolute annual risk of stone formation in spinal cord injury patients is significantly higher with an indwelling catheter compared to those voiding with CISC or spontaneously.	2b

The incidence of bladder stone formation after bladder augmentation or vesico-entero-cystostomy is between 2-53% in adults and children.	2b
The risk of bladder stone formation in spinal cord injury, bladder augmentation or continent urinary diversion patients is reduced by performing regular bladder irrigation.	2b

Recommendations	**Strength rating**
Use ultrasound (US) as first-line imaging with symptoms suggestive of a bladder stone.	Strong
Use cystoscopy or computed tomography (CT), or kidney-ureter-bladder X-Ray (KUB) to investigate adults with persistent symptoms suggestive of a bladder stone if US is negative.	Strong
All patients with bladder stones should be examined and investigated for the cause of bladder stone formation, including: • uroflowmetry and post-void residual; • urine dipstick, pH, ± culture; • metabolic assessment and stone analysis (see sections 3.3.2.3 and 4.1 of the Urolithiasis guidelines for further details). In selected patients, consider: • upper tract imaging (in patients with a history of urolithiasis or loin pain); • cysto-urethroscopy or urethrogram.	Weak
Offer oral chemolitholysis for radiolucent or known uric acid bladder stones in adults.	Weak
Offer adults with bladder stones transurethral cystolithotripsy where possible.	Strong
Perform transurethral cystolithotripsy with a continuous flow instrument in adults (e.g., nephroscope or resectoscope) where possible.	Weak
Offer adults percutaneous cystolithotripsy where transurethral cystolithotripsy is not possible or advisable.	Strong
Suggest open cystolithotomy as an option for very large bladder stones in adults and children.	Weak
Offer children with bladder stones transurethral cystolithotripsy where possible.	Weak
Offer children percutaneous cystolithotripsy where transurethral cystolithotripsy is not possible or is associated with a high risk of urethral stricture (e.g., young children, previous urethral reconstruction, and spinal cord injury).	Weak
Open, laparoscopic, and extracorporeal shock wave lithotripsy are alternative treatments where endoscopic treatment is not advisable in adults and children.	Weak
Prefer “tubeless” procedure (without placing a catheter or drain) for children with primary bladder stones and no prior infection, surgery, or bladder dysfunction where open cystolithotomy is indicated.	Weak
Individualise imaging follow up for each patient as there is a paucity of evidence. Factors affecting follow up will include: • whether the underlying functional predisposition to stone formation can be treated (e.g., TURP); • metabolic risk.	Weak
Recommend regular irrigation therapy with saline solution to adults and children with bladder augmentation, continent cutaneous urinary reservoir or neuropathic bladder dysfunction, and no history of autonomic dysreflexia, to reduce the risk of stone recurrence.	Weak

8. CONFLICT OF INTEREST

All members of the Urolithiasis Guidelines Panel have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publicly accessible through the European Association of Urology website: http://www.uroweb.org/guidelines/. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

9. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Paris 2024. ISBN 978-94-92671-23-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, the Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aims and scope

The European Association of Urology (EAU) Urethral Strictures Guidelines aim to provide a comprehensive overview of urethral strictures in male, female, and transgender patients. The Panel is aware of the geographical variations in healthcare provision.

It must be emphasised that guidelines present the best evidence available to the experts; however, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Urethral Strictures Guidelines panel consists of an international multidisciplinary group of clinicians with particular expertise in this area. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guideline/urethral-strictures/.

1.3 Available publications

Alongside the full text version, a quick reference document (Pocket Guidelines) is available in print and as an app for iOS and Android devices. These are abridged versions which may require consultation together with the full text version. All documents can be viewed through the EAU website: http://www.uroweb.org/ guideline/urethral-strictures/. A list of supplementary tables supporting this text can also be found online, along with an appendix of abbreviations specific to this text: https://uroweb.org/guideline/urethralstrictures/?type=appendices-publications.

1.4 Publication history

This Guideline was first published in 2021. Additional information can be found in the general Methodology section of this print, and online at the EAU website: http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2. METHODOLOGY

2.1 Methods

For the 2021 Urethral Strictures Guidelines, new and relevant evidence was identified, collated, and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the Guidelines was performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between 2008 and 2019 and restricted to English language publications. The panel defined by consensus inclusion and exclusion criteria for each topic before the scope search. Detailed search strategies are available online: https://uroweb.org/guideline/urethral-strictures/.

Recommendation within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences [1, 2]. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [3];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention.

Strong recommendations typically indicate a high degree of evidence quality and/or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [4].

The Panel wants to highlight that "success" in urethral stricture treatment is poorly defined and subjective. "Success" is usually defined as urethral patency, either subjective by the absence of voiding symptoms or objective by imaging or urethral calibration. Despite urethral patency, the patient themselves might not consider the treatment as successful because of functional consequences (e.g., post-void dribbling, erectile/ejaculatory dysfunction, altered genital appearance). In this Guideline, the Panel agreed to avoid the term "success". Instead, the term "patency rate" or "stricture recurrence rate" will be used to clarify that only stricture recurrence was taken into consideration (as assessed by the authors).

The Panel would like to stress that patency after urethral surgery is dependent on the general principles of wound healing. These principles have stood the test of time and need to be respected [5]. Some examples:

- An anastomosis should be made between healthy urethral ends and without any tension.
- A graft requires a well-vascularised graft bed with a close contact between the graft and graft bed to promote imbibition and inosculation.
- If the full circumference of the urethral mucosa is destroyed, spontaneous regeneration will not take place.
- Contraction and fibrosis in a wound only stops after it is covered by its epithelium.

The Panel conducted two systematic reviews (SR) to support guideline recommendations, which were published in 2021:

- What is the role of single-stage oral mucosa graft urethroplasty in the surgical management of Lichen Sclerosus-related stricture disease in men? A systematic review [6];
- Free Graft Augmentation Urethroplasty for Bulbar Urethral Strictures: Which Technique Is Best? A Systematic Review [7].

The results of these reviews are included in the 2023 Urethral stricture guidelines.

In addition, the panel drafted three summary papers of the guidelines which were published in European Urology and European Urology Focus:

- EAU guidelines on urethral stricture disease (part 1): management of male urethral stricture disease [8];
- EAU Guidelines on urethral stricture disease (part 2): diagnosis, perioperative management, and follow-up in males [9];
- EAU guidelines on urethral stricture disease (part 3): management of strictures in females and transgender patients [10].

2.2 Review

The Urethral Strictures Guidelines were peer reviewed prior to initial publication in 2021.

3. DEFINITION, EPIDEMIOLOGY, AETIOLOGY AND PREVENTION

3.1 Definitions

In males, a urethral stricture refers to a narrowed segment of the anterior urethra due to a process of fibrosis and cicatrisation of the urethral mucosa and surrounding spongiosus tissue ("spongiofibrosis") [11, 12]. In the male posterior urethra, there is no spongiosus tissue and at this location the terms stenosis is preferred [11, 12]. The definition of meatal stenosis is generally accepted as a short distal narrowing at the meatus, without involvement of the fossa navicularis [12].

There is no universal definition for what constitutes a female urethral stricture (FUS). Female urethral stricture is defined by most authors as a 'fixed anatomical narrowing' causing reduced urethral calibre [13, 14]. This reduced urethral calibre is variously defined as between < 10 Fr to < 20 Fr [15, 16] with the majority of series defining < 14 Fr as diagnostic, compared with a 'normal' urethral calibre of 18-30 Fr.

In transgender patients, the term stricture is also used to define a narrowing of the reconstructed urethra despite the absence of surrounding spongious tissue.

3.2 Epidemiology

In males, a sharp increase in incidence is observed after the age of 55 years, with a mean age of 45.1 [17, 18]. Overall, the incidence is estimated to be 229-627 per 100,000 males [17]. The anterior urethra is most frequently affected (92.2%), in particular the bulbar urethra (46.9%) [18].

In females, 2-29% of patients presenting with refractory lower urinary tract symptoms (LUTS) have bladder outflow obstruction (BOO) [19-22] of whom 4-20% will have a urethral stricture [21-23]. True FUS therefore occurs in 0.08-5.4% of women with refractory LUTS. There is a markedly increased incidence in women over 64 years of age [24].

After hypospadias repair, meatal stenosis and urethral strictures are reported in 1.3-20% of cases, depending on the severity of the hypospadias and the technique used [25]. There is a significantly higher incidence of this type of strictures in well-resourced countries due to a higher surgical repair rate [26].

Up to 18% of all urethral strictures have been reported to involve the meatus or fossa navicularis, usually due to failed hypospadias repair (FHR), lichen sclerosus (LS), trauma/instrumentation or idiopathic causes [27-30]. Meatal stenosis post-circumcision has been reported in less than 0.2% of children undergoing circumcision as neonates [17].

In female-to-male (FtM) transgender patients ("transmen"), 2-56% will suffer a urethral stricture. Strictures almost exclusively arise at the neomeatus in male-to-female (MtF) transgender patients ("transwomen") and occur in 4-40% of cases [31].

3.3 Aetiology and prevention

Stricture aetiology differs significantly throughout different regions in the world, due to differences in healthcare quality and environmental and practice patterns [26]. Regardless of geography, urethral stricture disease adversely impacts physical health and quality of life (QoL) [32, 33], notwithstanding costs associated with the treatment of primary and recurrent disease [34, 35]. The rationale for preventing urethral strictures is to avoid morbidity to the individual and costs to society. Prevention of urethral strictures encompasses reducing the causes of stricture (e.g., infection, trauma, iatrogenic injury) and where this is not possible, mitigating the risk.

*3.3.1 **Aetiology and prevention in males***

a. Sexually transmitted infection

Urethritis due to sexually transmitted infection (STI), in particular gonorrhoea, was previously a major cause of urethral strictures in well-resourced countries accounting for 40% of all cases [36]. The wide-scale promotion of safe sexual practices and easier access to sexual health services, resulting in timely treatment with antimicrobials, is thought to have led to the considerable reduction in the problem [36]. Infective urethritis now accounts for 0.9% to 4.6% of cases in contemporary series from well-resourced countries [36, 37] but continues to be the major cause of strictures in low-resourced countries comprising 41.6% of all strictures [38].

Summary of evidence	**LE**
Access to investigation and treatment of STI is associated with a temporal decline in the incidence of infective urethritis related strictures.	3

Recommendation	**Strength rating**
Advise safe sexual practices, recognise symptoms of sexually transmitted infection, and provide access to prompt investigation and treatment for men with urethritis.	Strong

b. Inflammation

Lichen sclerosus involves the urethra in 20% of cases [39] and is the most common cause of panurethral stricture disease (48.6%) [18]. The aetiology of LS has not been fully elucidated but is thought to have an autoimmune origin [40]. Lichen sclerosus may be associated with environmental factors and non-autoimmune comorbidities. Uncircumcised men are far more likely to suffer LS than circumcised men (age-adjusted odds ratio [OR] of 53.55; 95% confidence interval [CI]: 7.24-395.88) [41]. Lichen sclerosus is also associated with higher mean body mass index (BMI), diabetes mellitus, coronary artery disease, tobacco usage, hyperlipidaemia, and hypertension [42-44].

c. External urethral trauma

External trauma to the urethra is the second most common cause of stricture formation in adults [36]. The urethra is vulnerable to trauma during certain activities including sport, driving a vehicle, sexual intercourse and during combat. The bulbar urethra is the site most frequently affected by blunt trauma [12], usually as a result of straddle injuries or kicks to the perineum. Penile fracture is associated with a urethral injury in 15% of cases [45]. Motor vehicle accidents are the main cause of blunt injuries to the posterior urethra associated with pelvic fractures [46]. Penetrating injuries of the urethra are uncommon during non-combat situations [47].

d. Iatrogenic urethral injury

Iatrogenic injury to the urethra is one of the most common causes of strictures in well-resourced countries [18, 36] accounting for 32-79% of all strictures [36, 48]. Preventing iatrogenic urethral injury represents the main way in which urologists can prevent urethral strictures. Iatrogenic urethral injury most commonly results from urethral instrumentation (e.g., catheterisation, cystoscopy), surgery for benign prostatic obstruction (BPO), surgery for prostate cancer, or radiotherapy [37].

d.1 Urethral catheterisation

Urethral strictures are a recognised complication of urethral catheterisation accounting for 11.2-16.3% of all strictures [18, 36]. In a meta-analysis by Hollingsworth *et al.*, the pooled percentage of patients who developed urethral stricture or erosion after short-term catheterisation (< 3 weeks) in higher-quality studies was 3.4% (CI: 1-7%) [49]. In studies comprised mainly of men with spinal cord injury with indwelling urethral catheters, the pooled estimate of urethral stricture or erosion was 8.7% (CI: 0.0-18.7%) [49].

Urethral strictures following catheterisation may arise as a consequence of injury during attempts at insertion or during the period a catheter remains *in situ*. During insertion, the urethra may be injured by formation of a false passage by the catheter tip (29.7%) or inflation of the balloon within its lumen (70.3%) [50]. The rate of urethral injuries due to catheterisation was found to be 3.2 per 1,000 inpatients [51]. A six-month prospective multicentre study found that of 37 patients with catheter-related urethral trauma referred to urologists, 24% continued to perform ISD once weekly and 11% required at least one urethral dilation for urethral stricture [52]. In another follow-up study of 37 patients with catheter-related urethral trauma, 78% of patients developed urethral stricture [50]. The most common locations of trauma are the bulbar and posterior urethra [53].

Catheter-related trauma can be prevented through several measures [54]. Studies have indicated around 25% of all indwelling catheterisations in hospitals were unnecessary and inappropriate [55, 56]. Implementation of guidelines [57, 58] and specific criteria [59] have been shown to reduce catheterisation rates. Several studies have identified deficits in the knowledge of urethral catheterisation amongst resident doctors [60, 61]. This is postulated to be a factor in catheter-related trauma [61]. A targeted training program on urethral catheterisation for nursing staff was shown to be effective in reducing iatrogenic urethral injuries in a prospective single institution study [62].

In addition to guidance and education, another approach to safer catheterisation is modification of the standard Foley catheter. A novel catheter balloon pressure valve safety system was developed to prevent balloon inflation injury though this has not been assessed in comparative studies [63, 64]. Bugeja *et al.*, studied the use of urethral catheterisation device (UCD) incorporating a guidewire, in prospective observational cohort study that included 174 patients. The incidence of adverse events was 7% with standard Foley catheterisation vs. 0% with the UCD (no statistical analysis was performed) [65]. A further prospective observational study found that Seldinger technique catheterisation could be used successfully by non-urology trained doctors [66]. These technologies need to be further assessed in prospective raondomised controlled trials (RCTs), incorporating cost-benefit analysis.

Catheter diameter is suggested as a possible contributing factor to urethral stricture due to a pressure effect on the urethral wall [67]. Decreasing the catheter size from 22 Fr to 18 Fr significantly decreased the risk of fossa navicularis strictures (6.9% vs. 0.9%, p=0.02) after radical prostatectomy (RP) [68]. Catheter material may also have an influence on the occurrence of stricture. In the 1970s/80s several comparative studies in patients undergoing cardiac surgery demonstrated that non-coated latex catheters were associated with a greater incidence of urethritis and more stricture formation than silicone catheters [69-71]. Other studies showed no difference [72-74]. Modern latex catheters have polymeric coatings [75] due to the concern with regards to stricture alongside the risk of hypersensitivity and the demonstrable *in vitro* toxicity of latex. Prolonged urethral catheterisation has also been implicated in the aetiology of stricture (e.g., poly-trauma, burns patients) [48].

Summary of evidence	LE
A significant proportion of catheter insertions in hospitalised patients were considered unnecessary.	2b
Education programs can reduce the incidence of catheter-related urethral injury.	2a
Larger catheter size was associated with a greater risk of navicular fossa strictures.	3
Non-coated latex catheters are associated with a greater degree of urethritis and possibly a greater risk of urethral strictures than non-latex catheters or coated latex catheters.	1a

Recommendations	Strength rating
Avoid unnecessary urethral catheterisation.	Strong
Implement training programmes for physicians and nurses performing urinary catheterisation.	Strong
Do not use catheters larger than 18 Fr if urinary drainage is the only purpose.	Weak
Avoid using non-coated latex catheters.	Strong

d.2 Transurethral prostate surgery

Urethral stricture following transurethral prostate surgery occurs in between 4.5-13% of patients [76], whereas bladder neck stenosis (BNS) occurs in between 0.3-9.7% [77]. Transurethral surgery is the most common cause of iatrogenic urethral stricture accounting for 41% of all causes [48]. The most common location for urethral stricture is the bulbomembranous urethra, followed by the fossa navicularis and penile urethra [78, 79]. Postulated mechanisms include friction at the penoscrotal junction, lack of adequate lubrication, repetitive 'in and out' movement of the resectoscope, breach of mucosal integrity leading to urine extravasation and monopolar current leak due to inadequate resectoscope insulation [80]. Bladder neck stenosis may be related to excessive and/or circumferential resection and the use of relatively large resection loops which may generate excessive heat in small intraurethral adenomas leading to scarring [77, 81]. Stenoses of the posterior urethra may also be due to a prolonged period of post-operative inability to void [82].

d.2.1 Risk factors for development of urethral stricture and bladder neck stenosis

Several risk factors for the development of urethral stricture and BNS following transurethral prostate surgery have been identified. Both prostatic inflammation (OR: 4.31) and operative time > 60 min (OR: 4.27) were found to be independent predictors of stricture after monopolar transurethral resection of prostate (TURP) [83]. In terms of bipolar TURP, slower resection rate (OR: 0.003), intraoperative urethral mucosa rupture (OR: 2.44) and post-operative infection were shown to be independent predictors (OR: 1.49) [84, 85]. A larger-calibre endoscopic sheath (26 Fr vs. 24 Fr) was associated with a greater risk of bulbar urethral stricture following monopolar TURP (11.4% vs. 2.9%, p=0.018) [86]. Room temperature irrigation solution was associated with a greater risk of urethral stricture following combined transurethral resection and vaporisation of the prostate compared to body temperature irrigation (21.3% vs. 6.3%, p=0.002) [87].

Bladder neck stenosis is known to occur more frequently in smaller prostate glands after both monopolar and bipolar TURP [88, 89]. Lee *et al*., found that adenoma weight was an independent risk factor for BNS after monopolar TURP [89]. Meanwhile, Tao *et al.*, found total prostate volume (< 46.2 g) (OR: 1.5), but not resected gland weight, to be an independent risk factor [84].

d.2.2 Incidence of urethral stricture and bladder neck stenosis with different energy modalities

A SR and meta-analysis by Cornu *et al.*, showed no significant differences in urethral stricture and BNS rates by energy modality (monopolar, bipolar, holmium laser enucleation, photoselective vaporisation) [76]. In another meta-analysis assessing outcomes of thulium (Tm:Yag) laser and bipolar TURP, no difference in urethral stricture and BNS rates were found between the two modalities [90]. The presence of potentially confounding factors such as endoscopic sheath diameter, energy setting used, procedural length and length of follow-up make inter-study comparisons between energy modalities problematic. Overall, there is no strong evidence that any single modality is associated with a clinically significant higher incidence of urethral stricture and BNS than others. Selection of modality should be based on a comprehensive evaluation of clinical safety and efficacy. A summary of incidences of urethral stricture and BNS with different modalities is presented in Table 3.1.

A systematic review analysing different techniques used for BPH surgery, showed the lowest incidence of urethral strictures in enucleation procedures, followed by B-TURP and ablation, and M-TURP. However, after twelve months of follow-up there were no significant differences in stricture rate [91].

Table 3.1: Incidence of urethral stricture and bladder neck stenosis by transurethral modality (adapted from Chen *et al*. 2016 [77])

Modality	Urethral stricture	Bladder neck stenosis
Transurethral resection of prostate (TURP) - monopolar and bipolar	1.7 to 11.7%	2.4 to 9.7%
Holmium enucleation of the prostate (HoLEP)	1.4 to 4.4%	0 to 5.4%
Photo-selective vaporisation (PVP)	0 to 4.4%	1.4 to 3.6%

d.2.3 Interventions to prevent urethral stricture and bladder neck stenosis

Sciarra and colleagues conducted a single-blind RCT (n=96) to assess the use of rofecoxib for stricture prevention following TURP. At twelve months follow-up a urethral stricture was found in 17% and 0% of cases in the placebo and rofecoxib groups, respectively (p=0.0039) [92]. Chung *et al.*, conducted a single blinded RCT (n=180) evaluating the effect of urethral instillation of hyaluronic acid (HA) and carboxymethylcellulose (CMC). Urethral stricture on urethrography was diagnosed in 1.25% and 8.64% of patients in the treatment and placebo group respectively (p=0.031). Further RCTs are needed to confirm these findings and the safety of the pharmacological interventions.

Several earlier comparative studies assessed whether routine preliminary urethrotomy with an Otis urethrotome prevented the incidence of stricture following TURP [93-96]. Only one of these reported at least twelve month follow-up, finding no significant difference in stricture rate in patients undergoing TURP alone vs. Otis urethrotomy followed by TURP (21% vs. 14%) [97]. Others have suggested performing internal urethrotomy where there are pre-existent meatal or urethral strictures [98].

Adjunctive transurethral incision of the prostate (TUIP) at the end of TURP to reduce the rates of BNS was studied by Lee *et al*. [89]. A total of 1,135 patients of whom 667 underwent TURP and 468 underwent TURP plus TUIP were retrospectively studied. At median follow-up of 38 months, the incidence of BNS was 12.3% for the TURP group vs. 6.0% for the TURP plus TUIP group ($p < 0.001$). In glands < 30 g, the incidence of BNS in the TURP vs. the TURP plus TUIP group was 19.3% and 7.7%, respectively ($p < 0.05$). The clinical efficacy and safety of additional surgical interventions to prevent urethral stricture and BNS need to be confirmed in larger prospective RCTs before their use can be recommended.

Summary of evidence	LE
An RCT with more than twelve months follow-up failed to demonstrate a significant reduction in stricture rate using routine urethrotomy prior to TURP.	1b

Recommendation	Strength rating
Do not routinely perform urethrotomy when there is no pre-existent urethral stricture.	Strong

d.3 Radical prostatectomy

Radical prostatectomy has been associated with vesico-urethral anastomosis stricture (VUAS) in 0.5-30% of patients [77], though most modern series report it in the range of 1-3% [99]. The risk of stricture formation after salvage RP is notably higher (22-40%) [100]. Most VUAS develop within the first two years [100, 101]. A 2012 meta-analysis by Tewari *et al.*, showed no significant difference in VUAS between open-, laparoscopic and robotic RP [102]. In contrast, a more recent analysis of a national cohort in the UK found that VUAS rate after robotic RP was 3.3%, which is significantly lower than following laparoscopic (5.7%) or open RP (6.9%) [103]. These findings are consistent with an earlier similar study conducted in the USA [104]. The difference in VUAS rates may be explained by the level of experience and surgical volume of surgeons [105]. The cohort studies represent "real world" data, including all levels of surgical experience and surgical volumes whereas the meta-analysis is based on clinical studies. Thus, the better outcomes for robotic RP in the population studies may be related to the shorter learning curve [106].

d.3.1 Risk factors for development of vesicourethral anastomosis strictures

These include higher grade cancer, more advanced stage, higher prostate volume, coronary artery disease, obesity, hypertension, diabetes mellitus, previous bladder outlet surgery and older age [99, 107, 108]. Surgical factors include the use of non-nerve-sparing technique, anastomotic urine leak, increased operative time and increased estimated blood loss [99, 107, 108]. In addition, low-volume surgeons (< 40/year) were shown to have higher VUAS rates, 27.7%, compared to high-volume surgeons (> 40/year), 22% [109].

d.3.2 Interventions to prevent vesicourethral anastomosis strictures

Srougi *et al*., studied bladder neck mucosal eversion in a prospective RCT of 95 patients. No significant difference was found in rates of VUAS at twelve months follow-up [110]. A meta-analysis by Kowelewski *et al.*, comparing interrupted vs. continuous vesico-urethral anastomosis suturing found no difference in VUAS rates [111]. Another SR by Bai *et al*., compared barbed sutures to conventional sutures, and although heterogeneity across studies precluded meta-analysis, no patients developed VUAS with either approach [112].

d.4 Prostate radiation and ablative treatments

Urethral strictures occur in 1.5% of patients undergoing external beam radiation therapy (EBRT), 1.9% having brachytherapy (BT) and 4.9% who receive combination EBRT-BT at around four years follow-up [113]. These strictures typically occur in the bulbomembranous urethra [114]. As opposed to RP, stricture incidence after irradiation increases with time [100, 113]. For the ablative treatments, the stricture incidence after cryotherapy and high-intensity focused ultrasound (HIFU) is 1.1-3.3% and 10.3%, respectively [100, 115]. The use of these modalities in the salvage setting is associated with increased risk of stricture formation: 3-10% after salvage EBRT, 5-12% after salvage cryotherapy and 15-30% after salvage HIFU [100]. Due to the increasing utilisation of prostate irradiation (EBRT, BT) and ablative treatments (cryotherapy, HIFU), an increasing number of respectively radiation-induced and ablative treatment-induced strictures are expected [116].

d.4.1 Risk factors for the development of radiation strictures

Awad *et al*., performed a multivariate meta-regression analysis including 46 studies, finding combining ERBT + BT and length of follow-up to be significant predictors of urethral stricture following prostate radiation [113]. Factors not shown to predict urethral stricture included biochemical equivalent dose, age, and androgen deprivation therapy [113]. Previous TURP was not included in the analysis, but has been found to be an independent predictor of stricture (HR: 2.81) in a previous multivariate analysis from a single institution [117] as well as PSA level < 10 ng/ml (HR: 0.47) [118].

d.4.2 Interventions to prevent radiation induced urethral strictures

Delaying adjuvant or salvage EBRT by nine months is associated with lower rates of urethral stricture (HR: 0.6) [119]. This has to be balanced with risk of delaying treatment in terms of cancer control [77]. In BT, it has been reported that downward movement of needle applicators occurs between fractions [120]. This may explain why strictures occur below the prostatic apex [118] in the so called "hot spot" [121]. Several measures taken together are thought to have contributed to a reduction in urethral stricture formation with BT including reduction of dose to the "hot spot", more careful needle placement, avoiding midline insertion and the introduction of plastic needles rather than steel [113].

e. Failed hypospadias repair

Although urethral strictures after hypospadias repair are sometimes considered as iatrogenic [36], they are a very specific subtype and should be considered as a separate entity. The main reasons for this are the absence of spongiosus tissue at different levels within the penile urethral segment, and the lack of high-quality local tissues for urethral reconstruction [122].

f. Congenital

The diagnosis of a congenital urethral stricture can only be made in the absence of other possible aetiology, such as iatrogenic, inflammatory, and traumatic causes [123]. Congenital strictures are thought to be consequent to incomplete or incorrect fusion of the urethra formed from the urogenital sinus with the urethra formed following closure of the urethral folds. They typically have a deep bulbar location and are usually short. In general, congenital strictures are diagnosed at a young age (Moorman's ring or Cobb's collar).

g. Idiopathic

Idiopathic strictures are seen in 34% of all penile strictures and in 63% of all bulbar strictures [124]. Unrecognised trauma is thought to be a possible aetiology of idiopathic urethral strictures [26].

3.3.2 *Aetiology in females*

The cause of FUS was idiopathic in 48.5%, iatrogenic in 24.1%, resulting from prior urethral dilations, difficult/traumatic catheterisation with subsequent fibrosis, urethral surgeries (mainly diverticulum surgery, fistula repair and anti-incontinence procedures) and trauma (mainly following pelvic fracture) in 16.4% [125-137]. Radiation therapy and infections are rare causes of FUS [138]. The most common segment of urethra affected is the midor mid-to-distal (58%). Panurethral strictures are rare (4%) [15, 125, 127, 128, 130-132, 137, 139].

For further information see online supplementary Tables S3.1 and S3.2.

4. CLASSIFICATIONS

4.1 According to stricture location

Classification according to stricture location is important as this will affect further management.

4.1.1 *In males*

4.1.1.1 *Anterior urethra*

The anterior urethra runs from the meatus to the urogenital diaphragm and is surrounded in its entire length by the corpus spongiosum [11, 140]. Further subdivision is made in three different areas (from distal to proximal) [12]:

Meatal strictures: these strictures are located at the external urethral meatus and may extend into the fossa navicularis of the glans.

Penile strictures: these are located in the segment between the fossa navicularis and the bulbar urethra. Externally, the penile urethra begins approximately at the balanopreputial sulcus and continues to the penoscrotal junction. The whole penile urethral segment lies in the groove ventral to corpora cavernosa and is surrounded by a thin layer of corpus spongiosum.

Bulbar strictures: the bulbar urethra starts at the penoscrotal junction and is surrounded by the bulbospongious muscle. It ends in the membranous urethra proximally at the level of the urogenital diaphragm. The bulbar urethra can be subdivided into a proximal and distal part. The proximal bulbar urethra is defined as the segment within 5 cm of the membranous urethra; the urethra lies eccentrically in this part with abundant ventral spongious tissue. The distal bulbar urethra is defined as the adjoining segment extending to the penoscrotal junction [141]. Strictures extending towards the membranous urethra are termed bulbomembranous strictures (BMS).

Penobulbar strictures: these extend from the penile urethra into the bulbar segment, compromising long segments of urethra.

The difference between penobulbar strictures and multifocal strictures should be noted. The latter are defined by two or more narrowed segments, either in the same or different subdivision of the urethra but preserving healthy lengths of urethra between them (e.g., iatrogenic strictures related to TUR procedures which typically affect the fossa navicularis and the penoscrotal junction with healthy urethra in between).

4.1.1.2 *Posterior urethra*

The posterior urethra is approximately 5 cm long, with three different segments [12]:

- The membranous urethra is the area of the urethra traversing the urogenital diaphragm, between the proximal bulbar and the distal verumontanum.
- The prostatic urethra runs through the prostatic gland, starting at the proximal membranous urethra and extending to the bladder neck.
- The bladder neck is surrounded by the internal urinary sphincter and is the junction between the prostatic urethra and the bladder. Stenosis (or contracture) of the bladder neck implies a prostate *in situ* (i.e., after TURP or simple prostatectomies). If the narrowing or obliteration appears at this level but after a RP, the correct term is VUAS [12].

4.1.2 *In females*

The female urethra is approximately 4 cm long and arbitrarily divided in an upper, mid, and lower part [15, 125, 127, 128, 130-132, 137, 139].

4.2 According to stricture tightness

Several classifications systems have been proposed over the years [142]. The definition of low- vs. high-grade strictures remains debatable [143-145]. A urethral plate less than 3 mm is considered a high-grade or tight stricture [146]. It has been demonstrated with a normally functioning bladder that flow rate will not diminish until the urethral lumen has a diameter below 10 Fr [144].

Table 4.1 presents a suggested classification for male patients with a normal functioning bladder. This classification was developed by the EAU Urethral Stricture Panel based on a consensus process.

Table 4.1: EAU classification according to the degree of urethral narrowing

Category	Description	Urethral lumen (French [Fr])	Degree
0	Normal urethra on imaging	-	-
1	Subclinical strictures	Urethral narrowing but ≥ 16 Fr	Low
2	Low grade strictures	11-15 Fr	
3	High grade or flow significant strictures	4-10 Fr	High
4	Nearly obliterative strictures	1-3 Fr	
5	Obliterative strictures	No urethral lumen (0 Fr)	

4.3 Strictures in transgender men and woman

*4.3.1 **Trans women***

After MtF gender confirming surgery, the penile urethra has been resected. Meatal strictures are defined as strictures occurring at the neomeatus, which is formed between the junction of the distal bulbar urethra and the neovagina. The other segments (bulbar and posterior) are the same as in a biological man.

*4.3.2 **Trans men***

Four different areas can be identified in the urethra after FtM gender confirming surgeries [147]:

- The native urethra is the female urethral segment which remains preserved during surgery. It goes from the bladder neck to the original external meatus.
- The fixed part (pars fixa) or perineal urethra follows the native urethra, starting at the original external meatus. This segment is reconstructed using local tissues, typically vestibular mucosa, or anterior vaginal mucosa. Its course is similar to the bulbar urethral segment in males, but without being covered by spongiosal tissue.
- The anastomotic part is the area where the pars fixa joins the neophallus.
- The phallic urethra is the segment located within the neophallus or the metoidioplasty and is usually made of skin tube. Its course is similar to the penile urethra in males, but without being covered by spongiosal tissue.

5. DIAGNOSTIC EVALUATION

A comprehensive diagnostic evaluation of urethral stricture disease encompasses clinical history and examination, urinalysis (+/- culture), uroflowmetry and post-void residual (PVR) assessment, radiography, and endoscopy.

5.1 Patient history

The purpose of history taking is to assess symptoms including severity and duration, possible aetiology, prior treatments, complications, associated problems, and patient factors that may impact upon surgical outcome.

The clinical presentation of urethral stricture disease is varied. In a retrospective analysis of 611 patients with an endoscopically confirmed diagnosis of urethral stricture, LUTS were the most common presentation (54.3%) followed by acute urinary retention (22.3%), urinary tract infection (UTI) (6.1%) and difficult catheterisation (4.8%) [148]. In a retrospective study of 214 patients who underwent anterior urethroplasty, weak stream was reported as the most common individual LUTS (49%) followed by incomplete emptying (27%) and urinary frequency (20%) [149]. A further retrospective series of 614 patients undergoing anterior urethroplasty found post-void dribble to be present in 73% [150].

Genitourinary pain is a common feature, affecting 22.9-71% [34, 148]. Pain may be felt in the bladder and/or urethra, is associated with more severe LUTS, is more likely to be felt by younger men and resolves in most following reconstruction [32]. Other complaints include spraying (9%), visible haematuria (3.1-5%), urethral abscess/necrotising fasciitis (2.3%), urgency (14%) and incontinence (1-4%) [148, 149].

To establish aetiology, an enquiry about a history of pelvic, genital, or perineal trauma, prior instrumentation, prior surgeries, irradiation or focal therapies and urethritis should be made. It is important to document prior surgical approaches and date of the most recent intervention (e.g., dilatation) as this may impact upon the timing of radiological evaluation or surgical treatment.

Problems of sexual function are common in patients with urethral stricture disease [151, 152] and sexual function may be impacted upon by surgical intervention [153, 154]; therefore, the status of erectile and ejaculatory function should be established and documented using validated tools.

The performance status of the patient should be determined as it may influence the choice of treatment (curative or palliative). A past medical history should assess for factors that may impact upon tissue healing including diabetes, immunosuppression, and smoking. Oral tobacco use or the chewing of betel leaves may increase the risk of morbidity at the harvest site or render oral mucosa too poor for use. Prior harvest of oral mucosa should be noted as alternative sources for tissue transfer may need to be considered [155] or alternative surgical approaches (e.g., perineal urethrostomy [PU]).

5.2 Physical examination

The abdomen should be examined for the presence of a palpable bladder. The location of any suprapubic tube should be noted to assess its potential utility for antegrade cystoscopy or the placement of a sound (to facilitate repair) [156]. Examination of the genitalia should note the presence of foreskin, the position and size of the meatus as well as any evidence of scarring suggestive of LS. Pre-operative biopsy to confirm LS may be performed if this alters management and is essential if malignancy is suspected [157].

The presence of penile or perineal fistulae should be noted. The urethra should be palpated to assess for induration suggestive of significant fibrosis. Rarely a mass may signify a urethral carcinoma. A rectal examination to assess for prostatic pathology, which may be the cause of urinary symptoms, should be undertaken. In patients with posterior urethral stenosis rectal adherence to the prostate and the mobility of the surrounding tissues should be assessed [158]. The oral cavity should be examined for the suitability of oral mucosa. Measurement of BMI will identify obese individuals who are at greater risk of leg compartment syndrome when placed in the lithotomy position for a prolonged time period [159]. Assessing hip mobility is important when considering an exaggerated lithotomy position as some patients may have limited hip flexion due to unresolved orthopaedic problems [156].

*5.2.1 **Further diagnostic evaluation***

5.2.1.1 Patient reported outcome measure (PROM)

The first validated urethral stricture surgery PROM (USS-PROM) was reported in 2011 [160]. It consists of six LUTS questions derived from the International Consultation on Incontinence Questionnaire Male LUTS (ICIQ-MLUTS) module, a LUTS-specific QoL question, the Peeling voiding chart and the EQ-5D to assess overall health-related QoL (HRQoL). The post-operative questionnaire contains an additional two questions to assess overall patient satisfaction. This PROM has been validated in several other languages (German, Spanish, Italian, Dutch, Turkish, Polish, Japanese) and is increasingly used in research studies as well as clinical practice. A further PROM is in development in North America but requires validation [161] (see section 11. Follow-up).

Summary of evidence	**LE**
A specific urethral stricture surgery patient reported outcome measure was found to have psychometric validity in the assessment of patient-derived benefit from surgical intervention for urethral stricture disease.	2a
Sexual dysfunction is prevalent in patients with urethral strictures and sexual function can be affected by surgical management of urethral stricture.	3

Recommendations	Strength rating
Use a validated patient reported outcome measure (PROM) to assess symptom severity and impact upon quality of life in men undergoing surgery for urethral stricture disease.	Strong
Use a validated tool to assess sexual function in men undergoing surgery for urethral stricture disease.	Strong

5.2.1.2 Urinalysis and urine culture

Urinalysis is an essential component of the work up of patients with LUTS. If infection is suggested, urine culture should be performed to confirm the diagnosis and identify the causative organism and sensitivity to antibiotics. Bacteriuria should be treated prior to surgical intervention to prevent peri-operative sepsis [162] (see section 10. Peri-operative care).

5.2.1.3 Uroflowmetry and post-void residual estimation

A reduced maximum flow rate with a prolonged plateau is characteristic of the constrictive obstruction caused by urethral stricture. However, interpretation of flow patterns is subjective and is not considered a reliable screening tool for the detection of stricture [163]. To overcome this, a statistical model based on uroflowmetry parameters was developed and was found to predict urethral stricture with a sensitivity of 80–81% and a specificity of 77–78% [163]. Uroflowmetry is usually combined with ultrasound (US) estimation of PVR to identify patients with urinary retention who may require emergent bladder drainage. Uroflowmetry parameters can also be used for monitoring patients and in the assessment of treatment response (see section 11. Follow-up).

Urodynamic studies are not indicated in the vast majority of patients with urethral stricture disease. In patients with suspected bladder dysfunction (e.g., severe storage LUTS, history of irradiation or neurological disease), an assessment of bladder function may help surgical decision making and patient counselling. Similarly, when there is concern that flow impairment or increased PVR are due to detrusor underactivity or an acontractile detrusor, a urodynamic study may help predict the likelihood that the patient would need to perform intermittent self-catheterisation (ISC) post-operatively. The only urodynamic parameter found to distinguish a diagnosis of urethral stricture from BPO is urethral closure pressure which is lower in the former due to the constrictive nature of the obstruction (22.07 vs. 28.4 cm H_2O, p=0.0039, r=0.61, BPO vs. stricture) [164].

Summary of evidence	LE
Uroflowmetry pattern interpretation by use of a statistical model was found to be predictive of urethral stricture disease.	3

Recommendation	Strength rating
Perform uroflowmetry and estimation of post-void residual in patients with suspected urethral stricture disease.	Strong

5.2.1.4 Urethrography

Retrograde urethrography (RUG) has widely been used as the investigation of choice for evaluating the stricture presence, location, length, and any associated anomalies (e.g., false passages, diverticula) [165].

The reported sensitivity and specificity of RUG in the diagnosis of strictures is 91% and 72%, respectively [166]. The positive predictive value (PPV) was 89% and the negative predictive value (NPV) was 76% [166]. Most reports suggest that RUG underestimates stricture length [167, 168]. Interpretation of RUG findings by urologists were found to be more accurate at predicting urethral stricture location and length as compared to evaluation by an independent physician [169].

Limitations of RUG include difficulty assessing very distal strictures and assessing the proximal extent of strictures which are too narrow to permit passage of adequate contrast. Combining a RUG with voiding cystourethrography (VCUG) can allow adequate visualisation of the urethra proximal to the stricture and a more accurate assessment of stricture length in (nearly) obliterative strictures, stenoses and gap in pelvic fracture urethral injury (PFUI) [170, 171]. In addition, urethrography provides only a two-dimensional assessment of stricture and the results may be affected by the amount of penile stretch [172], degree of pelvic rotation and patient body habitus [173]. Risks of the procedure include infection, discomfort [164], contrast reaction from intravasation of contrast [174] in addition to the risk of radiation exposure. Urethrographic clamp devices (Brodny, Knutson) are available and were found to be less painful than using the Foley catheter technique [175].

Summary of evidence	LE
Retrograde urethrography is a widely available and easy to perform method of diagnosing and assessing urethral stricture but may underestimate stricture length.	2a
Retrograde urethrography alone is not able to assess stricture length (or gap) in obliterative strictures or stenosis.	2a
Urethrographic clamp devices are less painful than using the Foley catheter technique.	2a

Recommendations	Strength rating
Perform retrograde urethrography to assess stricture location and length in men with urethral stricture disease being considered for reconstructive surgery.	Strong
Combine retrograde urethrography with voiding cystourethrography to assess (nearly)-obliterative strictures, stenoses and pelvic fracture urethral injuries.	Strong
Use clamp devices in preference to the Foley catheter technique for urethrographic evaluation to reduce pain.	Weak

5.2.1.5 Cystourethroscopy

Cystourethroscopy allows for accurate visual detection of a suspected stricture or can rule out a stricture as cause of obstructive voiding [166]. It can detect narrowing of the urethral lumen before changes in uroflowmetry and symptoms [145]. Cystourethroscopy can also assess the presence of LS or other pathology but cannot usually assess stricture length as the calibre of most cystoscopes is greater than most symptomatic strictures [176]. To overcome this, use of smaller calibre ureteroscopes (6.5 Fr and 4.5 Fr) has been reported [176]. This also allows an assessment of the bladder prior to surgery and may identify other pathology such as bladder stones. Cystourethroscopy is particularly helpful for diagnosing proximal BMS which may be missed on RUG [177] .

Retrograde urethroscopy combined with antegrade cystoscopy via the suprapubic tract may be used to evaluate PFUI and plan the surgical approach. It allows an assessment of the length of the defect, the competence of the bladder neck, the involvement of the bladder neck in scarring in addition to identifying the presence of bony spicules or other abnormalities (e.g., fistulae, stones) [178]. Combined retrograde and antegrade cystoscopy was found to provide similar estimates of length of urethral defect in patients with PFUI as combined retrograde and antegrade cystourethrography, but was more likely to detect fistulae, false passages, and calculi [178].

Summary of evidence	LE
Cystourethroscopy will reliably detect the presence of a urethral stricture.	3
Combined retrograde urethroscopy and antegrade cystoscopy is more accurate than retrograde and voiding cystourethrography at identifying associated abnormalities such as fistulae, false passages, and calculi in patients with PFUI.	3

Recommendations	Strength rating
Perform cystourethroscopy as an adjunct to imaging if further information is required.	Weak
Combine retrograde urethroscopy and antegrade cystoscopy to evaluate pelvic fracture urethral injuries as an adjunct to imaging if further information is required.	Weak

5.2.1.6 Ultrasound

Ultrasound of the urethra or sonourethrography (SUG) provides a non-invasive three-dimensional assessment of anterior urethral stricture disease; including stricture location, length, and the degree of associated spongiofibrosis [179].

Several studies have compared SUG to RUG and cystoscopic or intraoperative findings. Sonourethrograpy was found to be more accurate at diagnosing stricture presence compared to RUG [175, 180]. Sonourethrography was also found to more accurately estimate stricture length (94% correlation with intraoperative findings) than RUG (59% correlation with intraoperative findings) ($p < 0.001$) [168]. A further study showed similar findings and found that the closest correlation for stricture length at operation was for strictures in the penile urethra [167]. Intraoperative sonourethrogram findings have also been found to change the planned reconstructive approach (based on pre-operative retrograde urethrogram) in 19% of men undergoing anterior

urethral reconstruction [173]. Sonourethrography incorporating real-time elastography can provide a qualitative and quantitative assessment of spongiofibrosis [181, 182]. The clinical relevance of assessing the degree of spongiofibrosis pre-operatively remains to be established. Three-dimensional reconstruction of sonographic images is investigational at present [183].

The advantages of SUG are that it can be performed in the outpatient setting, provides information on the degree of spongiofibrosis and its relatively low cost [179]. Limitations of the technique include lower sensitivity for detection of strictures in the bulbar urethra, operator dependency, and the need for urethral distension requiring intraurethral anaesthesia. Sonourethrography requires specialised training in the use of US and is currently not in widespread usage.

Table 5.1: Diagnostic accuracy of sonourethrography compared to other modalities and surgical findings

Study	N	Segment of urethra studied	Comparator	Accuracy of SUG		
				Diagnosis	Location	Length
Berne-Mestre *et al*. 2018 [175]	113	Anterior and posterior	RUG, VCUG, surgical findings	SUG more accurate than RUG ($p < 0.05$)	-	-
Ravikumar *et al*. 2014 [180]	40	Anterior and posterior	RUG, VCUG, surgical findings	Anterior: SUG 100% sensitivity, 100% specificity Posterior: SUG 75% sensitivity, 50% specificity.	-	-
Kalabhavi *et al*. 2018 [168]	30	Anterior	RUG, surgical findings	-	-	-
Krukowski *et al*. 2018 [167]	66	Anterior	RUG, surgical findings	-	-	-

N = number of patients; RUG = retrograde urethrography; SUG = sonourethrography; VCUG = voiding cystourethrogram.

5.2.1.7 Magnetic resonance imaging

Magnetic resonance imaging (MRI) has been used to image PFUIs, posterior urethral stenoses and anterior urethral strictures.

Several studies have compared MRI urethrogram to RUG and intraoperative findings. Magnetic resonance imaging urethrogram was found to be as accurate as RUG at detecting stricture site in anterior urethral strictures [184]. In terms of stricture length both MRI urethrogram and RUG reliably correlated with intraoperative findings [184]. On the other hand, a further study of patients with anterior urethral strictures found MRI urethrogram stricture length to correlate more closely with surgical findings than RUG [185].

In a mixed group of anterior urethral strictures and posterior urethral stenoses, MRI urethrogram was as accurate (sensitivity = 100%, specificity = 91.7%) as combined RUG and sonourethrography (sensitivity = 100%, specificity = 91.7%) at diagnosing strictures [186]. There was no significant difference in the measurement of stricture length [186]. In a further study of patients with posterior urethral stenosis, MRI estimation of stenosis length correlated more closely with operative findings compared to RUG [187]. In patients with PFUI, MRI measurement of pubo-urethral stump angle (angle between long axis of pubis and line between the distal end of the proximal urethral stump and lower border of inferior pubic ramus) was predictive of an elaborated approach on multivariate analysis [188].

Magnetic resonance imaging was also found to be more accurate at diagnosing associated pathologies e.g., diverticula, tumours, fistulae, and stones [186]. In cases of fistulation between the urinary tract and pubic symphysis after irradiation for prostate cancer, the fistula tract can be clearly demonstrated on MRI [189]. Other imaging modalities, including computed tomography (CT), may fail to identify the tract and the problem may be misdiagnosed as isolated osteomyelitis of the pubic bone leading to medical management with antibiotics rather than surgical excision [189].

The main advantage of MRI is greater anatomical detail, which is countered by the expense of the procedure and the greater complexity in interpreting images. The technique is not commonly used for routine situations, but it may be helpful in diagnosing associated pathologies which may alter patient management.

Table 5.2: Diagnostic accuracy of MRI compared to other modalities and surgical findings

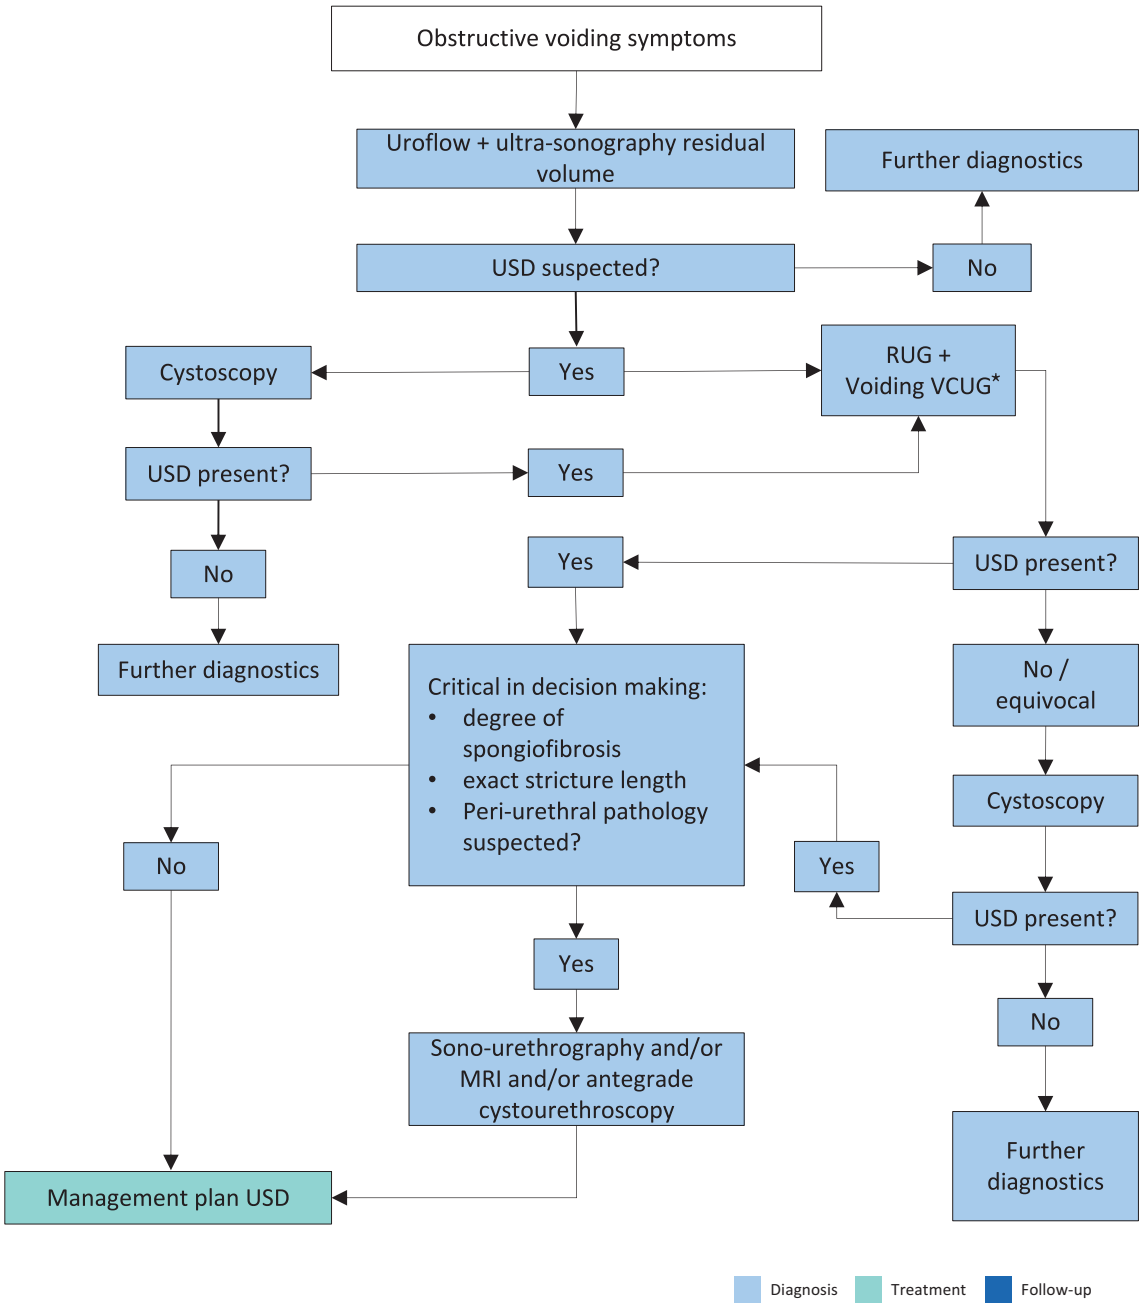
Study	N	Segment of urethra studied	Comparator	Accuracy of SUG		
				Diagnosis	Location	Length
Murugesan *et al*. 2018 [184]	32	Anterior	RUG, Surgical findings	MRI and RUG equivalent (100% sensitivity, 100% specificity)	-	-
Fath El-Bab *et al*. 2015 [185]	20	Anterior	RUG, Surgical findings	-	-	MRI more accurate than RUG.
El-Ghar *et al*. 2010 [186]	30	Anterior and posterior	RUG + SUG, Surgical findings	MRI and RUG equivalent (100% sensitivity, 91.7% specificity)	-	MRI and RUG equivalent.
Oh *et al*. 2010 [187]	25	Posterior	RUG + SUG, Surgical findings	-	-	MRI more accurate than RUG + VCUG.

MRI = magnetic resonance imaging; n = number of patients; RUG = retrograde urethrography; SUG = sonourethrography; VCUG = voiding cystourethrogram.

Summary of evidence	LE
Magnetic resonance imaging is more accurate than retrograde urethrography and voiding cystourethrography at determining length of posterior urethral stenoses and can detect alternative associated pathologies e.g., diverticula, fistulae.	2a

Recommendation	Strength rating
Consider magnetic resonance imaging urethrography as an ancillary test in posterior urethral stenosis.	Strong

Figure 5.1: Diagnostic flowchart of patients with suspected urethral stricture disease



**Use VCUG in case of (nearly-) obliterative strictures or stenosis.*
MRI = Magnetic resonance imaging; RUG = retrograde urethrography, USD = urethral stricture disease; VCUG = voiding cystourethrogram.

6. DISEASE MANAGEMENT IN MALES

6.1 Conservative options

6.1.1 ***Observation***

A stricture will usually result in diminution in flow once the calibre of the urethral lumen is < 10 Fr [144]. In other strictures (> 10 Fr), the diagnosis is often made by coincidence in asymptomatic patients because of a urologic examination for other reasons (e.g., cystoscopy, need for urethral catheterisation) [144]. Purohit *et al*., performed observation and repeated cystoscopic evaluation of 42 subclinical, incidentally encountered strictures (> 16 Fr). After a median follow-up of 23 months, only five (12%) strictures progressed to a low-grade stricture (11-15

Fr). No patient developed symptoms and none of them needed surgical intervention [144]. These patients are candidates for observation although no evidence exist on the long-term evolution of these strictures.

In a series of anatomic stricture recurrence (< 16 Fr) after urethroplasty, only 65% of patients were symptomatic [145]. Some asymptomatic patients refused further intervention because they had experienced substantial improvement after their primary urethroplasty. These patients were considered as functional "success" [145]. A multicentric study of the Trauma and Urologic Reconstructive Network of Surgeons observed an important discrepancy between cystoscopic recurrence and need for further intervention [143]. Patients with a large calibre (> 16 Fr) recurrence had a one and two-year need for intervention rate of 4% and 12%, respectively. Of note, patients with small-calibre (< 16 Fr) recurrence had a one and two-year need for intervention rate of only 41% and 49%. Patients who needed intervention had poorer PROMs suggesting clinical symptoms and bother. There is no information on long-term complications in patients with recurrences who did not undergo intervention. In cases of an asymptomatic stricture recurrence, it might be an option not to intervene but to perform regular follow-up.

Care must be taken about the term "asymptomatic" stricture (recurrence) as patients might conceal their bother and symptoms by different means (not drinking, social avoidance) and might only search for medical help once concealment is no longer tenable [190].

*6.1.2 **Suprapubic catheter***

Radiation-induced urethral strictures are a difficult to treat population as stricture-free rates for urethral reconstruction are lower compared to those in non-irradiated patients [191]. Fuchs *et al*., evaluated 75 patients who were initially treated by suprapubic diversion for radiation-induced isolated BMS [192]. Only 51% eventually decided to undergo urethroplasty after a mean follow-up period of 25 months. Although there was no significant difference in overall performance status between patients with a chronic suprapubic catheter vs. those undergoing urethroplasty, all patients with a poor performance score remained with a suprapubic catheter. Patients with concomitant stress urinary incontinence (SUI) opted more often to keep their suprapubic catheter as the SUI improved in 61% of cases. On the other hand, patients who kept their suprapubic catheter suffered from catheter-related complications in 27% of cases. Urinary diversion by ileal conduit was performed in 30% of patients who remained with a suprapubic catheter while this was only the case in 8% who underwent urethroplasty. A suprapubic catheter is also an option in frail patients not able to undergo surgery or in patients who do not want (further) urethral surgery and are willing to accept the complications of a suprapubic catheter [193].

Summary of evidence	**LE**
Patients with asymptomatic incidental (> 16 Fr) strictures have a low risk of progression and to develop symptoms.	3
Only half of the patients initially treated with a suprapubic catheter for radiation-induced bulbomembranous strictures will proceed with urethroplasty.	3

Recommendations	**Strength rating**
Do not intervene in patients with asymptomatic incidental (> 16 Fr) strictures.	Weak
Consider long-term suprapubic catheter in patients with radiation-induced bulbomembranous strictures and/or poor performance status.	Weak

6.2 Endoluminal treatment of anterior urethral strictures in males

The ability to treat the majority of strictures by less invasive and time-consuming means, offers obvious benefits particularly when specialist surgical services are not available, or patients simply prefer a more pragmatic immediately available solution.

*6.2.1 **Direct vision internal urethrotomy***

In contemporary practice, direct vision internal urethrotomy (DVIU) is commonly performed as a first-line treatment of urethral strictures [194]. It is usually performed under general or spinal anaesthesia in well-resourced countries but shown to be well tolerated under local anaesthesia with or without sedation [195].

6.2.1.1 Indications of "cold knife" direct vision internal urethrotomy

6.2.1.1.1 Direct vision internal urethrotomy for primary stricture treatment

In the only high-level evidence study, Steenkamp *et al*., randomised 210 patients with seemingly comparable non-obliterative strictures at all locations of the urethra to either filiform dilatation vs. DVIU with local anaesthesia on an outpatient basis [196]. They collected objective data with RUG performed at seven follow-up visits (3, 6, 9, 12, 24, 36 and 48 months). This unique study showed that urethral dilatation is equally effective as DVIU but both procedure modalities become less effective with increasing stricture length (see section 6.2.1.1.3.1).

A retrospective cohort series on the primary treatment of patients with iatrogenic urethral strictures reported a significantly poorer patency rate for DVIU compared to urethroplasty techniques (32.2 versus 82.4-83.5%) [197].

Patency rates vary considerably between 8% and 77% after DVIU (predominantly without prior urethroplasty) in retrospective cohort studies with minimum follow-up of one year [67, 198-204] (Table 6.1). Median time to recurrence was less than twelve months in most series [67, 198-202]. This large variation in patency rate can be in part explained by the heterogeneous nature of the strictures and various definitions of patency used by the authors in these series. Indication to perform DVIU is dependent on various stricture characteristics that are prognostic for a successful outcome.

Table 6.1: Results of DVIU in series with minimum follow-up > 12 months

Study	N	Age (years)	Follow-up (months)	Location	Length (cm)	Previous interventions	TTR (months)	Patency rate (%)
Al Taweel *et al*. [200]	301	37 (range: 17-82)	36	Bulbar: 227 (75%)	1.3 (0.4-4.2)	Primary: 47%	10	8.3

DVIU = Direct vision internal urethrotomy; IQR = interquartile range; N = number of patients; NR = not reported SD = standard deviation; TTR = time to recurrence.

6.2.1.1.2 Direct vision internal urethrotomy for recurrent strictures and as salvage treatment after failed urethroplasty

In the OPEN trial, a recurrent stricture was defined as at least one previous failed intervention (endoscopic urethrotomy, urethral dilatation, urethroplasty) [205]. The previous intervention was predominantly DVIU. Despite poor recruitment, 108 and 112 patients were randomised to urethroplasty and DVIU respectively in a 24-month study protocol. Both groups had a similar improvement in voiding score symptoms after intervention. However, patients undergoing urethroplasty had 2.6 higher odds of experiencing an improvement of > 10 ml/s in their maximum urinary flow compared to those undergoing urethrotomy (p=0.001) [205]. Need for re-intervention was observed in 13.8% vs. 25.9% of cases respectively allocated to urethroplasty and DVIU resulting in a 48% lower risk for re-intervention with urethroplasty (HR: 0.52; 95% CI: 0.31-0.89; p=0.017) [205]. Of note, self-dilatation was not considered a re-intervention [205]. Despite more re-interventions in the DVIU group, both treatments resulted in a similar improvement in quality of life but with a higher cost for urethroplasty with the limitation that the follow-up is only two years. [206]. Direct vision internal urethrotomy is also used as salvage treatment for recurrent strictures after urethroplasty. Brown *et al.*, used DVIU for stricture recurrence (mean length: 4 cm; range: 1.5-7 cm) after excision and primary anastomosis (EPA), buccal mucosa grafts (BMG) urethroplasty and penile skin graft urethroplasty [207]. Patency was obtained in thirteen out of 37 cases (35%) after a single DVIU. After free graft urethroplasty (FGU), a short, veil-like stricture (or "diaphragm") might develop at the distal or proximal end of the graft. Rosenbaum *et al.*, used DVIU to a selected cohort of 43 patients with a short (< 1 cm), veil-like stricture after BMG urethroplasty [208]. After a mean follow-up of twelve months, patency rate was 51%.

6.2.1.1.3 Predictors of failure of "cold knife" direct vision internal urethrotomy

Several groups tried to identify prognostic factors to predict which patients are most likely to fail initial treatment (Table 6.2).

In the absence of well-designed, adequately powered multi-centre trials it is difficult to answer the question as to which clinical factors are predictive of failure of DVIU in men with urethral strictures. However, based on the predictors evaluated above, one can summarise that the best candidates are previously untreated patients with a single, short (max. 2 cm) bulbar stricture. Barbagli *et al.*, reported a five-year patency rate of 71% for patients with untreated short (1-2 cm) bulbar urethral strictures [199].

Table 6.2: Predictors for urethral patency after direct vision internal urethrotomy

Author	Location	Length	Calibre	Multiplicity	Prior DVIU
Steenkamp *et al*. [196] / Heyns [209]	RR for recurrence penile vs. bulbar: 1.85 (95% CI: 0.94 to 3.67, p = 0.077)	< 2 cm: 60% (@12 months)	NR	NR	None: 50-60% (@48 months)
	-	2-4 cm: 50% (@12m)	-	-	1: 0-40% (@48 months)

6.2.1.2 Indications of "hot-knife" direct vision internal urethrotomy

6.2.1.2.1 Laser urethrotomy

Lasers available for urological applications, including Neodymium:YAG, Argon, Holmium:YAG, Potassium titanyl phosphate (KTP) and Tm:Yag, have been used for the treatment of urethral strictures. A SR identified four RCTs comparing laser urethrotomy and the "cold knife" urethrotomy. All studies were limited by short-term outcome evaluation and none of these four studies specified the results based on the location of the stricture. Two of these studies reported specific recurrence rates and meta-analysis showed a relative risk (RR) for recurrence of 0.55 (95% CI: 0.18-1.66; p=0.29), 0.39 (95% CI: 0.19-0.81; p=0.01) and 0.44 (95% CI: 0.26-0.75; p=0.003) in favour of laser urethrotomy after three, six and twelve months respectively [210]. Jin *et al.*, performed a SR including 44 case series on laser urethrotomy or "cold knife" DVIU [211]. This included nineteen articles on laser urethrotomy and 25 articles on "cold knife" DVIU. The overall weighted average stricture-free rate was 74.9% (371/495) and 68.5% (1874/2735) for laser vs. "cold knife" DVIU, respectively (p=0.004). Although statistically significant, the results must be interpreted with caution because of heterogeneity and because no details are provided on follow-up duration. Specifically looking at first DVIU, laser and "cold knife" DVIU obtained a stricture-free rate of 58.6% and 42.7%, respectively and the difference was no longer statistically significant (p=0.09). At the bulbar urethra, laser and "cold knife" DVIU yielded a stricture-free rate of 52.9% and 60%, respectively (p=0.66) [211].

After publication of this SR, the EAU Guideline Panel scope search identified three additional RCTs [212-214]. In the RCT of Yenice *et al.*, patients with a primary, bulbar stricture were randomised either to "cold knife" DVIU (n=29) or holmium:YAG laser urethrotomy (n=34). After twelve months follow-up, no significant difference in patency rate was identified (79% for "cold knife" DVIU vs. 68% for laser urethrotomy, p=0.3) [213]. In their RCT, Chen *et al.*, reported a better patency rate after one year with laser (n=24) compared to "cold knife" (n=22) DVIU (respectively 88% vs. 18%; p < 0.05). However, after two years the benefit for laser disappeared and after five years both techniques showed a low patency rate: 9% for "cold knife" DVIU vs. 12% for laser DVIU (p > 0.05) [212]. Gamal *et al.*, randomized patients between "cold knife" DVIU (n=40) and Holmium:Yag laser DVIU (n=40). At one year, they found an equally effective improvement of maximum urinary flow in both groups.

6.2.1.2.2 Plasmakinetic (bipolar) urethrotomy

Cecen *et al.*, conducted an RCT comparing plasmakinetic with "cold knife" DVIU (n=136) [215]. They reported patency rates for plasmakinetic and "cold knife" urethrotomy at nine months in respectively 86% and 70% of cases (p=0.025). At eighteen months, patency rates for plasmakinetic and "cold knife" urethrotomy were 63% and 67%, respectively (p=0.643) [215]. A prospective cohort study on primary strictures < 2 cm reported a patency rate at twelve months in 23/30 (77%) cases for plasmakinetic DVIU vs. 19/30 (63%) cases with "cold knife" DVIU (p=0.04) [216]. A retrospective case series (n=27) reported a 74% patency rate for short (1-2.5 cm) strictures after a mean follow-up of fourteen months [217]. They reported negligible blood loss during the procedure and no post-operative incontinence.

Based on the conflicting results described above and considering the heterogeneity of series and absence of long-term follow-up, overall, the available studies do not support the efficacy of one technique of DVIU over another. Given the similar complication rates between techniques (see section 6.2.1.3), no recommendation can be made in favour of one technique over another.

6.2.1.3 Complications of direct vision internal urethrotomy

6.2.1.3.1 Complications of "cold knife" direct vision internal urethrotomy

An overall complication rate of 6.5% was reported in a SR of Jin *et al.*, based on twelve articles including 1,940 patients [211] (Table 6.3).

Notably, erectile dysfunction (ED) was reported in 5.3% of cases in this review [211]. In addition, Graversen *et al.*, reported ED in eleven out of 104 (10.6%) patients [218]. This risk appears higher in strictures located in the penile urethra and, in addition to the poor patency rates, the use of DVIU in the penile urethra must be discouraged [218, 219].

6.2.1.3.2 Complications of "hot knife" direct vision internal urethrotomy

The SR of Jin *et al.*, reported a total complication rate of 11.8% (39/330) [211] (Table 6.3).

6.2.1.3.3 Complications of "cold knife" vs. "hot knife" direct vision internal urethrotomy

In a SR of RCTs comparing "cold knife" DVIU vs. laser DVIU, only 1/4 series reported complications [210].
In the laser group, an 8.9% complication rate was found due to contrast extravasation to the perineum and stricture recurrence. For the "cold knife" DVIU, a 15.5% complication rate was reported related to bleeding [210]. Two later RCT's reported similar rates of urinary extravasation [212, 213] and urinary incontinence (UI) [212] with both techniques.

The SR of retrospective case series of Jin *et al*., found no significant differences in the incidence rates of UI, urinary extravasation and UTI between laser and "cold knife" DVIU [211]. However, urinary retention and haematuria were more frequent with laser compared to "cold knife" DVIU [211]. Conversely, In the series of Yenice *et al*., haematuria was only reported after "cold knife" DVIU but not after laser DVIU (p=0.6) [213] (Table 6.3).

Table 6.3: Complications after "cold knife" DVIU vs. laser DVIU

Study/Complication	"Cold knife" DVIU (%)	Laser DVIU (%)	p-value
Jin *et al*. [211]			
Urinary extravasation	2.9	3.1	0.938
Urinary incontinence	4.1	2.1	0.259

Erectile dysfunction	5.3	NR	NA
Urinary tract irritation	NR	11.4	NA
Urinary fistula	NR	1.5	NA

Dysuria	NR	5.1	NA
Yenice *et al*. [213]			
Urinary extravasation	0	2.9	0.6
Haematuria	10	0	
Chen *et al*. [212]			
Urinary extravasation	9.1	4.2	0.5
Urinary incontinence	4.5	4.2	

DVIU = direct vision internal urethrotomy; NA = not applicable; NR = not reported.

6.2.1.3.4 Complications of direct vision internal urethrotomy vs. dilatation

A Cochrane review found no significant differences for overall intra-operative complications (single dilatation vs. DVIU respectively 14% vs. 11%; RR: 0.75; 95 CI: 0.36-1.55) nor for individual complications (difficulty urinating, haematuria, false passage, pain, knotting/breaking/bending filiform leader) [196, 220]. The low rate of false passage for both DVIU and dilatation (respectively 0.96 and 0.94%) might be explained by the systematic use of a filiform leader in both groups which was inserted endoscopically in the dilatation group followed by coaxial dilatators [196, 220].

A small retrospective study comparing balloon dilatation (n=31) with DVIU (n=25) showed less urethral bleeding (6.5 vs. 32%; p=0.017) and UTI (3.2 vs. 24%; p=0.037) with balloon dilatation [221].

Apart from acute peri-operative complications described above, the stricture length and number of strictures were reported to increase after DVIU. Other authors mention that repeat urethral manipulations (DVIU and/or dilatation) can increase stricture complexity and delays time to urethroplasty [222].

6.2.1.3.5 Complications of "cold knife" direct vision internal urethrotomy vs. urethroplasty

The OPEN-trial reported adverse events of any type in 61% and 26.1% after urethroplasty (all types) and DVIU respectively [205]. In the urethroplasty group, mouth pain (related to oral mucosa graft [OMG] harvesting) and wound infection was noted as complication in respectively 14.6% and 4.9% of cases. Erectile dysfunction was 4.9% and 2.6% after urethroplasty and DVIU, respectively. Serious adverse events were reported in 8.5% and 8.7% after urethroplasty and DVIU respectively [205].

Summary of evidence	**LE**
Direct vision internal urethrotomy performs poorly in penile strictures. Direct vision internal urethrotomy at the penile urethra might provoke venous leakage from the corpora cavernosa with subsequent risk of erectile dysfunction.	1b
Increased stricture length is associated with higher risk of failure of direct vision internal urethrotomy (DVIU).	1b
In selected patients with a primary, single, short (< 2 cm) and non-obliterative bulbar stricture, a five-year stricture-free rate of up to 77% can be expected.	3
Direct vision internal urethrotomy has a stricture-free rate of 51% if performed for a short, veil-like recurrent stricture after prior bulbar urethroplasty.	3
There is conflicting evidence that "hot knife" (laser, plasmakinetic) DVIU would be superior compared to "cold knife" DVIU after more than one year of follow-up.	1a

Recommendations	**Strength rating**
Do not use direct vision internal urethrotomy (DVIU) for penile strictures.	Strong
Do not use DVIU/dilatation as solitary treatment for long (> 2 cm) segment strictures.	Strong
Perform DVIU/dilatation for a primary, single, short (< 2 cm) and non-obliterative stricture at the bulbar urethra.	Weak
Perform DVIU/dilatation for a short, veil-like recurrent stricture after prior bulbar urethroplasty.	Weak
Use either "hot" or "cold knife" techniques to perform DVIU depending on operator experience and resources.	Weak

6.2.2 *Single dilatation*

6.2.2.1 *Modalities of dilatation and results*

Dilatation can be done in the office, under local anaesthesia and without complex resources [223, 224]. With dilatation, the urethral mucosa at the stricture site is stretched and the scarring is disrupted. This is opposed to DVIU where the stricture is incised. However, both treatment modalities use the same principle to achieve urethral patency: a breach of the urethral mucosa at the site of the stricture in which re-epithelialisation should occur faster than wound contraction [220].

When dilators are used to dilate bulbar urethral strictures, considerable experience is required to avoid accidental perforation of the urethra at the level of the stricture. In order to reduce the risks (esp. false passage, spongiosal perforation, urethral bleeding) of "classic" blind dilatation with rigid sounds [224], other strategies have been developed and evaluated in which the dilatation is visually controlled after a guidewire has been inserted (Table 6.4).

Although no direct comparative studies of blind vs. visually controlled dilatation are available, several studies have reported a low complication rate with visually controlled modifications of dilatation. The recurrence rate largely varies between 23.5-64.5% (Table 6.4).

Table 6.4: Results of visually controlled dilatation

Study	Technique	N	FU (mo)	recurrence	Definition of failure	Complications			
						Haematuria	False passage	Procedural failure	UTI
Hosseini *et al*. [224]	Nelaton urethral catheters	333	43 (36-52)	138 (41,4%)	Need for additional intervention	12 (3.6%)	2 (0.6%)	NR	15 (4.5%)
Kallidonis *et al*. [225]	Coaxial S-curved	310	12	90 (33%)	No recurrence @1 yr with maximum one additional procedure	11 (3.5%)	0 (0%)	7 (2.2%)	33 (10.6%)
Nomikos *et al*. [226]	Amplatz + DVIU + ISD (1 yr.)	34	12	8 (23.5%)	Stricture recurrence on urethroscopy/ urethrography	2 (5.8%)	NR	NR	3 (8.8%)
Yu *et al*. [221]	Balloon	31	15 (5-36)	20 (64.5%)	Need for subsequent urethroplasty	2 (6.5%)	0 (0%)	NR	1 (3.2%)

DVIU = direct vision internal urethrotomy; FU = follow-up; ISD = intermittent self-dilatation; mo = months; N = number of patients; NA = not applicable; NR = not reported; UTI = urinary tract infection; yr = year.

6.2.2.2 *Effectiveness of dilatation compared with direct vision internal urethrotomy*

A SR identified only one prospective RCT comparing dilatation with DVIU and failed to detect any differences [196, 220]. In a small (n=56) retrospective cohort study, the three-year estimated stricture recurrence-free survival was 35.5% and 28% for respectively balloon dilatation and DVIU (p=0.21) [221].

At present, there is lack of evidence to support the claim that dilatation is superior to DVIU (or *vice versa*) and therefore, the indications for single dilatation are the same as for DVIU.

Repetitive dilatation/DVIU with curative intent (see also section 6.2.1.1.3.6 Previous interventions) should be avoided as no long-term freedom of recurrence can be expected [223] and because of the significant risk of increasing stricture length and complexity and prolonging the time to urethroplasty (which has better patency rates) [222].

Summary of evidence	LE
Visually controlled dilatation after endoscopic or fluoroscopic guidewire placement has a low complication rate.	3

Repetitive dilatations/direct vision internal urethrotomy have no long-term freedom of recurrence and increase stricture complexity.	1b

Recommendations	Strength rating
Use visually controlled dilatation in preference to blind dilatation.	Weak
Do not perform repetitive (> 2) direct vision internal urethrotomy/dilatations if urethroplasty is a viable option.	Strong

*6.2.3 **Post-dilatation/direct vision internal urethrotomy strategies***

Several strategies have been developed and evaluated to prevent wound contraction, improve the stricture-free rate and time to stricture recurrence after dilatation or DVIU.

It is noteworthy that these strategies tend to stabilise the stricture rather than to keep the patient stricture-free and the reported outcomes should be understood in this respect.

6.2.3.1 Intermittent self-dilatation

6.2.3.1.1 Results

A SR identified six randomised and quasi-randomised trials comparing intermittent self-dilatation (ISD) with no ISD with a follow-up between eight and 24 months [227]. Stricture recurrence was reduced in men performing ISD (85/197, 43%) vs. those who did not (128/207, 62%) (RR: 0.70; 95% CI: 0.48-1.00; p=0.05). There was significant heterogeneity, and the quality of included studies were very low, which led the authors to conclude there is uncertainty about the estimate [227]. This review found no significant difference in adverse events between ISD and no ISD (RR: 0.60; 95% CI: 0.11-3.26; p=0.56) [227]. One trial containing 48 patients found no significant difference in six vs. twelve months duration of ISD (RR: 0.67; 95% CI: 0.12-3.64) and another trial (n=59) found no significant difference from using a low-friction hydrophylic vs. a polyvinyl chloride catheter (RR: 0.32; 95% CI: 0.07-1.40) [227]. Other studies have been published after this SR of 2014. Chhabra *et al*., reported that patients complying with ISD after dilatation had a lower need for re-intervention than those who did not, 12.3% vs. 20.5% respectively (p=0.2) [228]. After a mean follow-up of 25 months, Greenwell *et al*., found a need for subsequent intervention in 13/31 (42%) men performing ISD vs. 47/95 (49%) who did not (p=0.46). The number of reoperations in patients with need for subsequent intervention was lower in the group performing ISD vs. those who did not (2.6 vs. 3.4). No major complications were reported in both groups [229].

6.2.3.1.2 Complications

The potential benefit of ISD in stabilising the stricture must be balanced against the drawbacks. Commonly reported complications are urethral bleeding (7.1%) [230] and UTI/epididymitis (4.7-18.1%) [231, 232]. A multicentric prospective study (n=85) reported that respectively 35% and 26% of patients had moderate to severe difficulties in catheterisation and respectively 32% and 17% of patients suffered moderate to severe pain while performing ISD. This had a serious impact on QoL which was rated moderate and poor in 32% and 55% of patients, respectively [33]. Younger age was identified as predictor for poor QoL, and QoL was more impaired in proximal stricture location (posterior and bulbar) [33]. In a study of 286 patients (mainly > 60 years old) performing ISD, 20% experienced problems with ISD and 33% had at least one infection annually. After a mean follow-up of 58 months 67% still continued with ISD [233]. Khan *et al*., reported eight “drop-outs” of 30 (26.7%) men randomised to ISD [232]. Of these eight “drop-outs”, two were unable to perform ISD and one stopped because of pain.

As mentioned above, repetitive dilatation (including ISD) increases stricture complexity and delays time to urethroplasty [222, 234].

6.2.3.1.3 Intermittent self-dilatation combined with intra-urethral corticosteroids

To delay wound contraction at the stricture site, intra-urethral corticosteroids (as a catheter lubricant) have been used to improve the results of ISD. In 2014, a SR identified three prospective RCTs comparing ISD and local steroid (triamcinolone) ointment vs. ISD without local steroid ointment [235]. These three studies included a total 67 and 68 patients randomised to local steroid, or not, with a follow-up ranging between twelve and 36 months. There were fifteen (22.4%) recurrences in the steroid group and 25 (36.7%) in the control group (OR: 0.51; 95% CI: 0.24-1.10; p=0.09) [235]. Time to recurrence was longer in the steroid group vs. the control group (weighted mean difference = 0.29; 95% CI: 0.08-1.00; p=0.05). There was no difference in adverse events between groups [235].

Since 2014, two additional RCTs have been published. Ergun *et al*., evaluated patients after DVIU for primary short (< 2 cm), bulbar (82%) or posterior (18%) strictures that were further randomised between ISD (n=30) and ISD + triamcinolone ointment (n=30) for six weeks. Stricture recurrence rate after 24 months was not significantly different between ISD and ISD + triamcinolone (respectively 33.3 and 30%) [236]. On the other hand, Regmi *et al*., found a lower stricture recurrence rate (22% vs. 46%, p=0.04) in patients performing ISD + triamcinolone (n=27) vs. ISD alone (n=28) [237]. In this study, median time to recurrence was 7.4 ± 4.5 months vs. 11.9 ± 3 months in respectively ISD alone and ISD + triamcinolone (p=0.16). Both studies reported no complications related to ointment of triamcinolone [236, 237].

In a small (n=28) cohort with LS-related strictures, an intra-urethral steroid regimen was successful (no need for subsequent escalation of therapy) in 25 (89%) patients after a mean follow-up of 25 months [157]. This regimen consisted of applying clobetasol cream 0.05% as lubricant on a calibration device (10-16 Fr catheter or dilator) twice a day during a minimum of two months. As most of these patients further continued with instillation of steroids on a calibration device, this high "success" rate must be viewed with caution and should be considered as a stabilisation of the stricture rather than a cure. Eventually, twelve (42.8%) patients could reduce the interval of instillation/dilatation and three (10.7%) of them could finally stop the treatment [157].

Summary of evidence	**LE**
Stricture recurrence was reduced in men performing intermittent self-dilatation (ISD) versus those who did not.	1a
Intra-urethral corticosteroids in addition to ISD delays the time to recurrence.	1a

Recommendations	**Strength rating**
Perform intermittent self-dilatation (ISD) to stabilise the stricture after dilatation/direct vision internal urethrotomy if urethroplasty is not a viable option.	Weak
Use intra-urethral corticosteroids in addition to ISD to stabilise the urethral stricture.	Weak

6.2.3.2 Intralesional injections

The rationale of adjuvant intralesional injections is to reduce fibroblast proliferation and excessive urethral scaring [238].

6.2.3.2.1 Steroids

A 2014 SR identified five studies comparing intra-urethral submucosal steroid injection vs. no intra-urethral submucosal steroid injection after DVIU, of which two were RCTs [235]. Meta-analysis of these two RCTs with 57 and 58 patients in, respectively, the steroid and control group showed no statistical difference in recurrence rate (OR: 0.53; 95% CI: 0.25-1.13; p=0.10). Time to recurrence was significantly longer in the steroid group (weighted mean difference = 4.43; 95% CI: 2.77–6.09, p < 0.00001). There were no significant differences regarding adverse events (infection, bleeding, extravasation) between both groups (weighted mean difference = 1.59; 95% CI: 0.71–3.58, p=0.26).

6.2.3.2.2 Mitomycin C

In 2021 a SR and meta-analysis of different adjuncts to minimally invasive treatment of urethral stricture in men, mitomycin C (MMC) was associated with the lowest rate of urethral stricture recurrence (intralesional injection: OR 0.23, 95% CI 0.11-0.48; P<0.001; intraluminal injection: OR 0.11, 95% CI 0.02-0.61; P=0.01) [239]. Another SR and meta-analysis in 2021 from Xu *et al*., on the efficacy of MMC combined with direct vision internal urethrotomy, revealed that the effect of MMC was significant in short (≤ 2cm), anterior urethral strictures, in the longer (>12 months) follow-up group [240].

In the absence of well-conducted and adequately powered RCTs along with the lack of standardisation (dose, technique, volume, etc.) in the current literatue, carefull clinical review and prospective data collection as part of a clinical trial is advised.

6.2.3.2.3 Platelet rich plasma

Rezaei *et al*., conducted an RCT comparing DVIU + platelet rich plasma (PRP) (n=44) vs. DVIU + saline (n=43) in primary, bulbar strictures < 1.5 cm in length [241]. The two-year stricture-free rate was 78% vs. 56% after DVIU with or without PRP, respectively (p=0.034). Complications were frequent but not significantly different between both groups (DVIU + PRP: 70%; DVIU + saline: 79%). All complications (urethral bleeding, haematuria, urethral pain, pelvic pain, urinary leakage and genitoperineal swelling) were classified as grade 1 according to the Clavien-Dindo system. Further validation of this treatment is needed before general clinical implementation.

Summary of evidence	**LE**
Intralesional injections after direct vision internal urethrotomy (DVIU) might improve stricture-free rates on the short-term compared to DVIU alone. Experience is limited and the use of these drugs are off-label. Significant uncertainty exists about drug, dose, volume and technique.	1a

Recommendation	**Strength rating**
Use intralesional injections only in the confines of a clinical trial.	Weak

6.2.3.3 Urethral stents

Urethral stents are designed with the aim to oppose wound contraction after dilatation or DVIU [242, 243]. Stent insertion is a short procedure (< 60 minutes) that can be done under local or spinal anaesthesia as “oneday” surgery [242, 244, 245]. Urethral stents are classified as permanent or temporary (removable, after six to twelve months).

6.2.3.3.1 Results

Permanent stainless-steel mesh stents are no longer commercially available. An RCT comparing dilatation/DVIU only vs. dilatation/DVIU followed by temporary stent insertion for bulbar strictures reported a significantly longer stricture-free survival time in favour of dilation/DVIU followed by stent (median 292 vs. 84 days; p < 0.001) [246]. Only 20.6% of patients treated with a stent developed a recurrent stricture within one year vs. 82.8% in the control group. These results are corroborated by a prospective series of Wong *et al*., who found a median stricture-free survival of two months after DVIU alone vs. 23 months after DVIU followed by temporary (three months) stent for bulbar strictures [243].

Failure and need for re-intervention are frequent (30-53%) and are usually because of stricture recurrence, stent encrustation, stent migration and urethral hyperplasia. Other complications include recurrent UTI, recurrent haematuria and genito-perineal pain (Table 6.5). Although stents are mainly used to treat bulbar strictures, they have been used for posterior stenoses as well. Stents used in the posterior urethra have a high risk (82-100%) of causing UI and this is most pronounced in patients with previous irradiation and/or strictures extending into the membranous or bulbar urethra [247]. In the bulbar urethra, the risk of UI is higher if stent placement is adjacent to the external sphincter [248]. The use of stents in the penile urethra is anecdotal. Jung *et al*., reported stent failure in 4/7 (57%) patients with a penile stricture after a mean follow-up of eight months. Of those patients who failed, no patient with distal or pan-penile strictures was rendered stricture-free [249]. In their series, stricture recurrence after stenting of the penile urethra was significantly higher when compared to the bulbar urethra [249]. Although no direct comparison is available, temporary stents tend to have fewer and less severe complications compared to permanent stents (Table 6.7).

6.2.3.4 Drug-coated balloon dilatation

Drug (paclitaxel)-coated balloon dilatation (DCBD) after standard dilatation or DVIU aims to reduce scar formation based on its antimitotic action. The ROBUST-3 trial prospectively randomized patients with predominantly bulbar strictures (< 3cm length) and at least two prior failed endoscopic treatments to DCBD (n=79) or standard dilatation/DVIU (n=48) [250]. Anatomic patency (assessed by cystoscopy) at six months was 75% for DCBD versus 27% after standard dilatation/DVIU (p<0.001). Estimated one year-retreatment free survival was 83% versus 22% for respectively DCBD and standard dilatation/DVIU (p<0.001). There were no serious adverse events related to DCBD although patients undergoing DCBD had a higher rate of hematuria and dysuria compared to controls (11.4% versus 2.1%). Paclitaxel was detected in semen up to six months after treatment which urges for contraception if the partner has child-bearing potential. If used, careful clinical review and prospective data collection ideally part of a post marketing registry or clinical trial is advised.

Summary of evidence	LE
Drug (paclitaxel)-coated balloon dilatation is associated with higher anatomic patency rates (at six months) and lower risk of retreatment (at one year) as compared to standard dilatation/DVIU in patients with short (< 3 cm), bulbar strictures that underwent at least two prior failed endoscopic treatments.	1b

Recommendation	Strength rating
Offer drug (paclitaxel)-coated balloon dilatation for a short (< 3 cm) bulbar stricture recurring after at least two prior endoscopic treatments, but only in patients for whom urethroplasty is not an option.	Weak

6.2.3.4.1 Treatment of stent failure

In the case of stent failure, subsequent urethroplasty (usually with stent removal) is possible, but this urethroplasty is very likely to be more complex than it would have been had it been performed initially [251-253]. Due to the fact that the stainless-steel wires are fully embedded into the urethral wall, over time the urethral spongiosum is severely damaged. Horiguchi *et al*., found that a history of urethral stenting was an independent significant predictor of increased stricture complexity (OR: 13.7; 95% CI: 1.7-318.3; p=0.01) and need for more complex urethroplasty (OR: 6.9; 95% CI: 1.1-64.5; p=0.04) [234]. The majority (62%) of patients in this study had a permanent stent and tend to be difficult to remove because they are epithelialised, usually within six months [234]. The type of urethroplasty required depends on the length of the stricture and quality of local tissues [252]. In the majority of cases, it is possible to preserve the urethral plate and to perform a one-stage substitution urethroplasty [251, 252, 254]. The patency rates after different types of urethroplasty vary greatly between 16.7-100% [251-254] and this variation probably reflects variation in complexity of the stricture, rather than that the superiority of one technique of urethroplasty over another (for further information see supplementary Table S6.2). Due to these limitations, the use of stents should be avoided if subsequent urethroplasty is considered [242, 253]. Urethral stents are not a first-line treatment for urethral strictures but can be considered in co-morbid patients who have a recurrent stricture after DVIU/dilatation and are unable to have more complex urethroplasty or who refuse urethroplasty [242, 246, 247].

Summary of evidence	LE
Permanent urethral stents have a high complications and failure rate and make subsequent urethroplasty more challenging if they fail.	3
Stents have a higher failure rate in the penile urethra.	3
Temporary stents after DVIU (direct vision internal urethrotomy) /dilatation at the bulbar urethra prolong time to next recurrence compared to DVIU/dilatation alone.	1b

Recommendations	Strength rating
Do not use permanent urethral stents.	Strong
Do not use urethral stents for penile strictures.	Strong
Use a temporary stent for recurrent bulbar strictures after direct vision internal urethrotomy to prolong time to next recurrence only if urethroplasty is not a viable option.	Weak

Table 6.5: Failure rate and complications associated with urethral stents

Study	Type of stent	Duration	N	FU (months)	Stricture length (cm)	Stricture location	Previous interventions	Failure rate	Defintion failure	Complications						
										UTI	haematuria	stent encrustation/ stone formation	stent migration	urethral hyper-plasia	Local pain	UI

DVIU = direct vision internal urethrotomy; FU = follow-up; NR = not reported; UI = urinary incontinence; UTI = urinary tract infection; VUAS = vesico-urethral anastomotic stricture; Q_{max}= maximum flow rate

6.3 Open repairs (urethroplasty): site and aetiology (clinical scenario) treatment options

6.3.1 The role of urethroplasty in the management of penile urethral strictures

Due to the specific aetiology and the associated problems, strictures related to failed hypospadias repair and LS will be discussed separately. However, many series reporting on the outcome of penile strictures have a mixed aetiology also including failed hypospadias repair and/or LS [255, 256]. Due to their specific location, distal penile strictures will be discussed separately.

6.3.1.1 Staged augmentation urethroplasty

Classically called "two-stage" urethroplasty, this approach may become a multi-stage urethroplasty as revision (usually due to graft contracture) after the first stage has been reported in 0-20% of cases [256-259]. Therefore, the term "staged" should be used instead [260]. Revision rates before second stage were 0-20%, stressing that a two-stage urethroplasty might become a multi-stage urethroplasty. In general, reconstructive urologists tend to follow this approach in men with more complex urethral stricture disease (multiple interventions in the past, unfavourable clinical findings such as significant spongiofibrosis or scarring that requires excision, poor quality of the urethral plate). An interval of at least four to six months has been proposed before proceeding to the tubularisation of the urethra, provided that the graft has healed uneventfully [261-263].

A SR by Mangera *et al*., has shown an average patency rate of 90.5% with the use of all types of grafts for staged penile urethroplasties with an average follow-up of 22.2 months [264]. Patency rates of staged oral mucosa graft (OMG) urethroplasty in specific locations vary between 73.3 and 100% [255, 256, 258, 259, 265, 266]. Post-operative urethrocutaneous fistula (UCF) rates were 17.2% and 2.6% in the studies of Ekerhult *et al*., and Joshi *et al*., respectively, and either not reported or unclear in the remaining studies [255, 256].

6.3.1.2 Single-stage augmentation urethroplasty

Single-stage urethroplasty offers the option for reconstruction of the stricture without the need for multiple operations, the associated peri-procedural risks, and the cosmetic and functional implications that by definition follow the first part of staged urethroplasties [267-269]. There is some evidence to suggest a considerable number of patients (50% or more in some studies) who were offered first stage urethroplasty never returned for the second stage because they were either satisfied with their functional status after the first stage (this particularly applied to older men or patients with multiple failed procedures in the past) or they were disappointed with the need for another operation [267, 268].

In the SR of Mangera *et al*., overall patency rate for all types of single-staged graft urethroplasties is 75.7% with an average follow-up of 32.8 months [264].

The patency rate for different one-stage techniques in particular are:

- dorsal OMG (n=320): 63-100% [265, 266, 259, 270-276];
- ventral OMG (n=54): 55-92.6% [265, 277, 278];
- double (dorsal + ventral) onlay with penile/scrotal skin graft /OMG (n=14/8/4): 88.5% [272];
- dorsal penile skin graft (n=44): 62-78% [272, 273];
- penile skin flap (n=367): 67-100% [265, 266, 272-274, 279].

No high-level evidence exists to state that one technique is superior to another, but it seems that the dorsal graft location is more commonly used compared to the ventral one. Mangera *et al*., reported that the patency rate was better with OMG compared to other grafts (mainly penile skin) [264]. Jiang *et al*., showed that combined (dorsal + ventral) BMG onlay had significantly better stricture-free rates for penoscrotal strictures (patency rate 88.9% vs. 60.9% with single-onlay approach); however, follow-up was significantly shorter in the double-onlay group [280]. Few studies have reported dedicated results on sexual function parameters that do not appear to be significantly impaired post-operatively [258, 281].

A critical factor with respect to single-staged procedures is the careful selection of patients, as men with long and complex strictures might not be good candidates for single-stage reconstruction and attempts to offer single-staged operations in these patients might lead to higher recurrence rates. Sometimes, this selection can only be done based on intra-operative findings. Therefore, any scheduled single-staged procedure might be converted into a staged one [267, 282]. Palminteri *et al*., highlighted the fact that single-stage augmentation urethroplasties in men with LS-related strictures enlarge rather than remove the diseased segment of the urethra; therefore, there is always a risk of recurrence in the future [283]. The role of previous interventions (especially multiple urethrotomies or history of previous urethroplasties) remains unclear as several studies on single-staged operations do not provide information on previous procedures, or excluded patients with operations in the past [274, 281]. Although favourable outcomes in patients with previous history

of urethrotomies/urethroplasties were reported by Barbagli and Kulkarni, in the study by Pfalzgraf *et al*., all recurrences post-previous urethroplasty took place in the single-stage group while Ekerhult *et al*., identified prior history of urethral operations as a risk factor for recurrence in the group of single-stage procedures [255, 258, 259, 272]. In addition to previous urethral surgery, high BMI has also been identified as a poor prognostic factor after single-stage penile urethroplasty [255].

6.3.1.3 Anastomotic urethroplasty in men with penile urethral strictures

Historically, the use of anastomotic urethroplasty in the management of urethral stricture disease has been discouraged due to the risk of chordee post-operatively [263, 284]. Nevertheless, it has been performed in selected patients with very short strictures (usually < 1 cm) with 80-93% patency rate, with satisfactory QoL and sexual function and without any case of chordee [285] and with results comparable to augmentation urethroplasty [286].

Summary of evidence	**LE**
Stricture-free rates for single-stage penile augmentation urethroplasties range from 70%-100% for dorsal OMG augmentation, 67-100% for penile skin flap (PSF) augmentation, 55-92.6% for ventral OMG augmentation and 62-78% for dorsal SG augmentation. Overall stricture-free rates for staged OMG penile augmentation urethroplasties range from 70-100%.	2b
In staged urethroplasties, an interval of at least four to six months has been proposed before proceeding to the tubularisation of the urethra, provided that the graft has healed uneventfully.	4
The use of anastomotic urethroplasty in the management of urethral stricture disease has been discouraged due to the risk of chordee post-operatively. Anastomotic urethroplasty can be offered in selected cases of very short (< 1 cm), injury-associated penile strictures.	3
In case of adverse intra-operative findings, a single-stage approach might not be feasible and must be converted into a staged approach.	3

Recommendations	**Strength rating**
Offer men with penile urethral stricture disease augmentation urethroplasty by either a single-stage or staged approach taking into consideration previous interventions and stricture characteristics.	Strong
Offer an interval of at least four to six months before proceeding to the second stage of the procedure provided that outcome of the first stage is satisfactory.	Weak
Do not offer anastomotic urethroplasty to patients with penile strictures > 1 cm due to the risk of penile chordee post-operatively.	Strong
Counsel patients with penile strictures that single-stage procedures might be converted to staged ones in the face of adverse intra-operative findings.	Strong

6.3.1.4 Specific considerations for failed hypospadias repair-related strictures

The term "failed hypospadias repair" (FHR) includes a wide range of abnormalities after previous attempts for reconstruction, such as glans deformity, recurrent urethral stricture, glans/urethral dehiscence, UCF and penile chordee [287-289]. The management of FHR is challenging as the urethral plate, penile skin and dartos fascia are often deficient/non-existent. Management of these patients is often made more difficult due to incomplete health records and a lack of critical information (original meatal site, number, and type of previous repairs) [261, 290]. In addition, multiple operations might need to be offered to reach satisfactory outcomes [287]. As a result, FHR should always be considered as a complex condition and it is advised that FHR management takes place in high-volume centres [288, 289, 291, 292].

"Hypospadias cripples" is a term widely used to describe the group of men with multiple previous failed attempts to correct the condition resulting in unfavourable results such as severe scarring, penile deformity and shortening, hair or stones in the urethra, UCF, chordee and functional disorders (e.g., urinary, or sexual dysfunction). This term should be avoided and a more neutral one should replace it as it further stigmatises men with hypospadias who have been shown to have reduced self-esteem and confidence due to unsatisfactory cosmesis, and problematic urinary and sexual function. Moreover, it has been reported that FHR patients experience high rates of disappointment after failure of attempted repair and a sense of helplessness as they are frequently advised that their failed hypospadias is too complex to correct and they should not pursue further repair [288-290, 293, 294].

Two main approaches are applicable: single-stage or staged procedures. In general, it is advised that staged procedures should be followed when the urethral plate is inadequate for a single-stage operation. Surgeons should consent patients for both types of urethroplasty as the surgical approach might need to be modified intra-operatively depending on favourable/unfavourable intra-operative findings. Besides poor-quality of the urethral plate, these unfavourable findings include high degree of scarring and presence of concomitant LS, UCF and/or chordee. It is not uncommon for men with FHR to have scarred skin or concurrent LS and thus, skin grafts or flaps should be avoided as the risk of recurrence due to LS is very high (90% in long-term follow-up as reported by Depasquale *et al*.) [39, 295, 296].

Staged repairs (using mainly BMG) reported patency rates ranging from 71-95% [293, 295, 257, 297, 298], while single-stage repairs had patency rates from 80-100% [295, 297, 299-302]. It needs to be highlighted that, as FHR is an umbrella term that covers various clinical conditions apart from urethral stricture disease only (such as UCF, chordee, penile deformity), "success" rates as reported by the authors in their studies do not represent urethral patency rates only. Unfortunately, the number of previous operations is either not reported or refers to the whole FHR study group collectively rather than to the subgroups of staged/single-staged procedures.

A comparative analysis is reported by Barbagli *et al*., in 345 FHR patients at five-year follow-up. Overall failure-free survival rate was 48% for all urethroplasties, and in sub-analysis, staged techniques had significantly lower treatment failure-free survival rates compared to single-stage techniques [303]. However, it is unclear whether these groups were comparable in terms of baseline characteristics such as age, length of stricture, number of procedures, comorbidities etc. [303]. If the patients in the staged group had a more unfavourable background, this on its own could explain the final outcome rather than the surgical approach itself.

Kozinn *et al*., reported a 16% and 14% revision rate after the first and second stage, respectively, and observed that these revision rates were higher in the FHR group compared to non-FHR patients with penile strictures [257]. There is conflicting evidence whether FHR as aetiology is a poor prognostic factor in the outcome of urethroplasty for penile strictures [255, 304-306]. Concomitant UCF can be successfully managed at the same time of urethroplasty [303].

Saavendra *et al*., reported 89.3% stricture-free rate in 56 FHR patients with penile urethral strictures at a median of 21 months follow-up using mainly staged urethroplasty and perineal urethrostomy. Verla *et al*., presented departmental experience with the use of various urethroplasty techniques in a total of 76 FHR patients with penile strictures. Follow-up was long, at a median of 89 months and stricture-free rates ranged from 29% (anastomotic repair) to 90% first stage only of multistage urethroplasty).

For further information see supplementary Table S6.3.

Summary of evidence	**LE**
Men with failed hypospadias repair (FHR) have history of multiple interventions, and poor-quality tissues, and might require complex procedures for a satisfactory functional and cosmetic outcome.	4
Men with FHR may have low self-esteem due to urinary and sexual dysfunction and unsatisfactory cosmesis.	2b
Men with FHR can have scarred penile skin or concurrent lichen sclerosus and outcomes with skin grafts or flaps can be unsatisfactory.	3

Recommendations	**Strength rating**
Men with failed hypospadias repair (FHR) should be considered complex patients and referred to specialist centres for further management.	Weak
Propose psychological and/or psychosexual counselling to men with unsatisfactory cosmesis and sexual or urinary dysfunction related to FHR.	Weak
Do not use penile skin grafts or flaps in failed FHR patients with lichen sclerosus or scarred skin.	Strong

6.3.1.5 Specific considerations for lichen sclerosus-related penile urethral strictures

Given the fact that LS affects the skin, the use of genital skin as a flap or graft is not advised as the risk of disease recurrence has been reported to be high (50-100%) and while most of recurrences tend to occur within the first two to three post-operative years, late recurrences have been reported [307].

Main strategies are single-stage or staged oral mucosa graft urethroplasty.

The EAU Urethral Strictures Guidelines Panel conducted a SR [6] to explore the role of single-stage oral mucosa graft urethroplasty in the management of LS-related urethral strictures and to compare its outcomes with alternative management options (surgical dilatations +/- ISD; surgical dilatations + local steroids +/- ISD; staged oral mucosa urethroplasty; penile skin urethroplasty; meatotomy/meatoplasty; urethrotomy [Otis, DVIU]; perineal urethrostomy; urinary diversion [e.g., suprapubic catheterisation]).

In total, fifteen studies met the inclusion criteria, recruiting a total of 649 patients (366 from five non randomised comparative studies and 283 from ten, single-arm retrospective observational studies). Singlestage OMG urethroplasty resulted in success rates ranging from 65-100% after twelve to 67 months mean or median follow-up. For staged OMG urethroplasty, the most commonly reported comparator, the success rates were somewhat lower and varied between 60-79%. Methodological issues (mainly selection bias) could explain the difference in success rates rather than the intervention itself. Complications were uncommon (0-12%) and mainly comprised Grade 1-3 events.

Due to the overall very poor quality of evidence, the SR did not provide a clear answer as to whether singlestage OMG urethroplasty is superior to other management options, although careful patient selection is highlighted. In the absence of adverse local tissue conditions, a single-stage approach could lead to high success rates with an improvement in voiding symptoms and QoL.

Summary of evidence	**LE**
Lichen sclerosus is a skin condition that can lead to scarring, and recurrence rates after skin graft/flap augmentation urethroplasties have been reported to be high (50-100%).	4
Single-stage oral mucosa graft (OMG) urethroplasty provides patency rates between 65 and 100% and is not inferior to staged OMG urethroplasty.	3

Recommendations	**Strength rating**
Do not use genital skin in augmentation penile urethroplasty in men with lichen sclerosus (LS) related strictures.	Strong
Perform single-stage oral mucosa graft urethroplasty in the absence of adverse local conditions in men with LS related strictures.	Weak

6.3.1.6 Distal urethral strictures (meatal stenosis, fossa navicularis strictures)

Open repair of distal urethral strictures can be in the form of Malone meatoplasty, skin flap meatoplasty or graft (skin [SG]/OMG) urethroplasty.

For short distal meatal strictures, the Malone meatoplasty (dorsal + ventral meatotomy) provides a technique with patency rates up to 100%, and 83% patient-reported satisfaction with the cosmetic results [308]. Similarly, Hofer *et al*., presented their technique variation (ventral excision of scar and eversion of the urethral mucosa) and showed 81% stricture-free rates at 41-month mean follow-up.

Skin flap meatoplasty showed excellent patency rates ranging from 90-96% based on three studies comprising 67 patients [309-311]. In addition, based on their results, patient satisfaction with post-operative outcomes and cosmesis was high, there were no cases of ED and functional complaints were minimal (mainly spraying of the urine flow).

Patency rates with the use of grafts (OMG or SG) ranged from 69-91% in 106 patients overall [312, 313, 300]. Where reported, patients were satisfied with cosmesis, and mild spraying of the urine flow self-resolved. Although tubularised grafts in a single-stage procedures are not routinely recommended (see also section 9. Tissue transfer), one series reported an 89.9% patency rate for this approach ("two-in one approach") in selected patients with mainly distal penile strictures [314].

Finally, Daneshvar *et al*., presented a novel transurethral ventral inlay OMG technique and showed excellent stricture-free rates (96%) at short follow-up though (median 16 months).

For further information see supplementary Table S6.4.

Summary of evidence	LE
Post-meatoplasty/urethroplasty patency rates in men with meatal stenosis or fossa navicularis/distal urethral strictures range between 57-100% depending on type of surgical intervention with high patient satisfaction and minimal complications.	3

Recommendation	Strength rating
Offer open meatoplasty or distal urethroplasty to patients with meatal stenosis or fossa navicularis/distal urethral strictures.	Weak

*6.3.2 **Urethroplasty for bulbar strictures***

6.3.2.1 "Short" bulbar strictures

The length of a "short" bulbar stricture is poorly defined. In general, "short bulbar strictures" are those amenable to stricture excision and subsequent tension-free anastomotic repair. The limit is usually around 2 cm [315].

In fit patients, the choice of urethroplasty is between EPA (transecting or non-transecting) and FGU.

6.3.2.1.1 Excision and primary anastomosis

6.3.2.1.1.1 Excision and primary anastomosis with transection of corpus spongiosum (transecting EPA)

Transecting EPA (tEPA) is based on the full thickness resection of the segment of the bulbar urethra where the stricture and surrounding spongiofibrosis is located. Reconstruction is performed by a tension-free spatulated anastomosis.

6.3.2.1.1.1.1 Patency rates

The International Consultation on Urological Diseases (ICUD) performed an extensive review of the literature and reported a composite patency rate of 93.8% for tEPA [316]. Based on this, they endorsed tEPA as treatment of choice for short bulbar strictures if other techniques have an expected patency rate below 90%. However, penile complicationswere not taken into account for this advice and as discussed below, these are a concern with tEPA.

Prospective data report a patency rate of 88% at twelve months follow-up [315].

Usually, no need for further intervention is used to evidence that the urethra is patent. In the few studies using an anatomic definition for failure (an inability to pass a 16 Fr endoscope) tEPA urethroplasty achieves a similar patency rate, ranging between 85.5-97% [145, 317-319] (Table 6.12). The median time for recurrence after tEPA is between 3.5 and thirteen months [145, 320, 321].

Several authors suggested that tEPA is the technique of choice for short post-traumatic bulbar strictures with complete obliteration of the urethral lumen and full thickness spongiofibrosis [319, 322]. These strictures are a specific entity and usually the result of a straddle injury with complete or nearly complete rupture of the bulbar urethra. These obliterations are predominantly short and can be treated with tEPA yielding a patency rate of 98.5% as reported in the series of Horiguchi *et al*., [323]. They also reported an improvement in erectile function after urethroplasty measured one year post-operatively. Straddle injury (and perineal trauma) are a common aetiology in papers published about tEPA; however, separate data on the outcomes for this specific aetiology is usually lacking.

6.3.2.1.1.2 Complications

Nilsen *et al*., conducted an RCT comparing tEPA with FGU for short (< 2 cm) bulbar strictures [315]. Compared to FGU, penile complications were more frequent with tEPA. After three months, worse ejaculation (26%), reduced glans filling (26%), penile shortening (16%) and penile chordee (10%) were significantly more reported with tEPA. After 12 months, reduced glans filling (19%) and penile shortening (26%) remained significantly more reported with tEPA. A scrotoperineal hematoma was significantly more frequent with tEPA compared to FGU (resp. 24 versus 4%). Despite these complications IIEF-5 was not significantly different between both groups at three and twelve months.

These latter complications (as well as ED) might be attributed to complete transection of the corpus spongiosum at the level of the stricture, thereby disrupting the antegrade blood flow of the urethra and corpus spongiosum. To spare this, the non-transecting EPA (ntEPA) has been described [324] and later modified [325].

6.3.2.1.1.2 Non-transecting excision and primary anastomosis

6.3.2.1.1.2.1 Patency rates

Except for straddle injuries that are usually associated with complete obliteration of the lumen and full thickness scarring of the corpus spongiosum [319, 326], ntEPA is a good alternative for short bulbar strictures of all other aetiologies. With median follow-ups ranging between 17.6 and 37.1 months, the patency rates reported are 93.2-99%; with the lack of further intervention as success criteria [322, 327, 328]. Even with the anatomic criteria (16 Fr cystoscopy passage) the success rate achieved was 97.9% at twelve months [319] (see supplementary Table S6.7).

Two comparative analyses evaluated tEPA vs. ntEPA. Waterloos *et al*., reported patency rates of 88.4% and 93.2%, respectively, for tEPA and ntEPA (p=0.33) but with significantly longer follow-up for tEPA (118 vs. 32 months, p < 0.001). Of patients scheduled for ntEPA, 11.1% were converted to tEPA, highlighting that ntEPA is not always possible. Chapman *et al*., using anatomic success criteria (16 Fr cystoscope passage), reported patency in 93.8% of tEPA vs. 97.9% of ntEPA. Follow-up was also significantly shorter at 74.1 (SD: 45.4) months for tEPA vs. 37.1 (SD: 20.5) months for ntEPA (p < 0.001) [319].

6.3.2.1.1.2.2 Complications

When erectile function after urethroplasty was assessed (at six months), ntEPA had significantly lower ED rates (a decrease of > 5 points on the sexual health inventory for men [SHIM] scale) compared to tEPA (4.3 vs. 14.3%, respectively) [319]. Urethral transection performed during tEPA was the only factor associated with sexual dysfunction in a multivariate analysis [319]. Other series reported ED lasting for more than six months in 2-6% of cases after ntEPA [322, 328, 329]. Grade > 2 Clavian-Dindo complications were 3.6-8.1% vs. 4.3-6.8%, respectively, for tEPA and ntEPA, without reaching statistical significance [319, 327].

To date, no trials comparing ntEPA with FGU have been published to report on comparative patency outcomes and complications.

6.3.2.1.2 Free graft urethroplasty

Despite the very high patency rates of EPA, FGU has been performed for short bulbar strictures as well. This is mainly driven by reports of ED after EPA. A meta-analysis of ten papers [340] comparing tEPA with BMG FGU for short strictures, found that tEPA is better than BMG FGU in terms of patency rates (91.5% vs. 70%), whilst BMG FGU has less erectile complications (9% vs. 25%). However, the methodology of this meta-analysis must be disputed as it was performed on cohort studies without risk of bias assessment and without further specification of timing of assessment of ED. On the other hand an RCT comparing tEPA with BMG FGU, found no significantly different patency rates for EPA compared to BMG FGU (88% versus 87% respectively) and no significant differences in erectile function for tEPA compared to BMG FGU [315]. As mentioned earlier, penile complications were more frequent with EPA.

Dogra *et al*., [283] looked prospectively at sexual function in 87 patients after different urethroplasties (EPA, penile/bulbar substitution) and found a 20% reduction in sexual function in all groups, which resolved after six months.

Details on where to place the graft during FGU are discussed below.

Summary of evidence	**LE**
For short post-traumatic strictures tEPA has good patency rates.	3
For short bulbar strictures not related to straddle injury tEPA, ntEPA and FGU have the same patency rates, but ntEPA and FGU have less erectile dysfunction or penile complications than tEPA.	1b-3*

**LE1b for comparison between tEPA and FGU and LE3 for tEPA versus ntEPA versus FGU*

Recommendations	Strength rating
Use transecting excision and primary anastomosis (tEPA) for short posttraumatic bulbar strictures with (nearly) complete obliteration of the lumen and full thickness spongiofibrosis.	Strong
Use non-transecting excision and primary anastomosis or free graft urethroplasty instead of tEPA for short bulbar strictures not related to straddle injury.	Weak

6.3.2.2 "Longer" bulbar strictures

6.3.2.2.1 Free graft urethroplasty

For strictures not amenable to EPA, FGU is the technique of choice and buccal mucosa is, at the moment, the most widely used graft. Other grafts (and flaps) are possible and discussed in the tissue transfer chapter. Patency rates of FGU of the bulbar urethra are 88-91% with twelve to 40 months follow-up [264, 330]. There is a suggestion that patency rates deteriorate with time [331].

During bulbar urethroplasty, the bulbospongiosus muscle is usually separated at the midline which may cause damage to the muscle and perineal nerves. This might subsequently provoke post-void dribbling and ejaculation disorders. In order to reduce this, the muscle and nerve-sparing perineal approach has been introduced [332]. Although it is mostly used in graft urethroplasty, this approach is also possible for EPA [333]. Elkady *et al*., [329] randomised 50 patients between a muscle and nerve-sparing perineal approach vs. a classic perineal approach and found no difference in operative time (100 vs. 105 min), but significantly less dribbling (4% vs. 36%, p=0.01), and significantly less ejaculatory changes (8% vs. 40%, p=0.02) in the nerve and muscle-sparing group. Fredrick *et al*., [333] did the same in 50 patients in a multicentric study with bulbar urethroplasty but could not find a statistical difference regarding post-void dribbling and ejaculatory changes. Due to the limited and conflicting evidence, no recommendation can be made about the routine use of nerve and muscle-sparing modification during bulbar urethroplasty.

See supplementary Table S6.8 for further information.

6.3.2.2.2 Augmented anastomotic repair

Augmented anastomotic repair has been described for these strictures. It has been mainly performed in cases where the stricture was just too long (+/- 2-4 cm) for tension-free EPA [334]. It can also be performed for longer strictures with a shorter (nearly) obliterative segment [335]. In this case, only the most obliterative segment is excised, the urethral plate is anastomosed, and the urethra is further reconstructed with an onlay graft [335]. Patency rates after AAR vary between 91.1 - 91.9% with twelve to 28 months follow-up [334]. The use of this technique has been challenged by Redmond *et al*., who found a 4.8 higher risk of recurrence when AAR was used compared to (dorsal) free graft urethroplasty [336] (see supplementary Table S6.9).

A non-transecting alternative has also been described to overcome the previously mentioned inconveniences related to spongiosal transection (augmented non-transecting anastomotic bulbar urethroplasty [ANTABU]). With this technique, Bugeja *et al*., [337] reported a 100% patency rate in sixteen patients after a median follow-up of thirteen months. One patient (6.7%) suffered permanent ED.

Summary of evidence	LE
For strictures not amenable to EPA, FGU provides an 88-91% patency rate at short to medium follow-up	1b
Augmented anastomotic repair provides good (88-92%) patency rates for bulbar strictures with a nearly obliterative segment, despite deterioration with time.	3

Recommendations	Strength rating
Use free graft urethroplasty for bulbar strictures not amendable to excision and primary anastomosis (EPA).	Strong
Use augmented anastomotic repair for bulbar strictures not amenable to EPA but with a short, nearly obliterative segment within the whole strictured segment.	Weak

6.3.2.2.3 Location of the graft during urethroplasty for bulbar strictures

The best location for graft positioning into the bulbar urethra remains to be determined. There are many techniques described with ventral, lateral, dorsolateral, or dorsal graft as an onlay or an inlay. Onlay means from the outside onto the urethra, inlay means from the inside after opening the urethra.

Regarding the site of graft placement, the Panel has conducted a SR assessing the literature from 1996 onwards, including studies with at least 20 patients and a minimum of twelve months follow-up [7]. This yielded one RCT, four non-randomised comparative series and 36 case series comprising 3,683 patients. The RCT of Vasudeva *et al*., compared ventral (n=40) with dorsal (n=40) onlay BMG urethroplasty and reported a patency rate of 90 - 92.5%, respectively at twelve months follow-up (p=0.51) [330]. The non-randomised comparative studies could not identify any significant differences in patency rates for dorsal onlay vs. ventral onlay, dorsal inlay vs. ventral onlay or dorsal onlay vs. ventral onlay vs. dorsolateral onlay. Case series reported a patency rate of 62.1-98.3% for dorsal onlay, 74.3-94.4% for ventral onlay and 78.4-92% for dorsal inlay. There are no arguments to assume a higher risk of ED with one of the four techniques. Post-void-dribbling was reported in 0-28.1% with dorsal onlay and in 20-21% with ventral onlay. Other complications were also similar in incidence between techniques. Urethrocutaneous fistula and urethral diverticulum were only reported with the ventral onlay technique although this consisted of only two and one cases, respectively.

Double ventral-dorsal onlay, proposed for high-grade/nearly obliterative strictures, yielded a patency rate of 90-91% after 22-33 months follow-up [146, 338].

Summary of evidence	**LE**
Location of the graft has no impact on patency rates.	1b

Recommendation	**Strength rating**
Use dorsal, dorsal-lateral, or ventral approach according to surgical practice, expertise, and intra-operative findings.	Strong

6.3.2.3 Staged urethroplasty for bulbar urethral strictures

6.3.2.3.1 Indications

Staged urethroplasty may be considered when:

- there are locally adverse conditions such as fistula, false passage, abscess, cancer [282, 339, 340];
- there has been a previously unsuccessful complex urethroplasty including failed hypospadias repair [257, 339];
- there is a lack of certainty on behalf of the surgeon regarding the most appropriate form of urethroplasty for the patient [339];
- the stricture is radiotherapy induced [257];
- the stricture is consequent to LS [257] (this is controversial and for some groups LS is a contraindication for a staged urethroplasty [305]; Kozinn *et al*., recommend leaving at least ten months between 1st stage and 2nd stage re-tubularisation in patients with LS to allow graft complication to develop) [257];
- there is severe spongiofibrosis [341].

6.3.2.3.2 Outcomes

Patency rates of 33.3-94.6% at mean follow-up of 11.2-50 months have been described for staged urethroplasty in series which include men with bulbar urethral stricture disease [257, 305, 318, 341-343]. Grafts (mesh graft, preputial skin, oral mucosa) can be used in staged augmentation as well as marsupialisation [318, 341]. In patients affected by LS, a 52.2% patency rate for staged urethroplasty was reported whereas this was 86% for single-stage buccal mucosa urethroplasty ($p < 0.01$) [305]. It is highly likely that different stricture and patient characteristics contributed to the differences reported and this should be kept in mind when interpreting the data. Of note, 19-45.5% of patients planned for staged urethroplasty declined to proceed to 2nd stage re-tubularisation [257, 342].

Early complications after staged procedures include wound dehiscence, UTI, epididymitis, scrotal abscess, and penile numbness. Specific to 2nd stage Johanson urethroplasty UCF occurs in 3-15%. The actual incidence of UCF is probably higher as many small fistulae close spontaneously with conservative management and are not formally reported [305, 318, 341].

Late complications of 1st stage urethroplasty include a need for revision in up to 19% - as a consequence of recurrence of LS in graft(s) (8.8%), graft contracture (6.6%) and stomal stenosis (3.3%) [257]. Late complications of 2nd stage urethroplasty include post-micturition dribble in 14-18%, SUI in up to 16%, penile curvature in up to 9%, ED in up to 4%, urethral diverticulum formation in 1% and cold glans [305, 341, 343]. Stress urinary incontinence, penile curvature and ED appear to be particularly associated with mesh graft stage urethroplasty [341, 343].

After their procedure, 86% and 96.6% of men with, respectively, mesh graft and buccal mucosa graft staged urethroplasty were satisfied. The patient groups included in the review were too small to detect significant differences [341]. All are retrospective series – with heterogenous indications, stricture locations (not exclusively bulbar), stricture lengths and patient groups. It is consequently difficult to draw meaningful conclusions from the little data that are available.

See supplementary Table S6.10 for more information.

Summary of evidence	LE
Staged urethroplasty for bulbar strictures and for strictures involving the bulbar urethra yields patency rates of 33.3-90% depending upon patient and stricture characteristics and patient satisfaction is high with all types of staged urethroplasty.	3
Lichen sclerosus is a relative contraindication for staged urethroplasty in the literature with lower long-term urethral patency rates of 52.2% compared to urethral patency rates of 64.3% in non-lichen sclerosis patients.	3
Up to 45.5% of men elect not to proceed to 2nd stage re-tubularisation after successful 1st stage.	3
Up to 19% of men required revision of their 1st stage urethroplasty.	3

Recommendations	Strength rating
Offer staged urethroplasty to men with complex anterior urethral stricture disease not suitable for single stage urethroplasty and who are fit for reconstruction.	Weak
Do not perform staged bulbar urethroplasty for lichen sclerosis if single stage urethroplasty is possible.	Weak
Consider staged procedure in patients unsure about perineal urethrostomy versus urethral reconstruction.	Weak
Warn men that staged urethroplasty may comprise more than two stages.	Weak

6.3.2.3.3 Risk factors

There is a lot effort in identifying risk factors affecting the success rate of urethroplasties.

The evidence is not clear about age, obesity, aetiology or prior radiation or prior surgery. The only clear risk factors in multivariate analysis are the length and the site of the stricture, success rates are better in shorter or bulbar strictures and worse in longer or penile strictures [317, 344-346]. Patient should be informed about the higher risk in longer and penile strictures.

6.3.2.3.4 Risk factors for adverse outcomes

In four series specifically dedicated to risk factors for failure after urethroplasty using multivariate analysis, there is conflicting evidence about several factors (aetiology, comorbidity, stricture length, prior therapy) that might be predictive for failure after urethroplasty (Table 6.6). Advanced age does not appear to be a risk factor for urethroplasty failure in the majority of studies, with the exception of Viers *et al*., 2017 [347] retrospective case series which found that the risk for recurrence was significantly higher beyond the age of 60 (< 50 yrs 94%, > 70 yrs 74%) in 184 patients having a wide variety of urethroplasties. Previous radiation therapy was also found to be a risk factor for stricture recurrence in both Viers' [347] retrospective case series and Ahyai's 2015 series [348] – with only a 71% patency rate at a median follow-up of 29 months in those with previous radiotherapy. Based on these data, a clear and evidence-based recommendation cannot be formulated.

Table 6.6: Risk factors for failure after urethroplasty based on multivariable Cox regression analyses

Study	N	Population	Comorbidity HR (95% CI)	Length HR (95% CI)	Aetiology HR (95% CI)	Prior stricture therapy HR (95% CI)
Breyer *et al*. 2010 [349]	443	Mixed	NS	NS	NS	Prior DVIU: 1.7 (1.0-3.0) Prior urethroplasty: 1.8 (1.1-3.1)

Kinnaird *et al.* 2014 [350]	604	Mixed	NS	≥ 5 cm: 2.3 (1.2-4.5)	Iatrogenic: 3.4 (1.2-10.0) LS: 5.9 (2.1-16.5) Infectious: 7.3 (2.3-23.7)	NS
Chapman *et al.* 2017 [317]	596	Isolated bulbar strictures	Overall comorbidity: 2.4 (1.1-5.3) Obesity: 2.9 (1.3-6.5)	1.2 (1.1-1.3)	Infectious: 3.7 (1.3-10.6)	NS
Verla *et al.* 2020 [351]	474	Anterior strictures	NS	NS	NS	NS

CI = confidence interval; HR = hazard ratio; LS = lichen sclerosus; N = number of patients; NR = not reported NS = not significant.

6.3.2.4 Management of recurrence after bulbar urethroplasty

Kahokehr *et al*., [334] followed nearly 400 patients after urethroplasty and found a recurrence rate of 6% (n=25). Ninety-two percent of the failed cases were treated successfully with DVIU and only 8% needed another open reconstruction. However, they did not mention characteristics of the recurrent cases nor the duration of follow-up. Rosenbaum *et al*., [352] and Javali *et al*., [353] retrospectively analysed the outcomes of BMG FGU for ReDo urethroplasty in 51 and 21 patients, respectively, using the other cheek as donor side. Patency rates were 82-86%, which is in the range of primary cases.

Vetterlein *et al*., [354] compared primary (no previous open urethroplasty) vs. ReDo (previous open urethroplasty with BMG) vs. secondary (previous open urethroplasty without use of BMG) cases in a retrospective series of 534 patients with BMG FGU. The patency rates in primary and ReDo cases were comparable (87%) whilst the outcome in secondary cases was worse (71%).

A small series (n=37) reported on the use of EPA for revision surgery after failed urethroplasty in strictures of 2.1 (range 1-3.5) cm length on average. Patency rates using EPA after failed primary EPA (51%) and after any other technique of urethroplasty (49%) were 95 and 94% respectively with a mean follow-up of 30 months [321].

Summary of evidence	**LE**
Buccal mucosa free graft urethroplasty after failed urethroplasty achieves the same patency rates as primary cases.	3

Recommendation	**Strength rating**
Use oral mucosa free graft urethroplasty for ReDo urethroplasty in case the of a long stricture.	Strong

*6.3.3 **Urethroplasty for penobulbar or panurethral strictures***

The possibilities for reconstruction are various and often include combinations of different techniques or grafts other than OMG. The patency rates are usually lower than in shorter reconstructions (Table 6.7). Hussein *et al*., [355] performed a RCT comparing skin grafts vs. skin flaps in strictures of mean length 15 cm and found no difference in patency rates (72% vs. 79%) or complications.

Warner *et al*., [305] performed a multi-institutional review in 2015 including 466 patients with stricture length > 8 cm and found an overall patency rate of 77.5%. As discussed previously, Kozinn *et al*., [257] reported on the outcome of staged urethroplasty in a cohort of which 54.9% had panurethral strictures (Table 6.7).

Kulkarni *et al*., [356] proposed a one-stage completely perineal approach with invagination of the penis and one-sided urethral dissection. After 59 months the overall patency rate was 83.7% in 117 men with a mean stricture length of 14 cm.

Another option in patients refusing or unfit for complex reconstructive surgery is PU (see section 6.3.4 Perineal urethrostomy).

Table 6.7: Study characteristics and patency rates of series on penobulbar strictures

Author	Study	Length in cm (min, mean, range)	Technique	N	FU months (mean, range)	Patency
Hussein *et al*. 2011 [355]	RCT	NR, 15, 9-21	Skin graft vs. flap	37	36, 12-60	72 vs. 79%
Hussein *et al*. 2016 [357]	Prospective	NR, 8, NR	BM vs. skin dorsal onlay	69	56, NR	90 vs. 84%
Warner *et al*. 2015 [305]	Retrospective review	> 8, 12.5, 8-24	BM/staged/skin	466	20, 12-344	77.5%
El Dahshoury *et al*. 2009 [358]	Retrospective	NR, 18, 15-20	Skin flap	30	24, NR	87%
Mathur *et al*. 2010 [359]	Retrospective	NR, 12, 8-16.5	Tunica albuginea graft	86	36, NR	89%
Meeks *et al*. 2010 [360]	Retrospective	NR, 11, 4-24	Abdominal skin graft	21	28, 11-52	81%
Kulkarni *et al*. 2012 [356]	Retrospective	NR, 14	BM dorsal onlay	117	59, NR	83.7%
Tabassi *et al*. 2014 [361]	Retrospective	NR, 14.4, NR	BM dorsal onlay	117(37)	19, NR	84%
Xu *et al*. 2017 [301]	Retrospective	> 8, 12, 8-20	BM/LM/combination	81	>12, 41, 15-86	83%
Alsagheer *et al*. 2018 [362]	Retrospective	> 8, 11.3	BM onlay vs. skin flap	50	NR, 16, NR	70 vs. 77%
Kozinn *et al*. 2013 [257]	Retrospective	NR, 9.6, 4-17	Staged urethroplasty	91	15, 12-69	90.1%

BM = buccal mucosa; LM = lingual mucosa; FU = follow-up; N = number of patients; NR = not reported; RCT = randomised controlled trial.

Summary of evidence	LE
Publications about panurethral urethroplasties generally come from high volume centres.	4
Different materials and techniques might be needed for reconstruction.	3

Recommendations	Strength rating
Offer panurethral urethroplasties in specialised centres because different techniques and materials might be needed.	Weak
Combine techniques to treat panurethral strictures if one technique is not able to treat the whole extent of the stricture.	Weak

*6.3.4 **Perineal urethrostomy***

6.3.4.1 Indications

Perineal urethrostomy offers a permanent or temporary solution for restoration of voiding in men with complex urethral stricture disease in whom:

- there are no further options to restore urethral patency either due to multiple previous failed urethroplasties [305, 339] or multiple co-morbidities precluding a more expansive surgical undertaking after failed endoscopic management [363];
- there is a lack of certainty on behalf of the surgeon regarding the most appropriate form of urethroplasty for the patient;
- following urethrectomy and/or penectomy for cancer [364].

6.3.4.2 Types of perineal urethrostomy

Johanson described an inverted anterior scrotal funnel PU in 1953. This was later modified by Gil-Vernet and Blandy to utilise a posteriorly based scrotal flap. Both these techniques utilise an inverted U or lambda incision. The Gil-Vernet-Blandy PU has been further modified with the addition of dorsal and/or ventral free OMG augment

to allow use of PU in men with strictures consequent to radiotherapy [365] or LS [259] and/or in men with PU stenosis or stricture extending into the proximal bulbar or membranous urethra ("augmented Blandy") [363].

More recently, the '7 flap' PU utilising a unilateral posteriorly based scrotal flap has been developed for use in the very obese, or in men of all BMI with stricture extension into the proximal bulbar or membranous urethra [366]. Initially this was performed with transection of the distal bulbar urethra but latterly the technique has been modified to a non-transection technique with loop mobilisation of the bulbar urethra ("loop PU") [367]. The "7-flap" utilises a midline incision – which has been shown to have a significantly reduced side-effect profile in terms of superficial wound infection (1.9% c.f. 18.6%) and superficial wound dehiscence (11.9% c.f. 23.3%) than the inverted U or lambda incision [368, 369] and may be associated with improved urethroplasty (and by inference PU) outcomes, at least in the short term (0% failure c.f. 6.2% failure at six months) [368]. Operative time is similar for all types of PU with mean operative time varying between 97.2 minutes to 112 minutes [364, 370].

The utilisation of PU is increasing [371] – constituting 4.5% of 403 procedures for complex urethral stricture disease in a tertiary centre in 2008 and 38.7% in 2017 [372]. Perineal urethrostomy patients are generally older than those having urethroplasty with a median of 62.6 years of age for men having PU in Fuchs *et al*., 2018 series compared with a median of 53.2 years for men having anterior urethroplasty [372]. Between 18.7% and 73.4% of men having staged urethroplasty for complex anterior urethral stricture decline to proceed to 2nd stage re-tubularisation after a successful 1st stage and remain voiding from the PU of their 1st stage urethroplasty [257, 339, 342].

6.3.4.3 Outcomes

6.3.4.3.1 Patency rates

Patency rates of 70-95% at mean/median follow-up of 20–63 months have been described [305, 339, 347, 363-366, 370, 372]. All reports are retrospective series – all of which are heterogenous in terms of indications and patients. There is consequently little data available to determine which is the best technique for PU.

McKibben *et al*., reported a patency rate of 92.9% in 42 patients for "7-flap" PU at median follow-up of 53.6 months, whilst they had a 100% patency rate with loop PU in twenty patients at a median follow-up of thirteen months [367].

Lumen *et al*., in 2015 reported a 74.3% patency rate for Johanson PU compared with an 87.5% patency rate for Gil-Vernet-Blandy PU (p=0.248), but with a significantly longer follow-up after Johanson PU (median 36 vs. nine months) [364]. Barbagli *et al*., published the largest series of PU patients to date – including 173 men (all of whom had been planned to have a staged urethroplasty for their complex anterior urethral stricture disease and 127 (73.4%) of whom declined to proceed with 2nd stage re-tubularisation). The median follow-up in this series was 62 months and the patency rate was 70% - confirming that patency rates for PU (and indeed for all urethroplasty [273, 346]) reduce with time [339].

See supplementary Table S6.11 for further information.

6.3.4.3.2 Complications

Perineal urethrostomy complications occur in 2.5-11.4% and include superficial wound dehiscence, scrotal abscess, UTI and urosepsis, bleeding, and transient scrotal pain and numbness [305, 364, 373]. The majority of complications are Clavien-Dindo grades 1 (2.9-18.8%) and 2 (0-2.9%). Grade 3 complications are rare and only occur in 5.7-6.2%. In the medium-term 22.2-30.8% of men with PU report post-micturition dribble [364].

6.3.4.3.3 Patient reported outcomes

Barbagli *et al*., reported that 168/173 (97.1%) of men were satisfied or very satisfied with the outcome of their Gil-Vernet-Blandy PU and would have the procedure again at median 62 months follow-up. Of these, 166/173 (95.9%) felt they had excellent or good results from their Gil-Vernet-Blandy PU, 145/173 (85%) felt it caused them no problems and 141/173 (82%) felt it caused their partner no problems [339]. The Trauma and Urologic Reconstructive Network of Surgeons (TURNS) collaborative found no significant change in sexual function and a significant improvement in urinary symptoms following PU in a small group of patients [374], whilst Lumen *et al*., found satisfactory or acceptable International Prostate Symptom Score (IPSS) outcomes in 26/32 (81.25%) of men with Johanson or Gil-Vernet-Blandy PU at a median follow-up of 32 months and nine months, respectively.

McKibben *et al*., found a mean patient global impression of improvement (PGI-I) of 1.3 in nineteen patients with either loop PU or "7-flap" PU [367] at median 31 months follow-up.

6.3.4.3.4 Risk factors for patency failure of the perineal urethrostomy

Lichen sclerosus, trauma and infection urethral strictures have poorer outcomes from PU, with PU patency failure in 36.7-67% at a median 62 month follow-up [339, 373]. Worse outcomes were also observed in patients with previous failed urethroplasty and multiple previous endoscopic and open treatments [339, 364, 365].

Barbagli *et al*., found that stricture length was inversely related to PU patency, as was patient age [339]. Conversely Viers *et al*., found outcomes worsened with age, reporting patency rates of 100% in men < 50 years old compared with 83% in men aged 60-69 years old [347]. Lopez *et al*., found increased risk of PU failure in men with ischaemic heart disease which makes sense and would be a putative explanation for the age-related worsening of outcomes noted by Viers *et al*., [373].

Failure of PU is most commonly treated with surgical revision of PU using V-Y plasty, augmentation or complete ReDo but can also be managed with periodic dilatation or urinary diversion [339, 363, 364].

For further information see supplementary Table S6.11.

Summary of evidence	LE
Perineal urethrostomy provides very good short- and long-term outcomes for men with complex urethral stricture disease.	1a
Perineal urethrostomy (PU) provides very good short and long-term outcomes for men who are unable to have complex reconstruction due to co-morbidities.	2b
All types of PU yield equivalent very good outcomes.	4
Augmented Gil-Vernet-Blandy or "7-flap" PU yield very good outcomes in men with extension of their urethral stricture disease into the proximal bulbar or membranous urethra.	2
"7-flap" PU yields very good results in obese men.	3

Recommendations	Strength rating
Offer perineal urethrostomy (PU) as a management option to men with complex anterior urethral stricture disease.	Strong
Offer PU for men with anterior urethral stricture disease who are not fit or not willing to undergo formal reconstruction.	Weak
Choose type of PU based on personal experience and patient characteristics.	Weak
Consider augmented Gil-Vernet-Blandy perineal urethrostomy or "7-flap" PU in men with proximal bulbar or membranous urethral stricture disease.	Weak
Consider "7-flap" urethroplasty in obese men.	Weak

*6.3.5 **Posterior urethra***

6.3.5.1 Non-traumatic posterior urethral stenosis

6.3.5.1.1 Treatment of non-traumatic posterior urethral stenosis

Several treatment modalities including conservative management (see section 6.1 Conservative options), endoluminal, open or minimally invasive surgical procedures are currently available, depending on patient's goals and health status.

6.3.5.1.2 Endoluminal management of non-traumatic posterior urethral stenosis

6.3.5.1.2.1 Dilatation of non-traumatic posterior urethral stenosis

This can be done under loco-regional anaesthesia [375-379]. Dilatation is used for VUAS [375-380] or radiation induced BMS [381] and in the majority of reported cases, patients were not previously treated for their stricture (see supplementary Table S6.12). Patency rates vary widely between 0-89% [117, 375-381]. The risk of *de novo* UI was low (0-11%) and no other complications were reported. It is of note that most series report on visually controlled dilatation [375-379] in VUAS without complete obliteration.

6.3.5.1.2.2 Endoscopic incision/resection of non-traumatic posterior urethral stenosis (Table 6.8)

Incisions can be performed at multiple locations according to surgeon's preference [382]. However, aggressive incisions at the six and twelve o'clock positions should be avoided because of the risk of, respectively, rectal injury and urosymphyseal fistulation [189, 383-385]. The risk of urosymphyseal fistulation is especially a concern after previous radiotherapy [386]. Result of bladder neck incision for VUAS are poorer after radiotherapy [387].

Direct vision internal urethrotomy is mainly performed in patients with primary or recalcitrant VUAS although one series performed it in a mix of patients with VUAS and BNS [388] and two series reported it for radiation-induced BMS [117, 381]. Direct vision internal urethrotomy/ dilatation for non-irradiated BMS are usually included in series reporting on anterior strictures (see section 6.2 Male endoluminal treatment of anterior urethral strictures). Patency after a 1st "cold/hot knife" DVIU ranges between 25-80% [375, 376, 380, 382, 388-393]. Laser incision yields a 69-100% patency rate [376, 380, 394, 395]. In a retrospective and unbalanced series, La Bossiere *et al*., found better patency rates for laser incision as compared to dilatation, "cold knife" DVIU and transurethral resection (TUR) [376]. Redshaw *et al*., reported inferior patency rates for "cold knife" incision vs. "hot knife" incision followed by MMC for BNS (50 vs. 63%; p=0.03) [236] (see supplementary Table S6.13).

Urinary incontinence largely varies between 0 and 53% but some series have not assessed urinary continence before DVIU [389, 391]. In series where pre- DVIU continence data were available, *de novo* urinary continence after DVIU ranges between 0% and 10% [375, 380, 390, 392, 394]. Noteworthy, of 21 patients that were incontinent pre-DVIU in the series of Giannarini *et al*., eleven (52%) patients became continent, and eight (38%) patients experienced improvement after DVIU [390]. As most recurrences will occur early [390, 391], it is advised to wait for three to four months after DVIU [382, 391, 396] to proceed with incontinence surgery, if necessary, although others wait for twelve months [397]. The presence of recurrence must be ruled out by cystoscopy prior to incontinence surgery [382, 391, 396, 397].

Another option is to resect the stenosis. Popken *et al*., reported a 47% patency rate with TUR for untreated VUAS and no patient suffered *de novo* SUI [392]. Kranz *et al*., compared the results of TUR in 87 and 60 patients with, respectively, VUAS after RP and BNS after TURP. After a median follow-up of 27 (range: 1-98) months, patency rate was 40.2% for VUAS and 58.3% for BNS (p=0.031). The rate of *de novo* incontinence was significantly higher in patients treated for VUAS compared to BNS (13.8 vs. 1.7%; p=0.011) [398]. There is conflicting evidence whether resection is associated with higher incontinence rate compared to incision. [379, 399] Brodak *et al*., compared TUR by bipolar resection (n=22) with holmium laser incision and vaporisation (n=17). After a mean follow-up of 42 months, two (9.1%) and four (23.5%) patients suffered a recurrence with bipolar and laser resection respectively (p=0.37). After six months, patients treated with bipolar resection had a significant better Qmax compared to laser treatment (13 vs. 6.1 ml/s; p < 0.001) [395]. Bipolar plasma vaporisation produced an 82% patency rate at a mean 24-month follow-up in 28 patients with VUAS who previously failed endoscopic treatment [400].

Cut-to-the-light technique for a complete obliterative stricture is not advised because of the very-low likelihood of durable patency and for the risk of false passage towards the rectum [396, 401, 402].

Repeat DVIU was often able to stabilise the stricture [117, 375, 376, 381, 388-390, 398], but ultimately 6-10% required urinary diversion [391] or chronic suprapubic cystostomy [381, 388].

Transurethral resection can be performed for prostatic obstruction due to sloughing after high-energy treatments (HIFU, cryoablation) [100]. Transurethral resection for obstructive necrotic debris after radiotherapy is possible but is of limited role. Risk of recurrence is 50% and risk of *de novo* UI is 15-25% [100].

Table 6.8: Results of endoluminal incision/resection for posterior non-traumatic stenosis

****all incontinent pre-operatively.*

6.3.5.1.2.3 Post-dilatation/direct vision internal urethrotomy strategies for non-traumatic posterior urethral Stenosis

6.3.5.1.2.3.1 Intermittent self-dilatation for non-traumatic posterior urethral stenosis

As for anterior strictures, ISD can be offered to patients for recurrent posterior stenosis after dilation/DVIU to stabilise the stenosis. This is especially relevant for patients unfit/unwilling to undergo surgery or in patients with radiation-induced BMS [117, 376, 381, 403]. Although ISD may be acceptable to many urologists and patients, it usually is associated with a reduced QoL and poor patient compliance [33].

6.3.5.1.2.3.2 Intralesional injections for non-traumatic posterior urethral stenosis

In order to stabilise the luminal fibrosis and consequently to reduce the risk of recurrence, injection of antifibrotic agents at the time of endoluminal treatment has been proposed. The majority of patients in these studies were patients with recalcitrant/recurrent non-obliterative VUAS/BNS. Two series used corticosteroids [379, 396], whilst the others used MMC [397, 401-405]. Patency rates with corticosteroid injections range between 50-100% [379, 396]. Patency rates with MMC vary between 50-94% [397, 404-406]. No trials comparing endoluminal treatment with or without adjuvant intralesional injections were identified.

See supplementary Table S6.13 for further information.

Complications are low across most studies, but all studies were retrospective in nature. Redshaw *et al*., also reported grade 3 complications in four out of 55 (7%) patients, including osteitis pubis (n=2), bladder neck necrosis (n=1) and rectourethral fistula (n=1) in one multi-institutional study [404]. Three of these patients ultimately required urinary diversion with additional faecal diversion in one patient [404]. Given the severity of these complications, although rare, MMC should not be used outside the framework of a clinical trial [407].

6.3.5.1.2.3.3 Urethral stent for non-traumatic posterior urethral stenosis

Stents have been used anecdotally in the posterior urethra [247, 248, 376]. Patency rates are relatively low (47-60%) [247, 248, 376] at the cost of a high-risk for UI (19-82%) [247, 248].

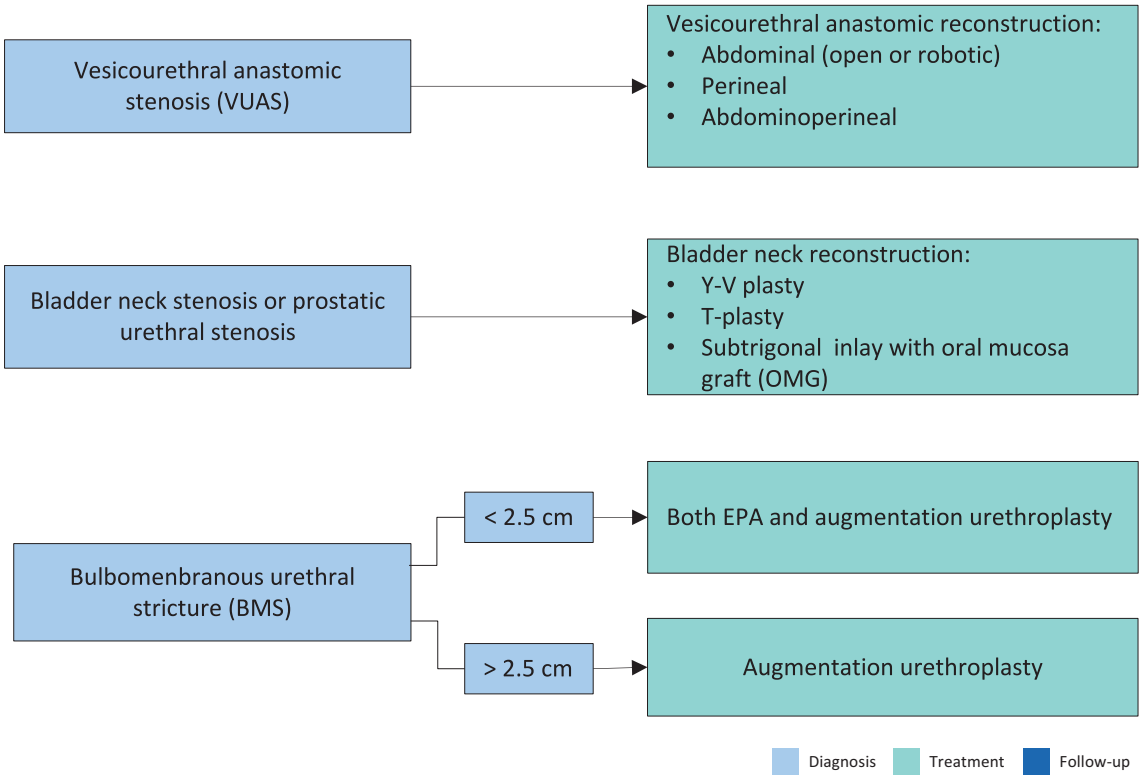
Summary of evidence	**LE**
For non-obliterative VUAS and radiation-induced BMS, visually controlled dilatation and DVIU yield a patency rate of respectively 0-89% and 25-100% with a low complication rate. It can be performed under loco-regional anaesthesia.	3
During DVIU, deep incision might provoke injury to the rectum at the six o' clock position and might provoke uro-symphyseal fistulation at the twelve o'clock position.	3
For BNS, TUR and "hot-knife" incision yield a patency rate of respectively 58.3 and 72% with a low complication rate.	3
Repeat endoluminal treatments in non-obliterative VUAS, radiation-induced BMS or BNS can stabilise the posterior stenosis and are easy to perform compared to reconstructive surgery.	3
Any form of endoluminal treatment might be associated with *de novo* UI (up to 25%) or worsening of existing UI (up to 15%).	3
Vesico-urethral anastomosis stricture, BMS and BNS with complete obliteration are not included in present series and endoluminal treatment is unlikely to be successful.	3
Urethral stents at the posterior urethra have a rather low patency rate (47-60%) and incontinence rate (19-82%).	3

Recommendations	**Strength rating**
Perform visually controlled dilatation or direct vision internal urethrotomy (DVIU) as 1st line-treatment for a non-obliterative vesico-urethral anastomosis stricture (VUAS) or radiation-induced bulbomembranous strictures (BMS).	Weak
Do not perform deep incisions at the six and twelve o' clock position during DVIU for VUAS or radiation-induced BMS.	Strong
Perform transurethral resection (TUR) or "hot-knife" DVIU as 1st line-treatment for patients with non-obliterative bladder neck stenosis (BNS) after surgery for benign prostatic obstruction.	Strong
Perform repeat endoluminal treatments in non-obliterative VUAS or BNS in an attempt to stabilise the stricture.	Weak
Warn patients about the risk of *de novo* urinary incontinence (UI) or exacerbation of existing UI after endoluminal treatment.	Weak
Do not perform endoluminal treatment in case of VUAS, BMS and BNS with complete obliteration.	Strong
Do not use stents for strictures at the posterior urethra.	Weak

6.3.5.1.3 Lower urinary tract reconstruction for non-traumatic posterior urethral stenosis

If endoluminal treatment (repeatedly) fails or in case of a completely obliterated posterior stenosis [401, 402, 408, 409], lower urinary tract (LUT) reconstruction may be considered in fit patients motivated to undergo surgery (Figure 6.1). The choice of LUT reconstruction will depend upon the length, location, calibre and aetiology of the stenosis, continence status, bladder function, previous radiotherapy, patient's preference, and surgeon's expertise.

Figure 6.1: Options for lower urinary tract reconstruction of non-traumatic posterior urethral obstruction (stenosis/stricture)



6.3.5.1.3.1 Redo vesico-urethral anastomosis for vesico-urethral anastomotic stenosis after radical prostatectomy

After excision of the stenosis, ReDo vesico-urethral anastomosis (ReDo VUA) can be performed. This may be performed via a retropubic, perineal, combined abdominoperineal or robot-assisted approach. Nikolavsky *et al*., proposes a retropubic approach for VUAS involving the bladder neck, a perineal approach for short VUAS with intact bladder neck and an abdominoperineal approach for long segment (> 3 cm) VUAS with bladder neck involvement [408]. The ReDo VUA must be performed in a tension-free fashion which can be achieved either by mobilisation of the bladder (retropubic approach), mobilisation of the bulbar urethra with corporal splitting and inferior pubectomy if necessary (perineal approach) or both (abdominoperineal approach) [408, 410]. Dinerman *et al*., reported a robot-assisted abdominoperineal approach in a case with 4.5 cm long complete obliteration [411]. Kirshenbaum *et al*., reported a pure robot-assisted abdominal approach. Regardless of the approach, the procedure is technically demanding due to the location deep under the pubic symphysis, and the proximity of the external sphincter [410]. As a consequence, surgical morbidity must be considered. As most patients with VUAS were healthy enough to undergo RP, most patients will likewise remain fit and eligible for VUAS surgical reconstruction [408, 410].

Table 6.9: Outcomes of redo vesico-urethral anastomosis

Study	N	Approach (%)	Previous RT (%)	FU (months)	Length (cm)	Patency (%)	Incontinence (%)	Complications (%)

FU = follow-up; NR = not reported; RT = radiotherapy; UTI = Urinary tract infection.
** incontinent before ReDo VUA.*
*** de novo incontinence in four out of eleven patients.*
****social continent (1 pad/day).*

ReDo VUA in non-irradiated patients yields patency rates of 60-91% (Table 6.9) [408-410, 412-414]. Prior radiotherapy is a risk factor for failure [410, 412]. In addition, radiation-induced bladder toxicity might provoke reduced bladder capacity, low bladder compliance, bladder spasms and pain, and urethral necrosis making reconstruction futile (see below) [386, 410, 415]. ReDo VUA should only be done in patients with adequate bladder function and in the absence of (peri)-urethral pathology (urethral necrosis, calcification, fistulation). Flaps (gracilis flap, peritoneal flap) to support and protect the anastomosis may be beneficial in irradiated patients [408].

With the transperineal approach, UI is inevitable, as this approach disrupts the external sphincter [409, 410, 412, 414]. With the retropubic approach, Pfalzgraf *et al*., reported *de novo* incontinence in only four out of eleven (36%) patients [413]. In the series of Nikolavsky *et al*., where a retropubic approach was predominantly used, incontinence rate was 58% [408]. Kirshenbaum *et al*., reported no incontinence in five patients treated by robot-assisted retropubic approach [409]. Giudice *et al*., reported incontinence in one out of four patients treated with the retropubic approach [414]. Therefore, some authors [100, 408, 409] have proposed a preference for the retropubic approach in patients with good pre-operative urinary continence, although both approaches have never been directly compared for UI. In addition, the lack of perineal dissection by a retropubic approach will preserve the perineal anatomy and vascularisation which makes subsequent artificial urinary sphincter (AUS) less demanding [409]. Artificial urinary sphincter implantation should be deferred because of the risk of VUAS recurrence and difficulty of treating any recurrent VUAS with the cuff of the AUS in place [391, 410]. The exact timing of AUS placement is not consensual in the literature but most advise waiting at least three to six months to ensure stability of the VUA patency [386, 407, 410, 412].

Due to the complexity of this pathology the EAU Urethral Strictures Panel advises that VUAS reconstruction should be performed only in experienced high-volume centres, particularly after prior radiotherapy or other energy ablative treatments.

Summary of evidence	**LE**
ReDo VUA has patency rates of 60-91% in non-irradiated patients and 67% in irradiated patients with obliterative VUAS or VUAS refractory to endoluminal treatment.	3
Urinary incontinence is inevitable after transperineal ReDo VUA. Artificial urinary sphincter placement can be offered after three to six months if patency of ReDo VUA is ensured.	3
De novo incontinence with retropubic ReDo VUA is 0-58%.	3

Recommendations	Strength rating
Perform ReDo vesico-urethral anastomosis (VUA) in non-irradiated patients and irradiated patients with adequate bladder function with obliterative vesico-urethral anastomosis stricture or vesico-urethral anastomosis stricture refractory to endoluminal treatment.	Weak
Warn patient that urinary incontinence (UI) is inevitable after transperineal ReDo VUA and that subsequent anti-UI surgery might be needed in a next stage, after at least three to six months.	Strong
Offer ReDo VUA by retropubic approach if the patient is pre-operatively continent.	Weak

6.3.5.1.3.2 Posterior stenosis after surgery for benign prostatic obstruction

6.3.5.1.3.2.1 Bladder neck reconstruction for bladder neck stenosis after surgery for benign prostatic obstruction

The bladder neck is augmented by advancement of local bladder flaps (Y-V or T-plasty) with or without resection of scar tissue. They are used for BNS refractory to endoscopic treatments [409, 416-418]. Patency rates vary between 83-100% with fourteen to 45 months follow-up [409, 416-418]. There is a trend to perform bladder neck reconstruction by minimally invasive approach (laparoscopic, robot-assisted) [409, 417, 418]. *De novo* incontinence rate ranges from 0-14% [409, 416-418]. Satisfaction among patient is high with 88.5% of patients stating that they are pleased with the surgery, with an improvement of QoL in 75% of patients [416, 418]. Recently, a robot-assisted augmentation technique with subtrigonal buccal mucosa inlay has been successfully reported in a case report, but this technique requires further investigation [419].

See supplementary Table S6.14 for further information.

6.3.5.1.3.2.2 Bulbomembranous strictures after surgery for benign prostatic obstruction

Bulbomembranous urethral strictures (BMS) after TURP or simple prostatectomy are managed as bulbar strictures and can be treated by EPA or augmentation urethroplasty with a graft, taking into account the length and tightness of the stricture [82]. Kulkarni *et al*. reported a similar patency rate for dorsal and ventral onlay urethroplasty (resp. 81.8% versus 84.6% after mean follow-up of 14 months) [420]. As reconstruction is in the proximity of the external sphincter and the bladder neck was already damaged during BPO surgery, the risk of incontinence (up to 25%) is present [82].

Summary of evidence	LE
Bladder neck reconstruction with Y-V or T-plasty for treatment refractory BNS has patency rates of 83-100%.	3
Incontinence occurs in up to 14% with bladder neck reconstruction and up to 25% after reconstruction of BMS after previous surgery for BPO.	3

Recommendations	Strength rating
Perform bladder neck reconstruction with Y-V or T-plasty for treatment refractory bladder neck stenosis (BNS).	Weak
Warn patients about *de novo* urinary incontinence after reconstruction for BNS or bulbomembranous urethral strictures with previous benign prostatic obstruction surgery as aetiology.	Strong

6.3.5.1.3.3 Radiation/high-energy induced posterior strictures

6.3.5.1.3.3.1 Bulbomembranous strictures secondary to radiation/high energy sources

The major challenge in treating radiation-induced strictures is the consequent tissue damage with impaired healing capacity, involving not only the stricture itself but also the adjacent proximal and distal areas of the scar [421]. Additionally, proximity of the stricture to the external sphincter can further complicate surgery [421]. Due to these challenges, patients with radiation-induced BMS have long been considered poor candidates for urethral reconstruction and have been treated with urinary diversion if endoscopic treatments failed or were not possible [421].

Most radiation-induced BMS are short and in these cases, EPA is possible avoiding the use of a graft or a local flap in an area of poor vascular health. However, EPA will not be possible for BMS with a long bulbar segment and in these cases, augmentation urethroplasty will be necessary despite the aforementioned concerns. A

systematic review reported a pooled patency rate of 80% with no significant differences between type of urethroplasty (EPA versus augmentation urethroplasty). Stress UI was reported in 19% of cases [421]. Rourke *et al*., reported no significant differences between EPA and augmentation urethroplasty regarding *de novo* UI (26 vs. 25%; p=1), new onset ED (35 vs. 0%; p=0.06) or other adverse events (30% vs. 33%; p=1) [422].

6.3.5.1.3.3.2 Prostatic strictures secondary to radiation/high energy sources

Radiotherapy and high-energy modalities (cryoablation, HIFU) might provoke prostatic necrosis, sloughing and obstruction [100]. Cases refractory to TUR and with good bladder capacity might be salvaged by prostatectomy taking into account the morbidity associated with salvage RP (rectal injury, VUAS, incontinence) [100, 423]. Mundy *et al*., treated nine patients with patency in six, (67%) and one (11%) needing an AUS for severe incontinence [410].

Cases with impaired bladder function, urethral necrosis and/or peri-urethral pathology should be considered for supravesical diversion, especially if a suprapubic catheter is not tolerated due to bladder pain or spasms [386, 407, 410, 415].

Recently, a "pull-through" procedure has been reported as an alternative to cutaneous diversion for reconstruction of the devastated posterior urethra associated with a defunctionalised bladder after radiation where tissue vascularity and quality is poor [424]. This novel technique of total LUT reconstruction combines salvage cystectomy, ileal neobladder formation and urethral pull-through. An AUS was implanted in a second stage. All eight patients maintained a patent posterior urethra after a median follow-up of 58 (range 16-84) months. Five patients experienced low-grade complications after the first stage, but no high-grade complications were reported. Four out of eight (50%) patients experienced cuff erosion with need for removal and subsequent reimplantation. After a median of two revision surgeries (range 0 to 4), all patients achieved social continence enhancing QoL [424]. This technique requires further validation before its use can be recommended.

Summary of evidence	**LE**
Patency rates of urethroplasty for radiation-induced BMS is 80% with no significant differences between EPA and augmentation urethroplasty.	3
Radiation-induced BMS longer than 2-2.5 cm are rarely amenable for EPA.	3
De novo incontinence and new onset ED after urethral surgery for radiation-induced BMS are reported in respectively 19-26% and 0-35% of cases.	3
Salvage prostatectomy can achieve patency in 67% of patients for prostatic strictures after irradiation or high-energy treatments but morbidity is substantial.	4

Recommendations	**Strength rating**
Use either excision and primary anastomosis (EPA) or augmentation urethroplasty for short (< 2.5 cm) radiation-induced bulbomembranous strictures (BMS) refractory to endoscopic treatment depending on surgeon's experience.	Weak
Perform augmentation urethroplasty for long (> 2.5 cm) radiation-induced BMS.	Weak
Warn patients about the risk of *de novo* incontinence and new onset erectile dysfunction after urethroplasty for radiation-induced BMS.	Strong
Offer salvage prostatectomy in motivated and fit patients with adequate bladder function in case of a prostatic stricture due to irradiation or high-energy treatment.	Weak

6.3.5.1.4 Extirpative surgery and urinary diversion for non-traumatic posterior urethral stenosis

In complex and/or recurrent cases [408], LUT reconstruction is not possible or not indicated due to severe necrosis, calcification and significant morbidity, especially severe pain [407]. Intractable haematuria or fistulation might be other reasons to abandon the urethral outlet. Typically, the patient has a history of pelvic irradiation or high energy prostate cancer treatment and several previous attempts to achieve cure. Moreover, and equally important, any of the options used to deal with a devastated posterior urethra are dependent upon good bladder capacity, compliance and function allowing for bladder preservation as well as healthy distal ureters [386, 407]. The last resort therapeutic option is urinary diversion (continent or incontinent) with or without cystectomy [410, 415]. Different techniques have been described and the choice between them largely

depends on the bladder capacity, presence of local symptoms, performance status and expectations of the patient. Cystectomy during urinary diversion is able to palliate symptoms of intractable bladder pain, spasms and haematuria which are especially prevalent after pelvic radiotherapy [425-428]. The satisfaction rate was reported to be 100% and the overwhelming majority of patients would have undergone this extirpative surgery an average of thirteen months sooner in a study of fifteen patients by Sack *et al*., [429]. In a report by Faris *et al*., 27% of the patients also required bowel diversion due to intractable gastrointestinal morbidity, highlighting the complexity of this pathology [415].

Summary of evidence	**LE**
Urinary diversion can improve QoL in patients with a devastated lower urinary tract with a high satisfaction rate.	3
Cystectomy is able to palliate symptoms of intractable bladder pain, spasms, and haematuria.	3

Recommendations	**Strength rating**
Perform urinary diversion in recurrent or complex cases with loss of bladder capacity and/or incapacitating local symptoms.	Weak
Perform cystectomy during urinary diversion in case of intractable bladder pain, spasms and/or haematuria.	Weak

6.3.5.2 Post-traumatic posterior stenosis

The acute and early management of PFUIs is discussed in the EAU Guidelines on Urological Trauma. A nonobliterative stenosis is the result of a partial injury at the membranous urethra or occurs after unsuccessful early realignment of a partial or complete injury. An obliterative stenosis is the consequence of a complete injury with a distraction defect between the ruptured urethral ends. The gap between these ends fills up with dense fibrotic tissue [11].

The deferred management of PFUI is at earliest three months after the trauma. After that period, the pelvic haematoma has nearly always resolved, the prostate has descended into a more normal position, the scar tissue has stabilised [430] and the patient is clinically stable and able to lie down in the lithotomy position [430].

6.3.5.2.1 Endoluminal treatment for post-traumatic posterior stenosis

6.3.5.2.1.1 Endoluminal treatment as primary treatment for post-traumatic posterior stenosis

Endoluminal treatment (dilation, DVIU) of an obliterative stenosis using the cut-to-the light principle will not be successful [46] and has a risk of creating a false passage towards the bladder base or rectum [431]. For a non-obliterative, short (< 1.5 cm) stenosis, one attempt of endoluminal treatment (endoscopic incision or dilation) can be performed. Kulkarni *et al*., reported a 92.3% and 96.5% stricture-free rate with "cold knife" and holmium laser urethrotomy, respectively (median follow-up respectively 61 and 57 months) [432]. These results are challenged by Barbagli *et al*., who reported a 51% stricture-free rate with holmium laser urethrotomy but with no data on length of follow-up available [433]. Cai *et al*., compared patient outcomes between bipolar plasma vaporisation and "cold knife" DVIU in 53 patients with posterior traumatic (80%) and iatrogenic (20%) urethral strictures with significantly different stricture-free rates of 81.5% vs. 53.8% at a mean follow-up of 13.9 months, respectively [434]. No severe complications were reported in either group. A statistically significant shorter operative time was found in the bipolar group [434]. Barratt *et al*,. calculated a composite stricturefree rate of 20% after all types of endoscopic treatments (but with a mix of obliterative and non-obliterative stenoses) [46]. *De novo* UI was reported in 4% of cases [46]. Repetitive endoluminal treatments are unlikely to be curative and must be discouraged as this delays the time to definitive cure and can lead to more complications [435, 436].

6.3.5.2.1.2 Endoluminal treatment after failed urethroplasty for post-traumatic posterior stenosis

In case of a non-obliterative and short (< 1 cm) recurrence after failed urethroplasty, endoluminal treatment can be performed [437]. Although a 1st and 2nd DVIU can be successful with a stricture-free rate of 22.9-77.3% and 0-60% respectively, three or more incisions are never successful (see supplementary Table S6.16) [437-440]. Therefore, repetitive endoluminal treatments (dilations and/or endoscopic incisions) can only be considered as a palliative option [441].

Summary of evidence	LE
Endoluminal treatment of obliterative stenoses is not successful and may create false passages towards bladder or rectum.	3
A 1st DVIU has stricture-free rates of 22.9-77.3% for a short and non-obliterative recurrence after excision and primary anastomosis.	3
Three or more endoscopic incisions are never successful for recurrence after excision and primary anastomosis.	3

Recommendations	Strength rating
Do not perform endoscopic treatment for an obliterative stenosis.	Strong
Perform one attempt at endoluminal treatment for a short, non-obliterative stenosis.	Weak
Do not perform more than two direct vision internal urethrotomies and/or dilatations for a short and non-obliterative recurrence after excision and primary anastomosis for a traumatic posterior stenosis if long-term urethral patency is the desired intent.	Weak

6.3.5.2.2 Urethroplasty for post-traumatic posterior stenosis

In view of the complexity and difficulty of urethroplasty and the fact that the best results are obtained with its first attempt, this surgery must be performed in high-volume centres [442]. It has been calculated that to achieve and maintain sufficient experience in the reconstruction of PFUI, one centre per twelve million inhabitants is sufficient (for well-resourced countries) [443].

6.3.5.2.2.1 First urethroplasty for post-traumatic posterior stenosis

6.3.5.2.2.1.1 Indication and technique of urethroplasty for post-traumatic posterior stenosis

Progressive perineal EPA is the standard treatment for an obliterative stenosis and for a non-obliterative stenosis as first attempt, or after failure of primary endoluminal treatment [46, 444].

Although both a midline and inverted U-incision are possible to gain access to the posterior urethra, a midline incision is associated with a significant reduction in trauma to the superficial perineal and posterior scrotal nerves and vessels, in the rate of surgical site infections (3.1% vs. 16.4%) and reduced length of hospitalisation [369].

A combined transpubic abdomino-perineal approach is only necessary in complicated cases such as those with associated para-urethral bladder base fistula, trauma-related recto-urethral fistula, and bladder neck injury [431]. Total pubectomy during transpubic abdomino-perineal reconstruction has a higher complication rate (bleeding, pelvic instability, dead space) compared to partial (superior or inferior) pubectomy with no gain in surgical exposure [445]. Although also considered complex situations, iatrogenic recto-urethral fistula (after misdirected endoscopic treatment), traumatic recto-urethral fistula < 5 cm from the anus, UCF and urinoma cavity can usually be corrected by a progressive perineal approach only [431, 446].

6.3.5.2.2.1.2 Patency rate after urethroplasty for post-traumatic posterior stenosis

The overall patency rate after deferred EPA is 85.7% [46]. Complete excision of scar tissue is a strong predictor for freedom of stricture whereas number (3-5 vs. 6-7) and size (3.0 vs. 4.0) of sutures are not [447]. A retrospective study showed an improved patency rate after eversion of the urethral mucosa of both urethral ends before anastomosis ("valgus urethral mucosa anastomosis") [448], but this finding has yet to be confirmed in a prospective fashion.

To preserve the antegrade arterial inflow of the bulbar urethra and reduce the surgical trauma of "classic" deferred EPA, bulbar artery sparing EPA has been described [449]. Initial patency rates vary between 88.5-100% with 20-45 months of follow-up (see supplementary Table S6.17) [449-451]. Xie *et al*., only used this technique for distraction defects less than 2.5 cm [451]. No evidence exists to date whether bulbar artery sparing EPA is superior to the "classic" EPA in terms of patency rate and potency and continence rates.

In case of a very deep location of the proximal urethral end that makes anastomotic suturing impossible, Badenoch described a pull-through technique which has a 33.3-96.5% patency rate after 43-126 months of follow-up (see supplementary Table S6.18 for further information) [432, 452, 453]. With the aim to reduce stricture recurrence, Wong *et al*., advise a 1.5 cm segment overlap of the bulbar stump within the prostatic

urethra during the pull-through technique [452]. To facilitate the suturing at the proximal part of the urethra located deep under the pubic bone, the robotic approach is under exploration but there is no evidence so far of improved outcome with this approach [454].

6.3.5.2.2.1.3 Sexual function, urinary continence, and rectal injury after urethroplasty for post-traumatic posterior stenosis

Regarding erectile function, a prospective study by Hosseini *et al*., found no significant difference before, and three or six months after EPA for posterior traumatic stenosis [455]. Another prospective study by Tang *et al*., also demonstrated no significant overall change in ED after urethroplasty. However, in the subgroup of patients with pre-operative non-vascular ED, a significant post-operative increase in ED was observed [456]. A meta-analysis of retrospective studies showed a significant decline of the rate of ED from 43.27% before to 24.01% after posterior urethroplasty ($p < 0.001$) [457]. Assessment of erectile function and its definitive treatment (e.g., penile prosthesis) should be performed two years after the trauma because of the potential return of normal erectile function within that time [458, 459].

After deferred EPA, antegrade ejaculation is present in 98.3-100% of cases [460, 461]. Decreased ejaculatory volume and/or diminished ejaculatory force were reported in 17.2-18.7% of cases but it cannot be assessed whether this is due to the trauma or due to the surgery [460, 461].

Continence after PFUI and urethroplasty is generally attributed to a competent bladder neck [46]. On the other hand, as most ruptures occur at the bulbomembranous junction just below the external sphincteric mechanism, at least a part of the external sphincter mechanism can be spared during urethroplasty [462]. Therefore, incontinence is rare with deferred EPA (6.8-8.5%) and is usually due to incompetence of the bladder neck although an incompetent bladder neck will not necessarily result in incontinence after urethroplasty [46, 462, 463].

Rectal injury is a relatively rare (0-10.2%) but severe complication after deferred EPA (see supplementary Table S6.19) [430, 438, 445, 463-467]. The risk of rectal injury tends to be higher in complicated cases or cases with previous urethral manipulations [430, 468, 469].

6.3.5.2.2.2 ReDo-urethroplasty for post-traumatic posterior stenosis

In case of a recurrent stenosis, a repeat ("ReDo") urethroplasty is possible. In the majority of cases, especially if not all consecutive length-gaining manoeuvres have been used during the 1st EPA, another EPA can be performed [463, 467, 468, 470-472]. The Badenoch pull-through technique is again an option if no adequate mucosa-to-mucosa suturing is possible (See supplementary Table S6.18) [452, 453]. In case of excessive dead space after resection of the fibrosis, gracilis muscle [469] or omental flaps (laparoscopically harvested if urethroplasty was performed using perineal approach only) [431, 465] have been advised to fill up this space and support the anastomosis. These flaps, or alternatively bulbospongious muscle or local subcutaneous dartos flaps, are also useful to separate the suture lines in case of a concomitant recto-urethral fistula [431, 442, 446, 469]. If the urethra cannot be anastomosed in a tension-free fashion, despite the aforementioned manoeuvres, or in cases of ischemic narrowing/necrosis of the bulbar urethra, options are a tubed preputial island flap, staged BMG urethroplasty with flap, staged buccal mucosa dartos flap, radial forearm free flap urethroplasty or entero-urethroplasty [442, 467, 471, 473]. In case of entero-urethroplasty, the sigmoid colon is preferred above ileum (which is in turn better than stomach) because of the proximity of the vascular pedicle to the perineum. Entero-urethroplasty should only be done in the presence of a competent bladder neck because subsequent implantation of an AUS is nearly impossible [473].

Patency rate of different types of ReDo-urethroplasty varies between 50-100% (Table 6.11) [442, 463, 467, 468, 471, 473]. An alternative is to abandon the normal urinary outlet and opt for Mitrofanoff-vesicostomy, PU (if local perineoscrotal skin is suitable) or permanent suprapubic diversion [467, 473].

Table 6.10: Outcome of different types of ReDo-urethroplasty

Study	Type	N	Follow-up (months)	Patency rate
Bhagat *et al*. [471]	Progressive perineal EPA	28	29 (12-108)	36 (83,72%)
	Transpubic EPA	12		
	Tubed preputial flap	1		
	Staged BMG + local flap	2		
Fu *et al*. [468]	Progressive perineal EPA	55	36 (18-47)	33 (60%)

Garg *et al*. [467]	Progressive perineal EPA	40	31 ± 11	30 (75%)
	Transpubic EPA	2	25	2 (100%)
	Tubed preputial flap	1	25	1 (100%)
	Staged BMG + local flap	2	17	1 (50%)
	Radial forearm free flap	1	15	1 (100%)
Sa *et al*. [463]	Progressive perineal EPA	102	35 (6-63)	93 (91.2%)
Kulkarni *et al*. [442]	Progressive perineal EPA	541	68 (12-240)	412 (79.1%)
	Tubed preputial flap	37		30 (81%)
	Staged BMG flap	10		6 (60%)
	Staged BMG + local flap	15		13 (86.6%)
	Entero-urethroplasty	2		2 (100%)
	Radial forearm free flap	3		3 (100%)
	Pedicled anterolateral thigh flap	1		1 (100%)
Mundy *et al*. [473]	Entero-urethroplasty	11	NA	7 (63.6%)

BMG = buccal mucosa graft; EPA = excision and primary anastomosis; N = number of patients; NA = not applicable.

Summary of evidence	**LE**
The best results are obtained after the 1st urethroplasty.	4
The overall stricture-free rate after EPA is 85.7%. By using the progressive perineal approach, a combined transpubic abdomino-perineal approach is usually not needed.	3
After failed endoluminal treatment, EPA is the standard treatment for a non-obliterative stenosis.	3
Both a midline and inverted U perineal incision equally gain access to the posterior urethra, but a midline incision is associated with less anatomical damage to local vessels and nerves, reduced risk of surgical site infection and hospital stay.	2b
Total pubectomy during transpubic abdomino-perineal reconstruction has a higher complication rate (bleeding, pelvic instability, dead space) compared to partial (superior or inferior) pubectomy with no gain in surgical exposure.	4
By using the progressive perineal approach, a combined transpubic abdomino-perineal approach is usually not needed except for very long distraction defects and in case of complicated situations, which include associated para-urethral bladder base fistula, trauma-related recto-urethral fistula, and bladder neck injury.	3
If the urethra cannot be anastomosed in a tension-free fashion or in case of ischaemic narrowing/ necrosis of the bulbar urethra, options are a tubed preputial island flap, staged buccal mucosa graft urethroplasty with flap, staged buccal mucosa dartos flap, radial forearm free flap urethroplasty or entero-urethroplasty.	3
In case of excessive dead space after resection of the fibrosis, local flaps have been advised to fill up this space and support the anastomosis. These flaps are also useful to separate the suture lines in case of a concomitant recto-urethral fistula.	3

Recommendations	**Strength rating**
Perform open reconstruction for post-traumatic posterior stenosis only in high-volume centres.	Weak
Perform progressive perineal excision and primary anastomosis (EPA) for obliterative stenosis.	Strong
Perform progressive perineal EPA for non-obliterative stenosis after failed endoluminal treatment.	Strong
Perform a midline perineal incision to gain access to the posterior urethra.	Strong
Do not perform total pubectomy during abdomino-perineal reconstruction.	Strong

Reserve abdomino-perineal reconstruction for complicated situations including very long distraction defect, para-urethral bladder base fistula, trauma-related recto-urethral fistula, and bladder neck injury.	Weak
Perform another urethroplasty after 1st failed urethroplasty in motivated patients not willing to accept palliative endoluminal treatments or urinary diversion.	Weak
Use a local tissue flap to fill up excessive dead space or after correction of a concomitant recto-urethral fistula.	Weak

7. DISEASE MANAGEMENT IN FEMALES

7.1 Signs and symptoms of female urethral strictures

The symptoms of female urethral strictures are non-specific and therefore generally non-diagnostic. Female urethral stricture presents with mixed filling and voiding symptoms with frequency in 63%, urgency in 55%, incomplete emptying in 36%, poor flow in 32%, urinary incontinence in 31% (stress, urge or mixed), strain void in 21.5%, UTI in 20.5%, nocturia in 20.5% and dysuria in 20%. It very rarely presents with urethral pain (2.7%), terminal dribble (2%), haematuria (1.6%) or renal failure (0.5%) (see supplementary Table S7.1).

There is often a significant delay in diagnosis of FUS from time of development of symptoms with mean delays of 4.3-12 years described (range 1-30 years) [137].

7.2 Diagnosis of female urethral strictures

Twenty-four studies detail investigations leading to a diagnosis of FUS (see supplementary Table S7.2). In all cases a full history was taken, and a detailed pelvic examination was performed to assess for prolapse, masses, scars and vulval dermatological disorders such as LS, lichen planus or vulvo-vaginal atrophy. Flow rate and US PVR assessment was evaluated in nineteen (75%) and eighteen (71%) studies, respectively. Lateral VCUG was performed routinely in sixteen studies (63%) and as required in one study (4%). Cystourethroscopy was performed routinely in fourteen studies (54%) and as required in two studies (8%). Urodynamics (UDS) were performed routinely in four studies (17%) and as required in seven studies (30%) whilst video-urodynamics (VUDS) were performed routinely in three studies (13%) and urethral calibration also in four studies (13%). Pelvic MRI was performed as required in four series (17%) whilst transrectal US (TRUS) and renal US were each performed routinely in two series (8%) and intravenous urography (IVU) in ten (4%).

Flow rate and PVR assessment make inherent sense as initial non-invasive screening tools and allow for simple monitoring of effect of treatment. Voiding cystourethrography and/or VUDS will permit diagnosis of BOO [23, 474], visualisation of ballooning above the proximal end of the FUS [135], and delineation of alternate or co-existent diagnoses such as detrusor overactivity (DO) and SUI [128], although VCUG, VUDS and UDS require the ability to insert a 6 Fr catheter and may not be possible without preliminary urethral dilatation in all cases of FUS [475]. Likewise, passage of a cystourethroscopy will require a preliminary dilation in the majority of cases even when a paediatric uretero-renoscope is utilised [126]. Cystourethroscopy will allow for formal identification of the distal end of the FUS and will also allow for exclusion of a functional cause of BOO [135]. Magnetic resonance imaging is performed mainly to exclude alternate pathology such as urethral diverticulum and urethral carcinoma and also allows assessment of the degree of urethral fibrosis associated with FUS [475]. Proponents of TRUS utilise it in lieu of MRI and also for visualisation of the dilated urethra above the proximal end of the FUS. Recent gel-infused USS has been assessed and found to more accurate means of diagnosing stricture and associated spongiofibrosis than cystoscopy and videourodynamics in a small preliminary study (n=8) [476].

7.3 Treatment of female urethral strictures

*7.3.1 **Minimally invasive techniques for treatment of female urethral strictures***

Several minimally invasive treatments have been reported; these include urethrotomy, dilatation, meatotomy and meatoplasty. Meatotomy and meatoplasty are essentially the same procedure in the female urethra and the term ‘meatoplasty’ will be used throughout this document.

7.3.1.1 Urethrotomy for treatment of female urethral strictures

No papers were found detailing the use and outcomes of urethrotomy specifically for the management of FUS. Internal urethrotomy or dilation was used by Massey and Abrams [477] to treat a variety of pathologies,

including FUS, causing symptoms of obstructed voiding, and resulted in symptomatic improvement in 80% of patients. As this study included women with a variety of complaints and did not assess urodynamic parameters, the results in the patient subset with true urethral stricture are unclear. If utilised, urethrotomy in the female urethra involves incisions at three, nine and occasionally twelve o'clock [477].

7.3.1.2 Urethral dilatation for treatment of female urethral strictures

With this treatment, the urethra is dilated to between 24 Fr and 41 Fr. Some patients will continue with ISD. Romman *et al*., 2012 [478] and Popat & Zimmern [475] also described suture plication of bleeding areas of the meatus if required post-urethral dilatation.

Four studies described the results after twelve to 59 months follow-up of, in total, 183 patients having dilatation only. Patency rates ranges from 7.5-51% (see Table 7.1) [128, 129, 475, 478]. In another four studies that included, in total, 31 patients that continued to perform ISD, stabilisation of the stricture with "patency" was obtained in 37.3-100% of cases at twelve to 21 months of follow-up (see Table 7.1) [13, 133, 136, 479].

New onset SUI (1.4%) and other complications are very rare after dilation (see supplementary Table S7.3). Due to the low complication rate, the minimally invasive nature of the technique and the reasonable success rate, it is acceptable to start with urethral dilation as a first-line treatment for an uncomplicated FUS. If the stricture recurs then repeat urethral dilatation is unlikely to be curative.

7.3.1.3 Meatoplasty for treatment of female urethral strictures

Meatal stenosis is extremely rare, with only 2/58 (3%) of females evaluated for voiding dysfunction found to have true meatal stenosis [480]. Only one meatoplasty paper contains more than five patients and has been included for analysis (see supplementary Table S7.4) The patency rate of meatoplasty in girls in this paper is excellent with 96% of the 50 girls in Heising's series having a successful outcome with no reported side effects at twelve months. Forty-eight of 50 patients experienced resolution of their recurrent UTIs and improved voiding symptoms one year after meatoplasty [481]. There was no incontinence or other acute complications reported. For short meatal strictures, meatoplasty is the first-line treatment option.

7.3.2 ***Urethroplasty for treatment of female urethral strictures***

Twenty-five papers report the outcomes of urethroplasty for FUS disease in 253 patients in total after the scope search of the Panel. The Panel have analysed the outcomes of these urethroplasty according to flap or graft type as: vaginal graft, vaginal flap, labial/vestibular graft, labial/vestibular flap and buccal or lingual graft. In female urethroplasty, a dorsal approach is via a stricturotomy at twelve o'clock, a ventral approach is via a stricturotomy at six o'clock and circumferential is a full circumference reconstruction.

7.3.2.1 Vaginal graft augmentation urethroplasty for treatment of female urethral strictures

There were five studies reporting vaginal graft urethroplasty containing 72 patients. All 72 vaginal graft urethroplasties were performed via a dorsal approach in women with a mean/median age of 47.5-60.6 years (range 28-79). At a mean/median follow-up time of 8.5-24.65 months (range 6-36) following vaginal graft urethroplasty 59 (82% range 73-94%) of patients had no recurrent stricture. No complications and no new onset urinary incontinence were reported. Mean/median flow rate (with range) improved from 6.2-8.23 mls/s (2.2-10.2) to 16.64-27.6 ml/s (12-32.7) whilst mean/median PVR (with range) reduced from mean/median 113.2-187.1 mls (44-420) to mean/median 20-90.31 mls (0-122).

See supplementary Table S7.5 for further information.

7.3.2.2 Vaginal flap augmentation urethroplasty for treatment of female urethral strictures

Vaginal flap urethroplasty was reported in 150 women and was always via a ventral approach, utilising an inverted U vaginal flap inlay in seven studies (n=96) [127, 128, 131, 482, 483], a lateral C vaginal flap in three studies (n=58) [125, 133, 137] and one vaginal island flap urethroplasty in one patient [131]. At a mean/median follow-up time of 12- 80.7 months (range 3-198), patency rates of 67-100% were reported (Table 7.1). Eight (5.3%) patients had a simultaneous pubo-vaginal sling (PVS), four (2.7%) had a simultaneous Martius fat pad flap interposition and one (0.7%) had a simultaneous excision of urethral diverticulum. Fourtheen (9.3%) patients developed new onset UI, and fourtheen (9.3%) developed other acute complications including UTI and intravaginal direction of the urinary stream.

See supplementary Table S7.6 for further information.

7.3.2.3 Labial/vestibular graft augmentation urethroplasty for treatment of female urethral strictures

There were four papers detailing the outcomes of 42 patients having labial or vestibular graft urethroplasty (see supplementary Table S7.7); fifteen had ventral labial minora graft [132, 139, 484] and thirteen had dorsal labia minora graft [136] and fourtheen had dorsal labia majora graft. At a mean follow-up of 18 to 24 months, patency rates of 75-86% were reported with ventral grafting whilst this was 100% with dorsal grafting at twelve to ninetheen month's follow-up (Table 7.1). One (2.4%) ventral graft patient developed an UTI post-surgery. There were no other complications (including UI). Post void residual volume reduced from 141.9 +/- 44.2 mls to 24.5 +/- 2-.9 ms post dorsal onlay labial minora graft urethroplasty.

7.3.2.4 Labial/vestibular flap urethroplasty for treatment of female urethral strictures

There were two papers detailing the outcomes of twenty-one patients having labial/vestibular flap urethroplasty: seventeen had a dorsal vestibular flap [16], whilst twelve had a dorsal labia minora flap [485]. At a mean/median follow-up of 24 months the two ventral flap patients (100%) remained stricture-free whilst fifteen (88%) dorsal flap patients remained stricture-free at a mean of twelve months follow-up (Table 7.1 and supplementary Table S7.8). There were no adverse short- or long-term effects reported in either group.

7.3.2.5 Buccal and lingual mucosal graft augmentation urethroplasty for treatment of female urethral strictures

There were eleven papers detailing the outcomes of 234 patients, all treated with BMG except in the series of Sharma *et al*., who used lingual mucosa graft (LMG) in fifteen patients at the dorsal urethra [126]; 44 patients with dorsal onlay oral (buccal or lingual) mucosa graft (DOOMG) [126-128, 131, 134, 474, 486-488]; 27 with ventral onlay BMG (VOBMG) [127, 135, 489, 490]. The outcome of circumferential BMG urethroplasty in two patients were only detailed in one paper [127]. At a mean/median follow-up of six to 33 months, 62.5-100% of DOOMG urethroplasty patients were stricture-free whilst 92-100% of VOBMG patients were stricture-free at a mean of six to 24.5 months follow-up. Both circumferential BMG patients were stricture-free at a mean of 21 months follow-up (Table 7.1). Twenty-four (10.7%) DOOMG patients suffered a low-grade short-term adverse effect and no patients in any subgroup developed new onset UI. No patients developed acute complications or new onset stress urinary incontinence following VOBMG urethroplasty or circumferential BMG urethroplasty (although this was only performed in two patients). Mean/median flow rate improved from 5.0-12.5 ml/s (range 3-11.2) to 12.1-28 ml/s (range 14-37) and mean/median PVR reduced from 101-270 mls (range 90-200) to 6.5-122.6 mls following DOBMG. Likewise mean/median flow rate improved from 5.1-7.6 ml/s (range 3-11.2) to 18-29.2 ml/s (range 5-33.4) whilst mean/median post void residual reduced from 100-149 ml (range 0-300) to 15-59.2 ml (range 0-360 mls) following VOBMG. The flow rate and post void residual changes following circumferential BMG urethroplasty have not been detailed as this technique was performed in two patients only and the outcomes detailed in the describing paper are not specific to this technique.

One prospective randomized trial compared VOBMG with DOBMG and found equivalent stricture free rates and improvements in maximum flow rate, post void residual and sexual function. However, there were only twelve patients in each group and follow-up was limited to six months [491].

For further information see supplementary Tables S7.9, S7.10 and S7.11.

7.3.2.6 Anastomotic urethroplasty

Anastomotic urethroplasty has only been described in two cases in the literature – both in women with very short mid-urethral stricture and both of whom were stricture-free at four and 24-months follow-up respectively. None of them suffered from UI post-operatively [127, 496] (see supplementary Table S7.12).

Table 7.1: Summary of available evidence on treatment of female urethral strictures

Treatment	No. of studies	No. of Patients	Patency rate (range %)	New Onset UI (%)	Mean/Median FU Months	Refs
Urethral Dilatation	6	257	40.1 (7.5-51)	1.4	12-59	[128, 129, 475, 478]
Urethral Dilatation + ISD/ planned repeat dilatation	4	109	97 (57-100)**	0	6-21	[13, 133, 136, 479]
Dorsal Vaginal graft urethroplasty	5	72	73-100	0	82 (73-94)	[15, 487, 492, 493]
Ventral Vaginal flap urethroplasty	9	150	83 (67-100)	9.3	12-80.7	[125, 127, 128, 131, 133, 137, 482, 483]

Ventral BMG urethroplasty	54	8927	93 (92-100)	0	610-24.5	[127, 135, 489, 490]

FU = follow-up; ISD = intermittent self-dilatation; N = number of patients; UI= urinary incontinence.
** Patent urethra NOT stricture free as ISC or urethral dilatation continues.*

Summary of evidence	LE
Female urethral stricture symptoms are long standing and non-specific, the most commonly reported are frequency, urgency, poor flow, incomplete emptying, and urinary incontinence. It is important to exclude FUS in female patients with LUTS.	3
Urethral dilatation alone to 24-41 Fr provides low stricture-free rates of mean 40.1% at mean follow-up 36 (12-59) months.	3
Isolated repeat dilatation yields patency rates of 26.6%. However, urethral dilatation followed by ISD or regular planned dilatation, as palliation, provides patencyrates of 97% at mean FU 6-21 months.	3
Urethroplasty provides patency rates of 62.5-100%. VOBMG and DOBMG reported patency rates are 92-100% and 62.5-100%, respectively.	3
Meatotomy/meatoplasty for short meatal strictures has a success rate of 97% at twelve months follow-up.	3

Recommendations	Strength rating
Perform flow rate, post-void residual and voiding cystourethrogram or video-urodynamics in all women with refractory lower urinary tract symptoms.	Strong
Perform urethral dilatation to 24-41 Fr as initial treatment of female urethral stricture (FUS).	Weak
Perform repeat urethral dilatation and start planned weekly intermittent self-dilatation (ISD) with a 16-18 Fr catheter for the 1st recurrence of FUS, or plan repeat dilatation.	Weak
Perform urethroplasty in women with a 2nd recurrence of FUS and who cannot perform ISD or wish definitive treatment. The technique for urethroplasty should be determined by the surgeon's experience, availability and quality of graft/flap material and quality of the ventral versus dorsal urethra.	Strong
Treat meatal strictures by meatotomy/meatoplasty.	Weak

ISC = intermittent self-catheterisation; MRI = magnetic resonance imaging; VUDS = video-urodynamics.

8. DISEASE MANAGEMENT IN TRANSGENDER PATIENTS

8.1 Treatment of strictures in trans men

In trans men, stricture treatment depends on the time after neophallic reconstruction, stricture location, stricture length and quality of local tissues tissues [147, 494].

8.1.1 Management of strictures early after neophallic reconstruction

Urethral surgery on tissues in the acute phase urethra has been stabilised. This usually takes six months [495]. Endoscopic incision for short (< 3 cm) urethral strictures has been performed, mainly at the anastomotic site, with a maximum stricture-free rate of only 16.7% when performed within six months after neophallic reconstruction [496]. Insertion of a suprapubic catheter is the first-line treatment in cases of obstructive symptoms severely affecting the patient's QoL, recurrent UTI or retention. The alternative is perineostomy, which is a specialist procedure and should be performed by a urologist familiar with transgender urethral anatomy. The perineostomy may be closed at the time of formal urethral reconstruction [497].

8.1.2 Treatment of meatal stenosis in trans men

Intermittent urethral dilatation is an option as palliative treatment for low-grade meatal stenosis [31]. Patients with high-grade meatal stenosis, those who refuse ISD, or those who want a durable solution should be offered simple meatotomy. Patency rates are 50% and 75% for transmasculine after respectively metoidioplasty and phalloplasty [147]. The drawback is that the meatus will be in a hypospadiac position. Alternatively, a staged urethroplasty can be offered [147].

8.1.3 Treatment of strictures at the neophallic urethra

The standard treatment for these strictures is staged urethroplasty with or without graft augmentation (BMG or full thickness SG). A patency rate of 50-88% [147, 495, 498] has been reported after phalloplasty and up to 100% after metoidioplasty [147, 495].

For complex (e.g., fully obliterated) or recurrent strictures at the neophallic urethra, a complete urethral substitution with a tubularised radial forearm free flap has been proposed with a 67% patency rate [147].

8.1.4 Treatment of strictures at the anastomosis neophallic urethra-fixed part of the urethra

Short, non-obliterative, strictures can be treated by endoscopic incision. A first endoscopic incision has a 37-45.5% patency rate, but this dropped to 0% in case of three or more attempts (median follow-up of 51 months) [495, 496]. Therefore, repetitive endoscopic incisions should be discouraged unless with palliative intent.

For very short (< 1.5 cm) low-grade strictures, Heineke-Mikulicz urethroplasty is an option reporting a 58-80% after phalloplasty and up to 100% after metoidioplasty [147, 495].

If the stricture is nearly or completely obliterative, options are EPA, graft augmentation urethroplasty or staged urethroplasty. Excision and primary anastomosis yields a patency rate of 46-57% after phalloplasty and 78% after metoidioplasty [147, 495]. Alternatively or if EPA is not possible (stricture length >2 cm), a graft augmentation urethroplasty can be performed with a 56-100% patency rate [147, 495]. In case of insufficient ventral tissue during graft urethroplasty, it is advised to support this graft by a local fasciocutaneous flap [147]. An alternative (especially after failure of the previous techniques) can be a staged approach [147, 495].

8.1.5 Treatment of strictures at the fixed part of the urethra

This part of the urethra has a more reliable blood supply, and the dorsal part of the urethra is supported by the corporal bodies of the clitoris. Therefore, single-stage dorsal inlay graft urethroplasty is possible for strictures at this site, especially after metoidioplasty, with up to 100% patency rate [495]. Staged repair with or without a dorsal graft is an alternative for these rare strictures [495].

8.1.6 Definitive perineostomy in trans men

Definitive perineostomy should be offered to patients with refractory strictures or to those with strictures who do not wish to have complex reconstructive surgery [147, 495].

8.2 Peri-operative care after treatment of strictures in trans men

Anecdotally, after endoscopic incision and urethroplasty, the urethral catheter is maintained for two to three weeks [496, 499]. Peri-catheter urethrography is advised before catheter removal as it might be challenging to reinsert the urethral catheter in case of urinary extravasation [499].

8.3 Strictures in trans women

It is acceptable to start with dilation of a short and non-obliterative stricture in trans women although no long term data about the effectiveness are available [31]. If this is not possible or if it fails, a short (< 1 cm) meatal stricture can be treated by Y-V meatoplasty with an 85% stricture-free rate [500]. Somewhat longer (1-2 cm) meatal strictures can be treated by a neovaginal advancement flap (inverted U or "7-flap") with no recurrence observed after 37 months median follow-up [501].

Summary of evidence	LE
After neophallic reconstruction, local tissues go through the different stages of wound healing and stable wound healing is usually achieved after six months.	3
After two attempts, endoscopic incision is no longer successful in trans men.	3
Two-stage urethroplasty for strictures at the neophallic urethra has a patency rate of 50-88% after phalloplasty and up to 100% after metoidioplasty.	3
Y-V meatoplasty for short (< 1 cm) meatal stenosis in trans women has a stricture-free rate of 85%.	3

Recommendations	Strength rating
Do not perform endoscopic incision or urethroplasty within six months after neophalloplasty.	Strong
Do not perform more than two endoscopic incisions for strictures in trans men unless with palliative intent.	Strong
Perform staged urethroplasty for strictures at the neophallic urethra if open reconstruction is indicated.	Weak
Perform Y-V meatoplasty for short (< 1 cm) meatal stenosis in trans women if open reconstruction is indicated.	Weak

9. TISSUE TRANSFER

9.1 Comparison of grafts with flaps

One small RCT (LS excluded) comparing OMG with PSF found no significant difference in urethral patency rate [502]. Penile skin flaps had a higher urogenital morbidity (superficial penile skin necrosis, penile torsion, penile hypoesthesia, and post-void dribbling) and longer operation time compared to OMG. Furthermore, patient dissatisfaction was significantly higher with penile flaps [502]. Another small RCT (LS excluded) comparing penile skin grafts with PSF confirmed these findings with longer operation time and more superficial penile skin necrosis in the group of the flaps, whereas the urethral patency rate was similar between both groups [355]. Several retrospective series also found a comparable urethral patency rate between PSF and grafts [272, 274, 503, 504] (Table 9.1).

Table 9.1: Comparative studies of grafts vs. flaps used in urethroplasty for anterior urethral strictures

Study	Type of study	LS	Follow-up (months)	Flap		Graft		p-value*
				Type	Urethral patency	type	Urethral patency	
Barbagli *et al.* [272]	Retrospective	Excl.	55	LIF	12/18 (67%)	OMG/PSG	36/45 (80%)	0.32
Dubey *et al.* [502]	RCT	Excl.	22-24	LIF	22/26 (84.6%)	BMG	24/27 (88.9%)	0.70
Fu *et al.* [274]	Retrospective	Excl.	>12	All types	166/199 (83.4%)	LMG	80/94 (85.1%)	0.71

Hussein *et al.* [355]	RCT	Excl.	36	TIF	15/19 (78.9%)	PSG	13/18 (72.2%)	0.25
Lumen *et al.* [504]	Retrospective	NR	42-43	All types	23/29 (79.3%)	OMG/PSG	63/75 (84%)	0.57
Sa *et al.* [503]	Retrospective	Excl.	28 (18-60)	TIF	28/34 (82.3%)	BMG	67/82 (81.7%)	0.851

BMG = buccal mucosa graft; Excl. = excluded; LIF = longitudinal island flap; LMG = lingual mucosa graft; LS = lichen sclerosus; mo = months; NR = not reported; OMG = oral mucosa graft; PSG = penile skin graft; TIF = transverse island flap; RCT = randomized controlled trial.
** if not reported: recalculated by EAU Urethral Strictures Panel with chi²-statistics.*

Due to their robust vascular pedicle, flaps can be used as a tube as well as a patch in a single-stage approach [442]. Castagnetti *et al.*, showed that grafts used as a tube have significantly higher complication rates as compared to onlay grafts (OR: 5.86; 95% CI: 1.5-23.4) [505]. A review by Patterson *et al.*, also reported high (circa 50%) complication and recurrence rates for tubularised grafts [506]. Iqbal *et al.*, have shown an encouraging 87% stricture-free rate in 23 patients who were offered single-stage circumferential skin flap urethroplasty [281]. Therefore, if there is a need to reconstruct a complete urethral segment with a tissuetransfer tube in a one-stage operation, flaps are usually the preferred option. As flaps carry their own vascular supply to the reconstruction site, they do not rely on the local vascularisation of the recipient site. Therefore, they need to be considered in case of poor urethral vascularisation (e.g., after irradiation or dense scarring after previous urethroplasty) [504, 507]. In addition, flaps survive well in the presence of active urinary infection [508].

Grafts and flaps should not be considered competitors in urethral surgery. A combination of a flap with a graft is possible for complex, multifocal or penobulbar strictures [504, 509, 510].

Summary of evidence	**LE**
Flaps have a higher urogenital morbidity, but a comparable patency rate compared to grafts.	1b
Grafts have a significantly higher complication rate compared to flaps when complete tubularisation in a single-stage approach is needed.	1b
Flaps do not rely on the local vascularisation of the recipient site.	3

Recommendations	**Strength rating**
Use a graft above a flap when both options are equally indicated.	Strong
Do not use grafts in a tubularised fashion in a single-stage approach.	Strong
Use flaps in case of poor vascularisation of the urethral bed.	Weak

9.2 Comparison of different types of flaps

Different local flaps have been described. Penile skin flaps are generally hairless, although the ventral penile skin can be hair-bearing around the raphe in some ethnic groups/phenotypes. They can be harvested as a transverse preputial skin flap [511], a transverse distal PSF [358, 508, 512, 513] or as a longitudinal island flap [514]. Urethral patency rates vary between 74.2-100% [274, 358, 508, 511-514]. Complications include skin necrosis (0-3.8%), fistula (0-7%), penile deformity (0-7%), post-void dribbling (0-79%) and sacculation (0-16.5%) (see supplementary Table S9.1). As there are no direct comparative series available about these flaps it is not possible to determine which performs better.

Hair-bearing perineal and scrotal flaps have been described as well. Fu *et al.*, demonstrated that PSF had a significantly better urethral patency rate compared to scrotal and perineal skin flaps (respectively 87.7%, 69% and 66.7%) [274]. The hair-bearing perineal and scrotal skin flaps are associated with hairball formation and chronic infection which may cause failure of the repair. A study of Blandy with long-term follow-up, reports 3% revision for calculi and 3% revision for diverticula [515].

An alternative is to epilate the needed scrotal skin prior to tissue transfer [516, 517] or to patch an OMG to the underlying dartos tissue of the scrotum after incision of the scrotal skin and use this patch as a flap in a second attempt [442].

Summary of evidence	LE
Hair-bearing flaps have a lower urethral patency rate compared to non-hair-bearing flaps.	3

Recommendation	Strength rating
Do not use hair-bearing perineal or scrotal flaps unless no other option is feasible.	Strong

9.3 Comparison of different types of grafts

Buccal mucosa is at present the most commonly used graft. A systematic review on anterior urethral strictures reports a urethral patency rates of buccal mucosa of 86.6% with an average follow-up of 31.5 months [518].

Penile skin is another popular graft, especially in uncircumcised men where the foreskin is an abundant source of graft material.

In case of LS, Trivedi *et al*., demonstrated a significantly higher urethral patency rate when using non-genital mucosal grafts for reconstruction (82.6%) compared to genital skin grafts (4%) [519]; therefore, the use of genital skin in LS cases is not indicated.

In one RCT (Pee'BuSt trial) comparing buccal mucosa with penile skin as a graft for dorsal onlay augmentation urethroplasty for anterior strictures, no significant difference in outcome could be observed [520]. A systematic review and meta-analysis suggests that BMG augmentented urethroplasty, may be superior to penile skin graft urethroplasty. However, there were a lot of confounding factors, and clear conclusions cannot be made [521]. Lengthy skin grafts (up to 20 cm) can be taken from the foreskin in a spiroid fashion which is clearly more difficult with OMG.

The main disadvantage of BMG harvesting is the oral morbidity and because of this morbidity, lingual mucosa has been proposed as alternative. A SR and meta-analysis of comparative studies comparing LMG with BMG (four prospective, two retrospective studies) showed no significant differences in urethral patency rate and overall long-term complication rate [522-524]. These studies revealed that LMG was associated with more difficulties in eating/drinking, speaking, tongue protrusion and dysgeusia [522, 523]. In 13.8-20%, speaking problems remained after six months [522, 523]. A retrospective study of Xu *et al*., reported difficulties in tongue movements, numbness over the donor site and speaking difficulties in 6.2%, 4.9% and 2.5% of patients, respectively after twelve months [301]. On the other hand, BMG harvesting provoked more oral tightness which was present in up to 24% of patients after six months [522, 523]. Chauhan *et al*., showed that immediate and early donor site complications were more common in the BMG group, except for bleeding being more common in the LMG group. Numbness (61%), difficulty in chewing (54%), swelling (48%) and articulation (40%) were the most common problems during the first week. Late donor site complications were rare [525]. Pal *et al*., describes more short-term complications (difficulty in tongue movement and slurring of speech) in the LMG group, compared to the BMG group. Long-term complications (after three months) at the donor site (persistent pain, perioral numbness, tightness of mouth, salivary disturbance, scarring of the cheeks) were only seen in the BMG group [526]. For long strictures, buccal mucosa can be combined with lingual mucosa [301].

The use of lower lip mucosa was described, especially when smaller grafts are needed, and has similar qualities to lingual mucosa. However, a narrative review based on the experience from retrospective series showed that these grafts have a higher post-operative donor site morbidity and can lead to permanent sequelae (persistent discomfort, neurosensory deficits, salivary flow changes and important aesthetic changes) at the donor site, which have not been described with lingual mucosa [527].

Beyond the oral mucosa and penile skin graft, a multitude of other autologous grafts have been described. These include: postauricular skin [510, 528], abdominal skin [360], split-thickness mesh graft from the thigh [341], inguinal skin [300] and colonic mucosa [529] (Table 9.2). Manoj *et al*., only used the postauricular skin when both genital skin and oral mucosa were not usable [528]. Marchal *et al*., used postauricular skin in addition to oral mucosa to reconstruct lengthy strictures [510]. Meeks *et al*., reported the use of abdominal skin graft mainly in patients with lengthy strictures where OMG harvesting would be insufficient, in case of prior OMG urethroplasty or if OMG was refused by the patient [360]. Pfalzgraf *et al*., reported a comparable urethral patency rate for split-thickness mesh graft and BMG (respectively 84 and 83%), but more penile deviation (9% vs. 0%) and lower satisfaction (83.3% vs. 96.7%) with split-thickness mesh graft [341]. Xu *et al*., used colonic mucosa for lengthy (> 10 cm) strictures. Urethral patency rate was 85.7% but graft harvest requires an abdominal procedure, and 1/35 (2.9%) patient developed a colonic-abdominal fistula [529]. Due to the limited experience with grafts other than oral mucosa and penile skin, they should only be considered if oral mucosa and penile skin are not available, indicated, or desired.

Table 9.2: Outcome of case series of other autologous grafts

Study	Type of graft	N	Follow-up (months)	Stricture length (cm)	Urethral patency (%)
Bastian *et al*. 2012 [302]	Inguinal skin	34	70 (3-86)	8 (1.5-14)	91
Manoj *et al*. 2009 [528]	Postauricular skin	35	22 (3-48)	8.9 (3-15)	89
Meeks *et al*. 2010 [360]	Abdominal wall skin	21	28 (11-52)	11 (4-24)	81
Pfalzgraf *et al*. 2010 [351]	Split thickness skin graft	57/68	32	NR	84
Xu *et al*. 2009 [529]	Colonic mucosa	35	53.6 (26-94)	15.1 (10-20)	85.7

N = number of patients; NR = not reported.

Summary of evidence	LE
Patency rates of buccal mucosa and lingual mucosa are comparable.	1a
Different types of oral grafts have distinct types of oral morbidity and some of the oral complications might last in the long-term.	1a
Patency rates with penile skin grafts are 79-81.8% versus 85.9-88.1% with buccal mucosa.	3
In LS related strictures, the use of genital skin graft is associated with poor patency rates (4%).	3

Recommendations	Strength rating
Use buccal or lingual mucosa if a graft is needed and these grafts are available.	Weak
Inform the patient about the potential complications of the different types of oral grafting (buccal versus lingual versus lower lip) when an oral graft is proposed.	Strong
Use penile skin if buccal/lingual mucosa is not available, suitable, or accepted by the patient for reconstruction.	Weak
Do not use genital skin graft in case of lichen sclerosus.	Strong

9.4 Tissue engineered grafts

9.4.1 Cell-free tissue engineered grafts

These grafts are derived from cadaveric or animal sources (e.g., porcine small intestine submucosa [SIS], acellular bladder matrix, acellular dermal matrix), are completely cell-free and serve as a scaffold for host cell ingrowth [530]. The main advantage suggested for their use is the off-shelf availability [530].

A small RCT (n=30) comparing acellular bladder matrix with BMG reported a urethral patency rate of respectively 66.6% and 100%. The poorer results of acellular bladder matrix were the most apparent in cases of an unhealthy urethral bed [531].

Several small retrospective case series using mainly porcine small intestinal submucosa, demonstrate varying patency rates from 20-110%. The patient groups were heterogenious in terms of aetiology, previous treatment, urethral location and definition of success rate. An overview can be found in Table 9.3. Most papers report a poorer outcome in case of extensive spongiofibrosis, poor vascular graft bed, previous treatments and longer strictures [531-535] (Table 9.3).

Table 9.3: Outcome of retrospective case series using cell-free tissue engineered grafts

Study	N	FU (mo)	Type of graft	Patency Rate (%)
el-Kassaby *et al*. 2008 [531]	15	25	cadaveric acellular bladder matrix	33-88
Palminteri *et al*. 2012 [535]	30	71	porcine small intestinal submucosa	76
Xu *et al*. 2013 [534]	28	24.8	porcine small intestinal submucosa	92
Tang *et al*. 2020 [533]	49	15	allogeneic acellular dermal matrix	85.7
Fiala *et al*. 2007 [532]	50	31.2	porcine small intestinal submucosa	80

Summary of evidence	LE
Patency rate of cell-free tissue engineered grafts decreases with large stricture length and unhealthy urethral bed.	1b

Recommendation	Strength rating
Do not use cell-free tissue engineered grafts in case of extensive spongiofibrosis, after failed previous urethroplasty or stricture length > 4 cm.	Weak

*9.4.2 **Autologous tissue engineered oral mucosa graftss***

These grafts contain a matrix seeded with autologous oral mucosa cells. Production requires a small oral mucosa biopsy (at 0.5 cm²) and the graft is further manufactured in the lab. The main advantage suggested is the reduction of oral donor site morbidity whereas the main disadvantages are costs and the strict time frame between manufacturing and implantation of the graft [530].

The clinical use of autologous tissue-engineered OMG was evaluated in a prospective, multicentre study including 99 patients [536]. Estimated twelve- and 24-months urethral patency rate was 67.3 and 58.2%, respectively. Oral adverse events were minimal. No comparative studies with acellular grafts or native OMGs are available nor are there any data about the cost-effectiveness [530].

Summary of evidence	LE
Safety, patency rate and cost-effectiveness of autologous tissue-engineered grafts is currently under research.	3

Recommendation	Strength rating
Do not use autologous tissue-engineered oral mucosa grafts outside the frame of a clinical trial.	Strong

9.5 Management of oral cavity after buccal mucosa harvesting

The post-operative morbidity of closure vs. non-closure of the buccal mucosa harvesting site has been evaluated by a number of prospective RCTs.

The results are summarised in Table 9.4. Based on these findings, no clear recommendation can be provided as to whether or not to close the harvesting site and the decision can be left to the treating physician.

Oral rinsing with chamomile [537] or chlorhexidine [523, 538] solution has been suggested in the first post-operative days without any evidence that this reduces pain or other oral complications.

Table 9.4: Effect of non-closure compared to closure on oral morbidity after buccal mucosa harvesting

Study	Early oral pain	Eating/ drinking problems	Altered taste	Altered salivation	Oral tightness	Perioral numbness	Oral bleeding	Slurred speech
Soave *et al*. [537]	=	=	=	=	=	=	=	=
Rourke *et al*. [539]	=	↓	NR	NR	↓	↓	=	NR
Muruganandam *et al*. [540]	↓	=	NR	=	=	=	=	NR
Wong *et al*. [538]	=	↑	NR	NR	=	=	=	NR
Lumen *et al*. [523]	↑	NR	NR	NR	NR	NR	NR	NR

↓ = less morbidity with non-closure; ↑ = more morbidity with non-closure; = = no significant difference; NR = not reported.

10. PERI-OPERATIVE CARE OF URETHRAL SURGERY

10.1 Urethral rest

After any form of urethral manipulation (urethral catheter, ISD, dilatation, DVIU), a period of urethral rest is necessary in order to allow tissue recovery and stricture "maturation" before considering urethroplasty. This improves the ability to identify the true extent of the fibrotic segments during subsequent surgery. If the patient develops incapacitating obstructive symptoms or urinary retention, a suprapubic catheter should be inserted. Terlecki *et al*., propose diagnostic evaluation after two months and urethroplasty after three months of urethral rest. These timings are based on the general principles of wound healing [541]. In their study, it has been shown that these periods allow for reliable stricture evaluation during urethrography which is, in turn, important to ensure selection of the most appropriate urethroplasty technique [541]. Utilising this strategy, similar outcomes were obtained compared to patients with stable previously unmanipulated strictures [541]. However, the optimal duration of urethral rest for all patients is not known and the degree of associated infection and inflammation should be taken into account as well, with longer periods of rest in those with greater degrees of infection and inflammation.

Summary of evidence	LE
After any form of urethral manipulation, a minimum period of three months urethral rest is necessary to allow for tissue healing before performing urethroplasty.	3

Recommendation	Strength rating
Do not perform urethroplasty within three months of any form of urethral manipulation.	Weak

10.2 Antibiotics

Post-operative wound infection and UTI are common post-operative complications and infection at the site of reconstruction may contribute to failure of urethroplasty. The vast majority of reconstructive urologists perform urine culture one to two weeks prior to surgery [542]. Urine culture is superior to urine-analysis which can be omitted in the pre-operative evaluation [542]. If infection or colonisation is present, a therapeutic course with antibiotics is recommended pre-operatively. Preoperative UTI, even when properly treated, could increase the risk of post-operative UTI [543]. In case of an indwelling catheter general principles would suggest at least an attempt to suppress the colonisation with pre-operative antibiotics [542]. These practices are in accordance with the strong recommendations of the EAU Guidelines on Urological Infections:

- "Screen for and treat asymptomatic bacteriuria prior to urological procedures breaching the mucosa."
- "Treat catheter-associated asymptomatic bacteriuria prior to traumatic urinary tract interventions."

An intra-operative prophylactic regimen with antibiotics (according to local antibiotic resistance profiles) is effective in reducing the rate of post-operative surgical site and UTIs [542]. Although most urologists continue with post-operative antibiotics upon and even beyond catheter removal, there is no evidence that such a prolonged administration would reduce the infective complication rate [542]. A retrospective study from Baas *et al*., revealed that extended postoperative antibiotic prophylaxis (three weeks until catheter removal versus 3 days around catheter removal) does not appear to affect UTI rates following urethroplasty [544]. The EAU Guidelines on Urological Infections do not routinely recommend the use of antibiotic prophylaxis to prevent clinical UTI after urethral catheter removal. There is no evidence that this recommendation would not apply to catheter removal after urethral surgery.

Summary of evidence	LE
An intra-operative prophylactic regimen with antibiotics is effective in reducing the rate of postoperative surgical site and urinary tract infections.	4

Recommendation	Strength rating
Administer an intra-operative prophylactic regimen with antibiotics at time of urethral surgery.	Strong

10.3 Catheter management

After uncomplicated DVIU, there is no advantage in maintaining the catheter for a prolonged period and it should be removed within 72 hours [545].

After one-stage urethroplasty and closure of the urethral plate after staged urethroplasty, urinary extravasation at the site of reconstruction must be avoided [546]. For this purpose, urinary diversion by either transurethral catheter or suprapubic catheter with urethral stent can be used. With respect to the type of catheter material, a prospective randomised (but underpowered) trial comparing silicone vs. hydrogel coated latex transurethral catheters showed no significant difference in the time to stricture recurrence nor in the overall recurrence rate [546]. The size of the urethral catheter utilised usually varies between 14 Fr and 20 Fr [547, 548]. Systematic use of anticholinergic drugs has not shown a significant reduction in the rate of involuntary pericatheter voiding whilst catheterised [549].

After urethroplasty an indwelling catheter is commonly left *in situ* for two to three weeks [548, 550]. After three weeks of urethral catheterisation, an extravasation rate of 2.2-11.5% at urethrography has been reported after different types of urethroplasty [550-553]. However, success with early catheter removal under three weeks has also been reported. A study after EPA for non-complicated anterior strictures demonstrated no significant difference in extravasation (6.8% vs. 4.5%) and recurrence rates (4.9% vs. 5.2%) between catheter removal at one or two weeks respectively [554]. Poelaert *et al*., reported an extravasation rate of 3.5% vs. 8.3%, when the catheter was removed < 10 days or > 10 days respectively after all types of urethroplasty (n=219) (p=0.158) [547]. Importantly, patients who had a duration of catheterisation of > 10 days had longer and more complex strictures [547]. Beiske *et al*., revealed a higher incidence of UTI in patients with a three week catheterization after open urethroplasty, compared to two weeks [555].

Prior to catheter removal after urethroplasty, it is important to assess for urinary extravasation to avoid ensuing complications including peri-urethral inflammation, abscess formation and fistulation [550, 552]. Importantly, some authors have identified urinary extravasation as a predictive factor for stricture recurrence [547, 556]. Other series, however, could not confirm the prognostic significance of urinary extravasation but they included any form of extravasation (including minor leaks) [552, 553]. Grossgold *et al*., found that high-grade leaks (defined as length > 1.03 cm and width > 0.32 cm) were significantly associated with higher restricture rates. This study also found length of extravasation > 1.03 cm alone to be an independent predictor of restricture [556]. In cases of persistent and significant urinary extravasation, the catheter should be maintained or reinserted and the examination repeated after one week [550]. However, low-grade ("wisp-like") extravasation does not appear to affect long-term restricture rate and the catheter can be removed in these cases without subsequent urethrogram [552, 556]. In case of any doubt about the significance of extravasation, it is safe to keep the catheter in for an additional week and ReDo the assessment.

The assessment of urinary extravasation is achieved by either pericatheter retrograde urethrography (pcRUG), classic RUG or VCUG [550]. A prospective study (n=80) comparing pcRUG and VCUG in a within-patient fashion demonstrated a comparable sensitivity for contrast extravasation. Moreover, pcRUG averts the risk of having to reinsert the catheter, avoids the problem of patients being unable to void during VCUG and requires significantly less radiation (120 mGy/cm^2 versus 241 mGy/cm^2; $p < 0.001$) [557].

In cases of attempted VCUG where the patient is not able to void during fluoroscopy after catheter removal, RUG should be performed [556].

Although limited evidence for urethroplasty care in trans men exists, one study advised a three-week period of transurethral catheterisation with pcRUG upon catheter removal [499].

After perineostomy or the 1st stage of staged urethroplasty, the catheter can be removed without need for urethrography after three to five days [339, 552].

Summary of evidence	**LE**
Prior to catheter removal after urethroplasty, it is important to assess for urinary extravasation with urethrography to avoid ensuing complications including peri-urethral inflammation, abscess formation and fistulation.	2b
After uncomplicated DVIU, there is no advantage in maintaining the catheter for a prolonged period.	3
Early catheter removal may be appropriate for a subset of patients with short, uncomplicated, strictures.	3

Recommendations	Strength rating
Perform a form of validated urethrography after urethroplasty to assess for urinary extravasation prior to catheter removal.	Strong
Remove the catheter within 72 hours after uncomplicated direct vision internal urethrotomy or urethral dilatation.	Weak
Consider 1st urethrography seven to ten days after uncomplicated urethroplasty to assess whether catheter removal is possible, especially in patients with bother from their urethral catheter.	Weak

11. FOLLOW-UP

11.1 Rationale for follow-up after urethral surgery

The rationale for following-up patients after urethral stricture surgery is to detect and manage any complication or recurrence. As with any surgical procedure, following urethroplasty some patients will present with complications at short to medium follow-up: up to 34-38% of all anterior urethroplasties. Most of these complications (92-99.1%) would be classified as Clavien grade 1 or 2 [558, 559]. Even though urethroplasty techniques provide the highest chances for successful treatment of urethral strictures, some patients will experience recurrence [346]. For further details on particular outcomes in each urethral segment, please review the individual chapters of this Guideline.

Summary of evidence	LE
After urethroplasty surgery, recurrent strictures appear with different frequency depending on stricture features and urethroplasty techniques.	3

Recommendation	Strength rating
Offer follow-up to all patients after urethroplasty surgery.	Strong

11.2 Definition of success after urethroplasty surgery

The "traditional academic" definition of post-operative success after urethroplasty has been considered as "The lack of any post-operative intervention for restricture" [560]. This definition, despite being widely used [305, 558] is problematic as it ignores asymptomatic or even symptomatic recurrences in patients not willing to undergo further surgeries [560]. There is some variation as to what is considered intervention with some groups accepting endoscopic treatments as success, while considering failure only as the requirement for a ReDo urethroplasty [306].

A more objective definition of success is the "anatomic success", defined as "Normal urethral lumen during RUG or cystoscopy, regardless of patient symptoms". Using this definition, stricture recurrence or anatomical failure is considered by some groups as urethral narrowing found to be endoscopically impassable – without force – with a 16 Fr flexible endoscope [145, 561]. This definition is certainly stricter, with up to 35% of cystoscopic recurrences after bulbar urethroplasty remaining asymptomatic, and thus would have been considered as successful if a "lack of further intervention" definition was used [145]. Other groups consider cystoscopic recurrence as any stricture that is visible on post-operative cystoscopy, even the so-called "large calibre re-strictures" (> 17 Fr) [143]. Not all anatomic recurrent strictures would need further treatment [560]. It was suggested to intervene when the anatomic recurrence is associated with recurrence of symptoms, stricture-related high post-void residuals or a stricture calibre of < 14 Fr – even if these are asymptomatic [560].

Over the last ten years, the evaluation of urethral surgery outcomes has shifted towards a "patient-reported definition of success". The aim of any urethral intervention is to allow patients to return to a normal state of voiding while maintaining QoL or to minimise symptoms, reduce disability, and improve HRQoL by restoring normal urinary function [562]. Even if the surgeon reconstructed a wide and patent urethra, if patients experience pain, sexual dysfunction or perceive their urinary function as not improved, they will not rate their outcome as successful [560]. On a multivariate analysis including both patient-reported and clinical parameters, urine flowmetry parameters failed to demonstrate significant contribution to satisfaction [563]. Kessler *et al*., reported that only 78.3% of patients with clinical success described themselves as (very) satisfied. More

dissatisfaction significantly appeared with penile curvature, penile shortening, worsening of erectile function and impairment of sexual life [564]. Conversely, 80% of patients defined as clinical failures considered themselves as (very) satisfied with their outcomes [564]. Regardless of anatomic success after urethroplasty, post-operative pain, sexual dysfunction and persistent LUTS were independent predictors of patient dissatisfaction [563]. Improvement in voiding function (i.e., statistical improvement on IPSS) alone does not predict patient satisfaction after urethroplasty [565]. On a multivariate analysis including both patient-reported and clinical parameters, after adjusting for disease recurrence and age, persistence in voiding symptoms (weak stream), genitourinary pain, and post-operative sexual function alterations were the greatest independent drivers of post-operative dissatisfaction [563]. In addition, penile shortening (OR: 2.26; 95% CI: 1.39-3.69) and chordee (OR: 2.26; 95% CI: 1.44-4.19) were independent predictors of patient dissatisfaction after urethroplasty [565] (Table 11.1).

Table 11.1: Predictors of patient dissatisfaction after urethral surgery

Predictor/Symptoms	Measure of effect	Authors
Weak/very weak urinary stream	< 0.001	Kessler TM *et al*. J Urol 2002 [564]
Penile curvature	0.001

SHIM = Sexual Heath Inventory for Men; MSHQ = Male Sexual Health Questionnaire;
CLSS = Core Lower Urinary Tract Symptom Score; IPSS = International Prostate Symptoms Score.

Due to this evident discrepancy between surgeon's assessment and patient assessment, PROMs have been developed for the follow-up after urethroplasty [160, 562].

A complete approach for urethral surgery outcomes would combine both anatomic, endoscopic, and Patient-reported success [560, 566]. The Panel suggest using a functional definition of success in clinical practice, namely "lack of symptoms and/or need for further interventions".

Collecting standardised documentation of the patient's subjective assessment of their symptoms and objective anatomic outcomes would be limited for academic purposes, in order to allow comparison of surgical outcomes among reconstructive urologic surgeons and centres. Those objective and subjective outcomes measures should therefore be assessed and reported (simultaneously but separately) when evaluating urethroplasty results [560].

11.3 Follow-up tools after urethral surgery

*11.3.1 **Diagnostic tools for follow-up after urethral surgery***

11.3.1.1 Calibration during follow-up after urethral surgery

The difference between calibration and urethral dilatation is usually subjective as soft strictures may be dilated during calibration [567]; therefore, urethral calibration should be used with caution for follow-up after urethroplasty. Dedicated calibration bougies should be used and not dilatators.

11.3.1.2 Urethrocystoscopy during follow-up after urethral surgery

Urethrocystoscopy has been considered the most useful tool to confirm the presence or absence of a recurrent stricture [143, 568], as up to 35% of patients with re-strictures remain asymptomatic [145]. Also, the cystoscope could be a measure to calibrate the strictured lumen, bearing in mind the most commonly used endoscopes: 15.7 Fr (5 mm diameter) or 17.3 Fr (5.5 mm diameter) [568]. Urethrocystoscopy allows differentiation of recurrences as diaphragm/cross-bridging – responding to simple intervention, or significant urethral restrictures – requiring repeated interventions or ReDo surgeries [569]. Endoscopic assessment at three months after anterior urethroplasty can predict the risk for further re-intervention at one year. Compared to normal endoscopy, large calibre (> 17 Fr) restrictures have a HR of 3.1 (1.35-7.29) for repeat intervention while small calibre (< 17 Fr) restrictures have a 23.7 HR (12.44-45.15) adjusted for age, stricture length, location, and aetiology [143]. The main problem with using urethrocystoscopy for routine follow-up is the low compliance of patients as only 54% of patients underwent endoscopy at one year after urethroplasty, even when it was a part of a study protocol [145].

11.3.1.3 Retrograde urethrogram and voiding cystourethrogram during follow-up after urethral surgery

Retrograde urethrogram combined with VCUG are commonly used to confirm suspected recurrence [570, 571] or as part of a routine protocol to assess post-operative urethral patency [572, 573].

11.3.1.4 Urethral ultrasound – Sonourethrography during follow-up after urethral surgery

The use of SUG as a follow-up tool is not very common. It would be a reliable tool for diagnostic recurrent strictures [570].

11.3.2 ***Screening tools for follow-up after urethral surgery***

These tools are used to assess whether there is suspicion of stricture recurrence and need for subsequent diagnostic evaluation (see section 5. Diagnostic evaluation).

11.3.2.1 Flow-rate analysis during follow-up after urethral surgery

Evaluating the Q_{max} is the commonest follow-up tool. Different cut-off points from Q_{max} 15 ml/s or 12 ml/s were suggested to consider the intervention as a failure or to trigger a confirmatory test for recurrence [574]. There is no clear threshold, and 19% of patients with Q_{max} < 14 ml/s would still have a patent urethra, allowing passage of 15 Fr cystoscope [146].

Flow rates may be affected by operator error, BPO/LUTS, bladder dysfunction, and variations in bladder capacity. Further limitations of uroflowmetry include the need for a minimum voided volume of 125-150 ml to reach a voided flow rate that reliably predicts an abnormality [567]. Even in controlled settings, the percentage of patients with adequate pre- and post-operative uroflowmetry analysis is only 31% [573]. Comparing both pre- and post-operative Q_{max} levels was suggested, and a difference in Q_{max} of 10 ml/s or less is found to be a reliable screen tool for recurrence (sensitivity 92%, specificity 78%). This measure also has strong reproducibility (R=0.52) [573]. Unfortunately, this improvement after urethroplasty is significantly different between age groups, with less than 10 ml/s average change in those over 65 years old, probably affected by BPO and/or bladder dysfunction [575]. Another parameter to consider is the shape of the voiding curve, recording it as flat (obstructed) or bell-shaped [576]. An obstructive voiding curve demonstrated 93% sensitivity to predict recurrent strictures, while a combination of urinary symptoms and obstructive voiding curve achieved 99% sensitivity and 99% NPV [576].

11.3.2.2 Post-void residual ultrasound measure during follow-up after urethral surgery

Post-void residual US measure is significantly increased in patients with recurrent strictures compared with those without recurrences [570]. Unfortunately, PVR measurement is affected by abdominal ascites, bladder diverticula and/or poor bladder function [567], with some studies reporting inconsistent correlation with obstruction in the presence of BPO. Also, US measures of PVR are user dependent, showing high interobserver variability. Combined with other tests – uroflowmetry, IPSS, and SUG – PVR achieves adequate predictive values [570], but currently there is no literature to support its solo use, to assess urethral stricture recurrence [577].

11.3.2.3 Symptom questionnaires during follow-up after urethral surgery

The IPSS questionnaire, despite being designed for BPO, showed significant improvement after successful urethroplasty and inverse significant correlation with Q_{max} [565, 567]. The mean improvement of IPSS is around -11 points (range -19 to -5) [575].

Table 11.2: Post-urethroplasty changes in IPSS values

Author	N	Mean pre-operative value	Mean post-operative value	Change	Significancy
Morey AF *et al*. 1998 [578]	50	26.9	4.4	NR	p < 0.0001
DeLong J *et al*. 2013 [575]	110	NR	NR	-11 (IQR -19 - -5)	p < 0.001
Maciejewski CC *et al*. 2017 [565]	94	18.7 (+/- 9)	5.8 (+/- 5)	NR	p < 0.0001

N = number of patients; NR = not reported; IPSS = International Prostate Symptoms Score; IQR = interquartile range.

Combination of IPSS and Qmax analysis was suggested to diagnose recurrences. Using an IPSS cut-off point of 10 points associated with Q_{max} > 15 ml/s would prevent further invasive studies in 34% of patients, while only 4.3% of strictures < 14 Fr would have been missed. Using an IPSS cut-off point of 15 points associated with Q_{max} > 15 ml/s would prevent further invasive studies in 37% of cases, while 6% of strictures < 14 Fr would have been missed [579].

The Visual Prostate Symptom Score (VPSS) was also used to diagnose recurrent urethral strictures, offering a significantly shorter time to completion compared with IPSS, especially in cases of illiteracy or limited education. Visual Prostate Symptom Score showed a good correlation with IPSS, Q_{max} and urethral diameter. A combination of VPSS > 8 with Q_{max} < 15 ml/s had a NPV of 89% and a PPV of 87% for recurrent urethral strictures [580].

Post-micturition dribble, assessed by the specific question of the USS-PROM questionnaire, was present in 73% of patients pre-operatively and 40% after anterior urethroplasty, while only 6.3% was *de novo*. Incidence was not predicted by stricture location nor urethroplasty type [150].

11.3.3 Quality of life assessment, including disease specific questionnaires during follow-up after urethral surgery

Urethral stricture affects QoL evaluated by EQ-5D-3L questionnaire. Pre-operative anxiety and depression was found in 29% of patients. *De novo* AD after urethroplasty is uncommon (10%) and has two predictors: decreased sexual function and poor reported image of overall health [581]. A more recommended approach is the assessment of the condition-related QoL [582]. The USS-PROM proved useful to assess outcomes in anterior urethroplasty patients [562]. Its use also received criticism, as some of the individual generic QoL questions do not improve after successful urethroplasty, as they are not condition-specific [583]. Currently, there is another version of PROM, being developed and validated by a North American collaborative group, including questions related to the sexual consequences of urethral stricture disease [161]. PROM questionnaires should be implemented in each visit to check for functional success, as they are able to show improvement over time.

The Core Lower Urinary Tract Symptom Score (CLSS) questionnaire was used to assess pre- and post-urethroplasty pain in the bladder, penis/urethra, and perineum/scrotum. Most of the parameters improved after urethroplasty, but up to 29% of patients reported worsening of perineal pain after surgery [584].

Sexual function should be evaluated by validated tools if not assessed in a PROM. The international index on erectile function (IIEF), SHIM, O´Leary Brief Male Sexual Function Inventory (BMFSI), SLQQ (Sexual Life Quality Questionnaire), Male Sexual Health Questionnaire (MSHQ) have all been used after urethroplasties for evaluation of erectile and ejaculatory functions. Other non-validated tools were suggested such as the Post-Urethroplasty Sexual Questionnaire (PUSQ) [585] or specific questionnaires for genital appearance (length, curvature) or sensitivity [586].

Summary of evidence	LE
Retrograde urethrography and urethrocystoscopy are able to identify anatomical success after a urethroplasty.	2a
A significant gap was demonstrated between objective and subjective outcomes after urethroplasties. PROM questionnaires are specific tools to assess subjective outcomes and patient satisfaction after urethroplasty surgeries.	2a
Validated questionnaires proved useful to assess the consequences of urethral surgery on sexual function.	2a

Recommendations	Strength rating
Use cystoscopy or retrograde urethrography to assess anatomic success after urethroplasty surgery.	Weak
Use PROM questionnaires to assess subjective outcomes and patient satisfaction.	Strong
Use validated questionnaires to evaluate sexual function after urethral stricture surgeries.	Strong

11.4 Ideal follow-up interval after urethral surgery

The optimal follow-up strategy must allow for an objective determination of anatomic and functional outcomes to assess surgical success whilst avoiding excessive invasive testing that leads to unnecessary cost, discomfort, anxiety, and risk [560].

After anterior urethroplasty, 21% of recurrences are clinically evident, and cystoscopically confirmed, after three months [587] and 96% after one year [569]. Early recurrences are more frequent in patients with LS and older age, in longer strictures and when skin grafts were used [587].

11.5 Length of follow-up after urethral surgery

The median time of recurrence after bulbar urethroplasty is approximately ten months [334]. In case series, between 55.4% [587] and 96% [569, 572] of all recurrences are detected during the first year of follow-up after urethral surgery. Twenty-three percent of bulbar stricture recurrences are detected during the second year of follow-up, and the percentage of recurrences decreases after the second year [346].

On the other hand, long-term follow-up studies highlighted the role of length of follow-up as a predictor for stricture recurrence after bulbar urethroplasty [346, 588]. Late recurrences – later than five years after urethroplasty – could be observed in up to 15% of cases [144, 331, 346]. This should be considered mainly after augmentation urethroplasties, especially in case skin grafts were used [571]. Certainly, patients should be instructed to seek urological evaluation if they experience late recurrent symptoms [588].

11.6 Risk-stratified proposals during follow-up after urethral surgery

Cost of follow-up after urethroplasty is higher in the first year after the procedure [589]. In a literature review it ranged between 205 to 1,784 US Dollars, with higher costs associated to posterior urethral repairs [589]. As the risk of recurrence and side effects are related to the type of stricture and urethroplasty, a different follow-up schedule was proposed and shown to be cost-effective in the USA, potentially saving up to 85% of costs after five years [561]:

- Urethroplasties with a low risk of recurrence (EPA urethroplasty without history of radiotherapy, hypospadias, or LS features) could be safely followed up based on monitoring of symptoms, using selfadministered IPSS questionnaire, every three months for one year, and annually thereafter.
- Urethroplasties with standard risk of recurrence (urethroplasty using grafts, flaps, and/or post-irradiation, hypospadias and/or LS patients) could combine IPSS questionnaire + flowmetry every three months for one year, and annually thereafter. Additionally, RUG at three and twelve months should be performed.

In this protocol, urethrocystoscopy is only performed if required [561]. Another suggested follow-up protocol includes urethrocystoscopy or RUG/VCUG at three months post-operatively, in order to rule out early failures, especially in case of graft use. If there is evidence of good anatomical outcome in these tests, flowmetry and questionnaire results at three months should be considered as the new baseline. Thereafter, follow-up could be safely and routinely performed with non-invasive tests (flowmetry – evaluating Q_{max} and the shape of curve – and questionnaires). Any deterioration should be further investigated with a urethrocystoscopy [577].

A recently suggested protocol also included assessment of LUTS, sexual function (erectile and ejaculatory), and LUT pain, that need to be compared with pre-operative findings which should include a PROM questionnaire [560]. Cystoscopy and flowmetry should be performed between three to six months postoperatively, and flowmetry findings should be considered as the new baseline for longitudinal follow-up. Future significant decline (25-30%) in Q_{max} or Q_{max} - (average flow rate) should trigger new cystoscopy to rule out anatomic recurrence, even in patients who are symptom-free [560]. A routine cystoscopy at twelve to fifteen months should be performed at the surgeon's discretion, based on risk assessment of three aspects: higher-risk patients, evidence of partial urethral narrowing at three-month assessment, low-volume surgeons [560].

Summary of evidence	LE
The higher percentage of recurrences presents during the first twelve months, after urethroplasty surgery.	2a
Risk-adjusted follow-up protocols are cost-effective and safe for the patients.	3

Recommendations	Strength rating
Offer a routine follow-up of at least one year after urethroplasty.	Strong
Adopt a risk-adjusted follow-up protocol.	Weak

11.7 Follow-up protocol proposal after urethroplasty

11.7.1 ***Surgeries with low risk of recurrence***

- Anastomotic urethroplasties in the bulbar/(bulbo)membranous segment with no history of radiotherapy, hypospadias, or balanitis xerotica obliterans (BXO)/LS features.

Table 11.3: Follow-up protocol for urethroplasty with low risk of recurrence

Surgery	3 months	12 months	24 months*
Uroflowmetry	+	+	+
PROM (incl. sexual function)	+	+	+
Anatomic evaluation: (Urethrocystoscopy/ RUG-VCUG)	+**	On indication	On indication

**Follow-up could be discontinued after two years, advising the patient to seek urological evaluation if symptoms worsen. Academic centres could increase the length of follow-up for research purposes.*
***The Panel suggests performing an anatomic assessment at three months.*

11.7.2 ***Surgical management options with standard risk of recurrence***

- Anastomotic urethroplasties in the bulbar segment with prior history of radiotherapy, hypospadias, or BXO/ LS features;
- Penile urethroplasties;
- Non-traumatic posterior urethroplasties;
- Graft or/and flap – substitution – urethroplasties.

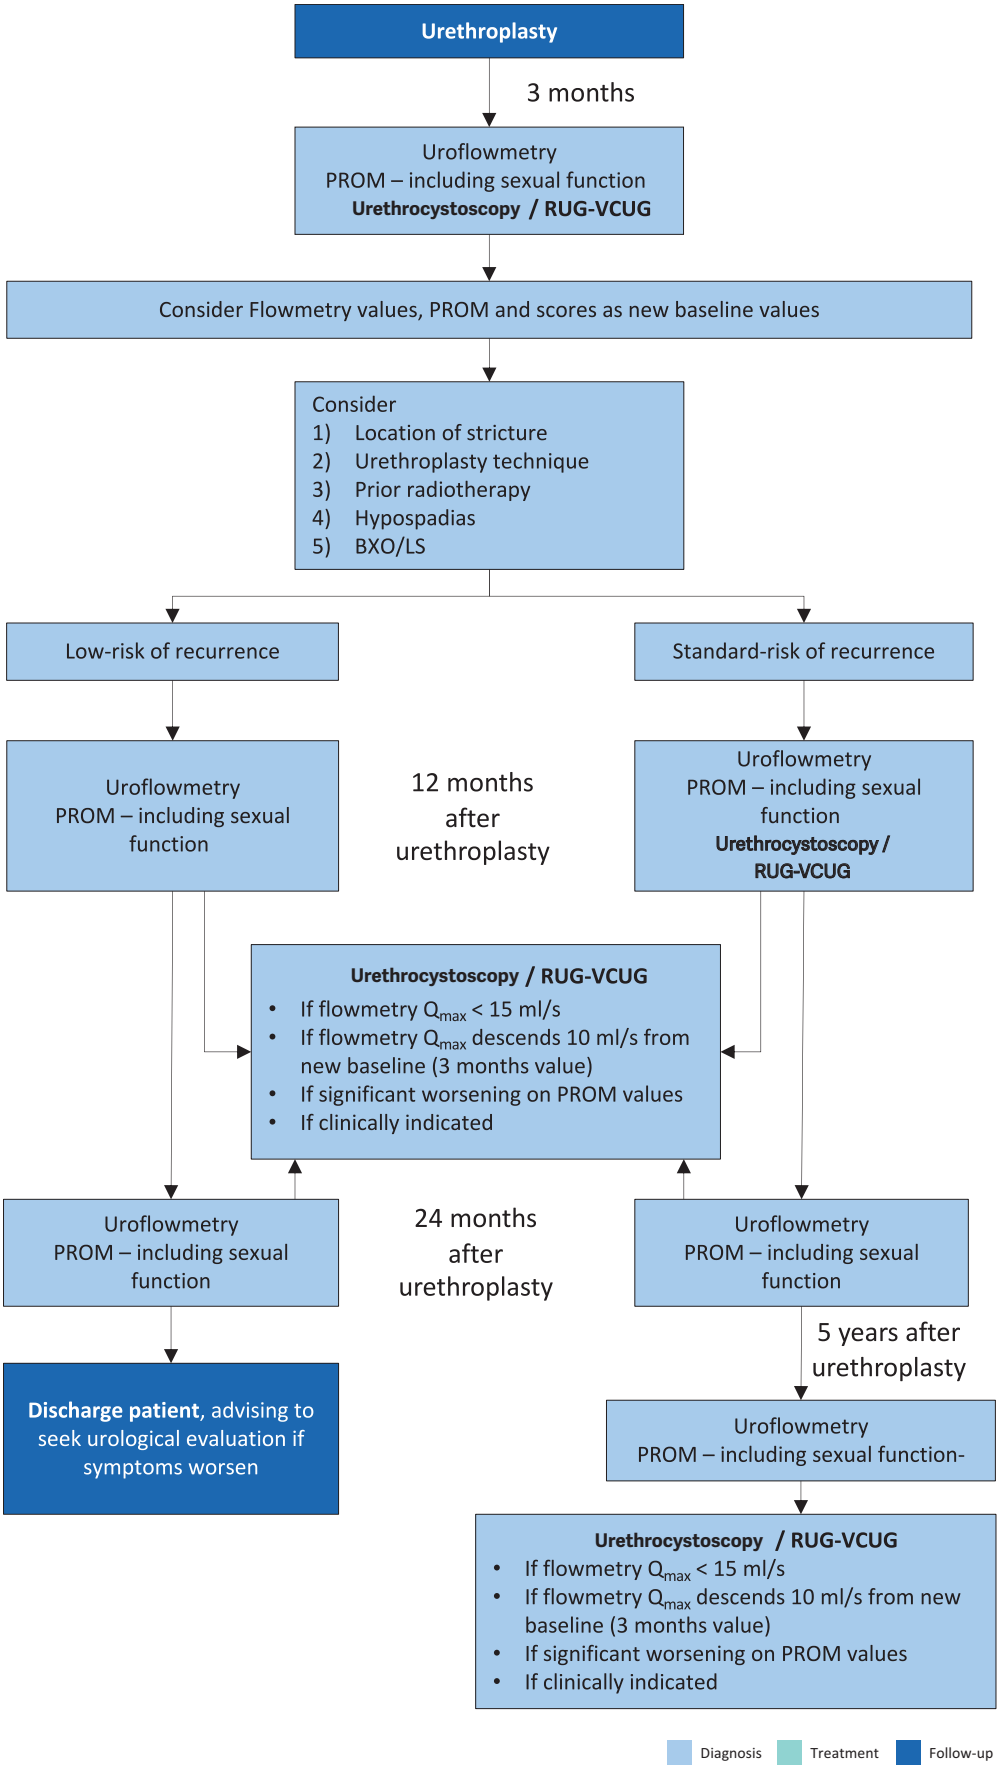
Table 11.4: Follow-up protocol for urethroplasty with standard risk of recurrence

Surgery	3 months	12 months	24 months	5 years *
Uroflowmetry	+	+	+	+
PROM (incl. sexual function)	+	+	+	+
Anatomic evaluation: (Urethrocystoscopy/ RUG-VCUG)	+	+	+	On indication

** Follow-up could be discontinued after five years, advising the patient to seek urological evaluation if symptoms worsen. A longer follow-up period should be considered after penile and substitution urethroplasties. Academic centres could increase the length of follow-up for research purposes.*

Please see Figure 11.1 for further guidance.

Figure 11.1: Follow-up after urethroplasty



BXO = balanitis xerotica obliterans; LS = lichen sclerosus; PROM = patient reported outcome measure; Q_{max} = maximum flow rate; RUG = retrograde urethrography; VCUG = voiding cystourethrography.

13. CONFLICT OF INTEREST

All members of the Urethral Strictures Guidelines Panel have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publicly accessible through the European Association of Urology website: http://www.uroweb.org/guidelines/.
This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

14. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Paris 2024. ISBN 978-94-92671-23-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, the Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aim and objectives

This overview represents the updated European Association of Urology (EAU) Guidelines for Urological Infections. The aim is to provide practical recommendations on the prevention and treatment of urinary tract infections (UTIs) and male accessory gland infections. These guidelines also aim to address the important public health aspects of infection control and antimicrobial stewardship. Separate EAU guidelines are available addressing paediatric urological infections [1] and infections in patients with neurological urinary tract dysfunction [2].

It must be emphasised that clinical guidelines present the best evidence available to the experts, but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and references/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Guidelines Panel on Urological Infections consists of an international multi-disciplinary group of urologists, with particular expertise in this area, an infectious disease specialist and a clinical microbiologist. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU website Uroweb: http://uroweb.org/guideline/urological-infections/.

1.3 Available publications

A quick reference document, the Pocket Guidelines, is available in print. This is an abridged version, which may require consultation together with the full text version. All documents are accessible through the EAU website Uroweb: http://uroweb.org/guideline/urological-infections/.

1.4 Publication history

The Urological Infections Guidelines were first published in 2001. This 2024 document presents a limited update of the 2023 publication.

1.4.1 Summary of changes

Key changes in the 2024 guideline:-

- Section 3.3 - Asymptomatic Bacteriuria in Adults – This section has been extensively updated resulting in a new recommendation and a revised recommendation.

Recommendations	Strength rating
Do not screen or treat asymptomatic bacteriuria in patients prior to cardiovascular surgeries.	Weak
Screen for and treat asymptomatic bacteriuria in pregnant women with standard short course treatment or single dose fosfomycin trometamol.	Weak

- Section 3.16.2.8 – Peri-Procedural Antibiotic Prophylaxis - Prostate Biopsy – The text of this section has been updated, following assessment of the literature.

2. METHODS

2.1 Introduction

For the 2024 Urological Infections Guidelines, new and relevant evidence was identified, collated and appraised through a structured assessment of the literature for sections 3.3 Asymptomatic Bacteriuria in Adults and 3.16.2.8 Peri-Procedural Antibiotic Prophylaxis - Prostate Biopsy. Broad and comprehensive literature searches, covering these sections were performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries. The time frames covered and the number of unique records identified, retrieved and screened for relevance for each section were:

Section	No. of unique records	Search time frame
3.3 Asymptomatic Bacteriuria in Adults	1,503	Dec 1st 2016 - June 1st 2023
3.16.2.8 Peri-Procedural Antibiotic Prophylaxis - Prostate Biopsy	179	June 1st 2022 - June 1st 2023

Detailed search strategies are available online: https://uroweb.org/guidelines/urological-infections/publications-appendices. In addition, the current evidence base of section 3.5 Recurrent UTI was re-assessed and the recommendations reviewed.

Recommendations within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [3];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact and certainty of patient values and preferences on the intervention.

Strong recommendations typically indicate a high degree of evidence quality and/or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [4].

Additional methodology information and a list of associations endorsing the EAU Guidelines can be found in the online: https://uroweb.org/eau-guidelines/methodology-policies.

2.2 Review

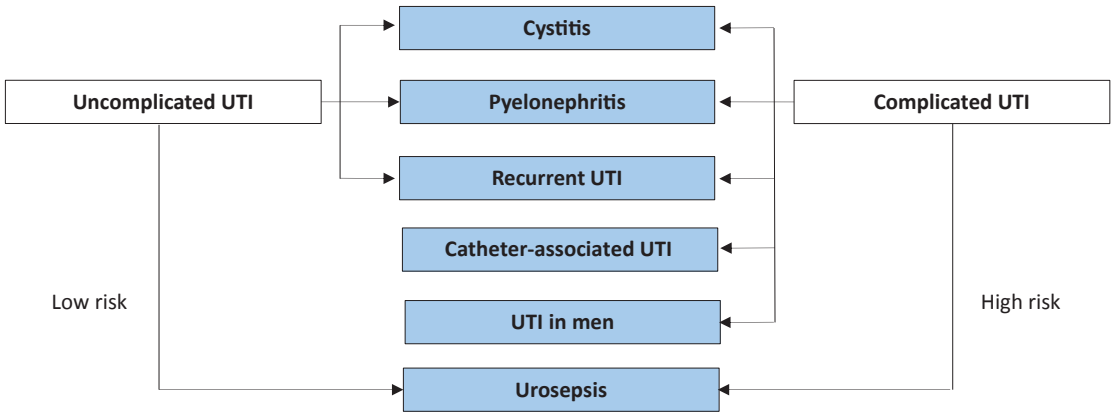
This document was subject to independent peer review prior to publication in 2019.

3. THE GUIDELINE

3.1 Classification

Different classification systems of UTI exist. Most widely used are those developed by the Centres for Disease Control and Prevention (CDC) [5], Infectious Diseases Society of America (IDSA) [6], European Society of Clinical Microbiology and Infectious Diseases (ESCMID) [7] as well as the U.S. Food and Drug Administration (FDA) [8, 9]. Current UTI guidelines frequently use the concept of uncomplicated and complicated UTI with a number of modifications (Figure 1). In 2011 the EAU Section of Infections in Urology proposed the ORENUC classification system based on the clinical presentation of the UTI, the anatomical level of the UTI, the grade of severity of the infection, the categorisation of risk factors and availability of appropriate antimicrobial therapy [10].

Figure 1: Concept of uncomplicated and complicated UTI



The following classification of UTIs is adopted in the EAU Urological Infections Guidelines:

Classification of UTI	
Uncomplicated UTIs	Acute, sporadic or recurrent lower (uncomplicated cystitis) and/or upper (uncomplicated pyelonephritis) UTI, limited to non-pregnant women with no known relevant anatomical and functional abnormalities within the urinary tract or comorbidities.
Complicated UTIs	All UTIs which are not defined as uncomplicated. Meaning in a narrower sense UTIs in a patient with an increased chance of a complicated course: i.e. all men, pregnant women, patients with relevant anatomical or functional abnormalities of the urinary tract, indwelling urinary catheters, renal diseases, and/or with other concomitant immunocompromising diseases for example, diabetes.
Recurrent UTIs	Recurrences of uncomplicated and/or complicated UTIs, with a frequency of at least three UTIs/year or two UTIs in the last six months.
Catheter-associated UTIs	Catheter-associated urinary tract infection (CA-UTI) refers to UTIs occurring in a person whose urinary tract is currently catheterised or has had a catheter in place within the past 48 hours.
Urosepsis	Urosepsis is defined as life threatening organ dysfunction caused by a dysregulated host response to infection originating from the urinary tract and/or male genital organs [11].

3.2 Antimicrobial Stewardship

Although the benefits to patients of antibiotic use are clear, overuse and misuse have contributed to the growing problem of resistance amongst uropathogenic bacteria, which is a serious threat to public health [12, 13]. In acute care hospitals, 20-50% of prescribed antibiotics are either unnecessary or inappropriate [14]. In response, a worldwide initiative seeks to incorporate Antimicrobial Stewardship programs in healthcare [15]. Antimicrobial Stewardship aims to optimise clinical outcomes and ensure cost-effective therapy whilst minimising unintended consequences of antimicrobial use such as healthcare associated infections including *Clostridioides difficile,* toxicity, selection of virulent organisms and emergence of resistant bacterial strains [16].

Stewardship programs have two main sets of actions. The first set mandates use of recommended care at the patient level conforming to guidelines. The second set describes strategies to achieve adherence to the mandated guidance. These include persuasive actions such as education and feedback together with restricting availability linked to local formularies. A Cochrane Review of effectiveness of interventions to improve antibiotic prescribing practices for hospital inpatients, updated in 2017, found high-certainty evidence that such interventions are effective in increasing adherence with antibiotic policy leading to reduced antibiotic treatment duration and that it may also reduce hospital stay. The review found no evidence that reduced antibiotic usage increased mortality [17].

The important components of antimicrobial stewardship programs are [18]:

- regular training of staff in best use of antimicrobial agents;
- adherence to local, national or international guidelines;
- regular ward visits and consultation with infectious diseases physicians and clinical microbiologists;
- audit of adherence and treatment outcomes;
- regular monitoring and feedback to prescribers of their performance and local pathogen resistance profiles.

A 2016 systematic review of evidence for effectiveness of various Antimicrobial Stewardship interventions in healthcare institutions identified 145 studies of nine Stewardship objectives. Guideline-driven empirical therapy using a restricted choice of antibiotics and including de-escalation, intravenous to oral switch, therapeutic drug monitoring, and bedside consultation resulted in a 35% (95% CI 20-46%) relative risk reduction (RRR) in mortality. Use of de-escalation (tailoring to a more narrow spectrum agent), showed a RRR of 56% (95% CI 34 – 70%) for mortality [19].

To facilitate local initiatives and audit, a set of valid, reliable, and applicable indicators of the quality of antibiotic use in the treatment of hospitalised patients with complicated UTI was developed [20]. Its use in the Netherlands appeared to result in shortened hospital stay [21]. A literature search of Pubmed from April 2014 [19], to February 2017 identified no further randomised controlled trials (RCTs) relating to stewardship programmes for UTIs. Studies to provide high-quality evidence of effectiveness of Stewardship programmes in urology patients are urgently needed.

3.3 Asymptomatic bacteriuria in adults

*3.3.1 **Background***

Urinary growth of bacteria in an asymptomatic individual (asymptomatic bacteriuria - ABU) is common, and corresponds to a commensal colonisation [22]. Clinical studies have shown that ABU may protect against superinfecting UTI, thus treatment of ABU should be performed only in cases of proven benefit for the patient to avoid the risk of selecting antimicrobial resistance and eradicating a potentially protective ABU strain [23, 24]. The aim of this section is to support the clinician in deciding when ABU should or should not be treated.

*3.3.2 **Epidemiology, aetiology and pathophysiology***

Asymptomatic bacteriuria occurs in an estimated 1-5% of healthy pre-menopausal females. Increasing to 4-19% in otherwise healthy elderly females and men, 0.7-27% in patients with diabetes, 2-10% in pregnant women, 15-50% in institutionalised elderly populations, and in 23-89% in patients with spinal cord injuries [25]. Asymptomatic bacteriuria in younger men is uncommon, but when detected, chronic bacterial prostatitis must be considered. The spectrum of bacteria in ABU is similar to species found in uncomplicated or complicated UTIs, depending on the presence of risk factors (see sections 3.4 and 3.7).

*3.3.3 **Diagnostic evaluation***

Asymptomatic bacteriuria is defined by a mid-stream sample of urine showing bacterial growth ≥ 10^5 cfu/mL in two consecutive samples in women [26] and in one single sample in men [27] in an individual without urinary tract symptoms. Cystoscopy and/or imaging of the upper urinary tract is not mandatory if the medical history is otherwise without remark. If persistent growth of urease producing bacteria, i.e. *Proteus mirabilis* is detected, stone formation in the urinary tract must be excluded [28, 29, 235]. In men, a digital rectal examination (DRE) has to be performed to investigate the possibility of prostate diseases (see section 3.11).

*3.3.4 **Evidence summary***

A systematic search of the literature from November 2016 to January 2000 identified 3,582 titles of which 224 were selected for full text review and 50 were included [30]. For the subgroups of pregnancy, prior to urologic surgeries, post-menopausal women and institutionalised elderly patients only data from RCTs were included, on which a meta-analysis was performed [30]. For the other subgroups non-RCTs were also included in the narrative analysis [30]. An update systematic literature search from 1st December 2016 to 1st June 2023 identified 1,503 titles of which 36 were selected for full text review and 18 were included. The following patient populations were not covered by the systematic review: immuno-compromised patients; and patients with indwelling catheters. For these groups the guideline was updated using a structured PubMed search. The evidence question addressed was: What is the most effective management for people with asymptomatic bacteriuria?

*3.3.5 **Disease management***

3.3.5.1 Patients without identified risk factors

Asymptomatic bacteriuria does not cause renal disease or damage [31]. Only one prospective, non-randomised study investigated the effect of treatment of ABU in adult, non-diabetic, non-pregnant women [32], and found no difference in the rate of symptomatic UTIs. Furthermore, as the treatment of ABU has been proven to be unnecessary in most high-risk patient subgroups, there is panel consensus that the results of these subgroups can also be applied to patients without identified risk factors. Therefore, screening and treatment of ABU is not recommended in patients without risk factors.

3.3.5.2 Patients with ABU and recurrent UTI, otherwise healthy

One RCT investigated the effect of ABU treatment in female patients with recurrent symptomatic UTI without identified risk factors [24] and demonstrated that treatment of ABU increases the risk for a subsequent symptomatic UTI episode, compared to non-treated patients (RR 0.28, 95% CI 0.21 to 0.38; n=673). This protective effect of spontaneously developed ABU can be used as part of prevention in female patients with recurrent symptomatic UTI; therefore, treatment of ABU is not recommended.

3.3.5.3 Pregnant women

3.3.5.3.1 Is treatment of ABU beneficial in pregnant women?

Twelve RCTs comparing antibiotic treatments of ABU with placebo controls or no treatment [33-44], with different antibiotic doses and regimens were identified, ten published before 1988 and one in 2015. Eleven RCTs (n=2,002) reported on the rate of symptomatic UTIs [33, 35-43, 45]. Antibiotic treatment significantly reduced the number of symptomatic UTIs compared to placebo or no treatment (average RR 0.22, 95% CI 0.12 to 0.40).

Six RCTs reported on the resolution of bacteriuria [33-35, 37, 40, 42]. Antibiotic treatment was effective in the resolution of bacteriuria compared to placebo (average RR 2.99, 95% CI 1.65 to 5.39; n=716). Eight RCTs reported on the rate of low birthweights [33, 35-38, 41, 44, 45]. Antibiotic treatment was associated with lower rates of low birthweight compared to placebo or no treatment (average RR 0.58, 95% CI 0.36 to 0.94; n=1689). Four RCTs reported on the rate of preterm deliveries [41, 42, 44, 45]. Antibiotic treatment was associated with lower rates of preterm delivery compared to placebo or no treatment (average RR 0.34, 95% CI 0.18 to 0.66; n=854). Three additional systematic reviews and meta-analyses have reported that treatment of ABU in pregnancy may be associated with a decreased rate of pyelonephritis, low birthweight or preterm delivery [46-48]. However, they also emphasised the low to very low quality of the evidence of the identified studies.

Based on the beneficial maternal and foetal effects of antibiotic treatment pregnant women should be screened and treated for ABU. However, the panel would like to emphasise that most available studies have low methodological quality and are from the 60s to 80s. Diagnostic and treatment protocols and accessibility to medical services have dramatically changed since then; therefore, the quality of evidence for this recommendation is low. In a newer study of higher methodological quality the beneficial effects of antibiotic treatment are not as evident [45]. Therefore, it is advisable to consult national recommendations for pregnant women.

3.3.5.3.2 Which treatment duration should be applied to treat ABU in pregnancy?

Sixteen RCTs comparing the efficacy of different antibiotic treatments in pregnant women with ABU were identified [49-64]. There was significant heterogeneity amongst the studies. Studies compared different antibiotic regimens or the same antibiotic regimens with different durations. The duration of treatment ranged from single dose to continuous treatment (until delivery). For practical purposes the grouping strategy used by the previously published Cochrane Review by Widmer *et al.* was adopted with some modifications [65]. The following treatment groups were used for comparison:

1. single dose (single day);
2. short course (2-7 days);
3. long course (8-14 days);
4. continuous (until delivery).

Nine studies compared single dose to short course treatment [50, 54, 55, 59-64], one study compared single dose to long course treatment [58] and one study compared long course to continuous treatment [51]. As long term and continuous antibiotic treatment is not used in current practice, only studies comparing single dose to standard short course treatment are presented.

3.3.5.3.2.1 Single dose vs. short course treatment

Three RCTs reported on the rate of symptomatic UTIs [54, 63, 64], with no significant difference between the two durations (average RR 1.07, 95% CI 0.47 to 2.47; n=891). Nine RCTs reported on the rate of ABU resolution [50, 54, 55, 59-64], with no significant difference between the two durations (average RR 0.97, 95% CI 0.89 to 1.07; n=1,268). Six RCTs reported on the rate of side effects [50, 54, 59, 60, 62, 63]. Single dose treatment was associated with significantly less side effects compared to short course treatment (average RR 0.40, 95% CI 0.22 to 0.72; n=458). Three RCTs reported on the rate of preterm deliveries [54, 56, 64], with no significant difference between the two durations (average RR 1.16, 95% CI 0.75 to 1.78; n=814). One RCT reported on the rate of low birthweights [64]. There were significantly more babies with low birthweight in the single dose duration compared to short course treatment (average RR 1.65, 95% CI 1.06 to 2.57; n=714).

According to the data analysis, single dose treatment was associated with a significantly lower rate of side effects but a significantly higher rate of low birthweight. A meta-analysis on the use of single dose fosfomycin trometamol in women with lower uncomplicated UTIs or ABU reported on a subgroup analysis of pregnant women with ABU [66]. The study identified five RCTs involving 577 patients. The resolution rate of ABU in pregnant women treated with single dose fosfomycin trometamol was not significantly different from those who received other antibiotics (OR 1.32, 95% CI 0.78–2.22, p=0.30). Therefore, standard short course treatment or single dose fosfomycin trometamol should be applied to treat ABU in pregnancy; however, it should be emphasised that the overall quality of the scientific evidence backing this recommendation is low.

3.3.5.4 Patients with identified risk-factors

3.3.5.4.1 Diabetes mellitus

Diabetes mellitus, even when well regulated, is reported to correlate to a higher frequency of ABU [67]. One RCT demonstrated that eradicating ABU did not reduce the risk of symptomatic UTI and infectious complications in patients with diabetes mellitus. The time to first symptomatic episode was also similar in both groups. Furthermore, untreated ABU did not correlate to diabetic nephropathy [68]. Screening and treatment of ABU in well-controlled diabetes mellitus is therefore not recommended. However, poorly regulated diabetes is a risk factor for symptomatic UTI and infectious complications.

3.3.5.4.2 ABU in post-menopausal women

Elderly women have an increased incidence of ABU [69]. Four RCTs compared antibiotic treatment of ABU with placebo controls or no treatment, in a post-menopausal female population, with different antibiotic doses and regimens [70-73]. Women in these studies were mostly nursing home residents, which may bias the results of this analysis. Three RCTs reported on the rate of symptomatic UTIs (average RR 0.71, 95% CI 0.49 to 1.05; 208 women) and the resolution of bacteriuria (average RR 1.28, 95% CI 0.50 to 3.24; 203 women) [54, 63, 64], with no significant benefit of antibiotic treatment. Therefore, ABU in post-menopausal women does not require treatment, and should be managed as for pre-menopausal women.

3.3.5.4.3 Elderly institutionalised patients

The rate of ABU is 15-50% in elderly institutionalised patients [74]. Differential diagnosis of ABU from symptomatic UTI is difficult in the multi-diseased and mentally deteriorated patients, and is probably a cause of unnecessary antibiotic treatment [75, 76]. Seven RCTs compared antibiotic treatment of ABU with placebo controls or no treatment in elderly patients, with different antibiotic doses and regimens [70-73, 77-79].

Three RCTs reported on the rate of symptomatic UTIs [70, 72, 77]. Antibiotic treatment was not significantly beneficial in reducing the rate of symptomatic UTIs compared to placebo or no treatment (average RR 0.68, 95% CI 0.46 to 1.00; n=210). Six RCTs reported on the resolution of bacteriuria [70, 72, 73, 77-79]. There was no benefit of antibiotic treatment compared to placebo in the resolution of ABU (average RR 1.33, 95% CI 0.63 to 2.79; n=328). One RCT compared the rates of incontinence in this patient group before and after the eradication of ABU and found no effect of antibiotic treatment [80]. A subsequent systematic review and meta-analysis of nine RCTs found that antibiotic treatment of ABU in this group was associated with significantly more adverse effects with no clinical benefit [81]. Therefore, screening and treatment of ABU is not recommended in this patient group.

3.3.5.4.4 Patients with renal transplants

Two RCTs and two retrospective studies compared the effect of antibiotic treatment to no treatment in renal transplant patients [82-85]. Meta-analysis of the two RCTs did not find antibiotic treatment beneficial in terms of reducing symptomatic UTIs between 12 and 22 months after renal transplantation (RR 0.86, 95% CI 0.51 to 1.45; n=200). The two retrospective studies reached the same conclusion. Furthermore, there were no significant differences in the rate of ABU clearance, graft loss or change in renal function during long-term follow-up to 24 months [82-85].

A further two RCTs [86, 87], one observational study [88] and two systematic reviews and meta-analyses [89, 90] were identified. The first RCT reported that during the first 2 months following renal transplantation the incidence of and risk for UTIs (25% vs. 10%, HR 2.8, 95% CI 0.8-9.1, p=0.07) and pyelonephritis (15% vs. 2.5%, HR 6.5, 95% CI 0.8-54.7, p=0.08) was higher in patients receiving antibiotic treatment for ABU vs. no treatment [86]. In the second RCT no difference in acute graft pyelonephritis was found between the treatment and no treatment group (12.2% vs 8.7%, RR 1.40, 95% CI 0.40-4.87) in the first year after renal transplantation; however, rates of antimicrobial resistance were higher in the treatment group [87]. The first of the two additional meta-analyses reported the same results as the original study [89]. The second meta-analysis of n=1,353 patients reported ABU incidence rates of 22% in the first month and 32% during the first year after renal transplantation [90]. The analysis did not find a correlation between ABU and acute graft pyelonephritis (OR 1.8, 95% CI 0.78-1.79), a benefit of ABU antibiotic treatment on the risk of UTI (OR 1.08, 95% CI 0.63-1.84) or a change of renal function (mean difference in serum creatinine concentration - 0.03 mg/dL [95% CI 0.15-0.10]) [90].

Therefore, treatment of ABU is not recommended in renal transplant recipients.

3.3.5.4.5 Patients with dysfunctional and/or reconstructed lower urinary tracts

Patients with lower urinary tract dysfunction (LUTD) (e.g., neurogenic lower urinary tract dysfunction (NLUTD) secondary to multiple sclerosis, spinal cord injury patients, patients with incomplete bladder emptying, patients using clean intermittent catheterisation [CIC], or patients with reconstructed lower urinary tract including ileal conduits, orthotopic bladder replacement or continent reservoirs frequently become colonised [91, 92]. A systematic review reported ABU prevalence rates ranging from 25-86% for intestinal conduits in 4 studies and 9.1-85% for orthotopic neobladders in 9 studies [93]. Studies have shown no long-term benefit in ABU treatment in these patient groups [84, 85, 93].

Furthermore, in LUTD patients who do not spontaneously develop ABU, deliberate colonisation with an ABU strain (*Escherichia coli* 83972) has shown a protective effect against symptomatic recurrences [94, 95]. Screening and treatment of ABU in these patient groups is therefore, not recommended. If these patient groups develop recurrent symptomatic UTI (see section 3.5) the potential protective effect of a spontaneously developed ABU against UTI must be considered before any treatment.

3.3.5.4.6 Patients with catheters in the urinary tract

Patients with indwelling or suprapubic catheters and nephrostomy tubes invariably become carriers of ABU, with antibiotic treatment showing no benefit [96]. This is also applicable for patients with ABU and indwelling ureteral stents [97]. Routine treatment of catheter-associated bacteriuria is not recommended. For detailed recommendations see section 3.8.

3.3.5.4.7 Patients with ABU subjected to catheter placements/exchanges

In patients subjected to uncomplicated placement/exchanges of indwelling urethral catheters ABU is not considered a risk factor and should not be screened or treated [98]. In patients subjected to placement/exchanges of nephrostomy tubes and indwelling ureteral stents, ABU is considered a risk factor for infectious complications [99].

3.3.5.4.8 Immuno-compromised and severely diseased patients, patients with candiduria

These patient groups have to be considered individually and the benefit of screening and treatment of ABU should be reviewed in each case. Patients with asymptomatic candiduria may, although not necessarily, have an underlying disorder or defect. Treatment of asymptomatic candiduria is not recommended [100].

3.3.5.5 Prior to urological surgery

In diagnostic and therapeutic procedures not entering the urinary tract, ABU is generally not considered as a risk factor, and screening and treatment are not considered necessary. On the other hand, in procedures entering the urinary tract and breaching the mucosa, particularly in endoscopic urological surgery, bacteriuria is a definite risk factor.

Two RCTs [101, 102] and two prospective non-randomised studies [103, 104] compared the effect of antibiotic treatment to no treatment before transurethral prostate or bladder tumour resections. Antibiotic treatment significantly reduced the number of post-operative symptomatic UTIs compared to no treatment in the meta-analysis of the two RCTs (average RR 0.20, 95% CI 0.05 to 0.86; n=167). The rates of post-operative fever and septicaemia were also significantly lower in case of antibiotic treatment compared to no treatment in the two RCTs. One RCT including patients with spinal cord injury undergoing elective endoscopic urological surgeries found no significant difference in the rate of post-operative UTIs between single-dose or 3-5 days short term pre-operative antibiotic treatment of ABU [105].

A urine culture must therefore be taken prior to such interventions and in case of ABU, pre-operative treatment is recommended.

3.3.5.6 Prior to orthopaedic surgery

One RCT (n=471) and one multicentre cohort study (n=303) comparing the treatment of ABU with no treatment prior to orthopaedic surgery (hip arthroplasty/hemiarthroplasty or total knee arthroplasty) were identified [106, 107]. Neither of the studies showed a beneficial effect of antibiotic treatment in terms of prosthetic joint infection (3.8% vs. 0% and 3.9% vs. 4.7%, respectively). The cohort study reported no significant difference in the rate of post-operative symptomatic UTI (0.65% vs. 2.7%) [107]. One further RCT investigated the efficacy of pre-operative ABU treatment with fosfomycin-trometamol for prevention of early-periprosthetic joint infections (PJI) after hip hemiarthroplasty for fractures. Asymptomatic bacteriuria was not predictive of early-PJI (OR: 1.06, 95% CI 0.33 - 3.38), and its treatment did not modify early-PJI incidence (OR: 1.03, 95% CI 0.15 - 7.10) [108]. Furthermore, four additional meta-analyses did not find a benefit for pre-operative screening or treatment of ABU prior to orthopaedic surgery [109-112]. Therefore, treatment of bacteriuria is not recommended prior to arthroplasty surgery.

3.3.5.7 Prior to cardiovascular surgery

One systematic review and meta-analysis including three retrospective non-randomised studies involving a total of 1,116 patients was identified [113]. The procedures performed were non-valvular coronary artery bypass grafting (42%), valvular replacements (51%) and thoracic aortic surgeries (7%). Pre-operative treatment of ABU in 116 patients did not result in significant benefit regarding the rate of SSI compared to no treatment (12.9% vs. 8.2%, p=.0.086). A moderate heterogeneity was observed in the meta-analysis and pre-operative treatment of ABU had no significant effect on the rate of infectious complications (OR: 1.38, 95% CI 0.56 - 3.39). Due to the very low number, retrospective and non-randomised design of the included studies limited conclusions can be drawn from this. Further studies with appropriate design and sample size are needed to confirm these findings.

3.3.5.8 Pharmacological management

If the decision is taken to eradicate ABU, the same choice of antibiotics and treatment duration as in symptomatic uncomplicated (section 3.4.4.4) or complicated (section 3.7.5) UTI can be given, depending on gender, medical background and presence of complicating factors. Treatment should be tailored and not empirical.

3.3.6 ***Follow-up***

There are no studies focusing on follow-up after treatment of ABU.

3.3.7 ***Summary of evidence and recommendations for the management of ABU***

Summary of evidence	**LE**
Treatment of asymptomatic bacteriuria is not beneficial in the following conditions: • women without risk factors; • patients with well-regulated diabetes mellitus; • post-menopausal women; • elderly institutionalised patients; • patients with dysfunctional and/or reconstructed lower urinary tracts; • patients with renal transplants; • patients prior to arthroplasty surgeries; • patients prior to cardiovascular surgeries.	 3b 1b 1a 1a 2b 1a 1a 1b
Treatment of asymptomatic bacteriuria is harmful in patients with recurrent urinary tract infections.	1b
Treatment of asymptomatic bacteriuria is beneficial prior to urological procedures breaching the mucosa.	1a
Treatment of asymptomatic bacteriuria in pregnant women was found to be beneficial by meta-analysis of the available evidence; however, most studies are old. A recent study reported lower rates of pyelonephritis in low-risk women.	1a

Recommendations	Strength rating
Do not screen or treat asymptomatic bacteriuria in the following conditions: • women without risk factors; • patients with well-regulated diabetes mellitus; • post-menopausal women; • elderly institutionalised patients; • patients with dysfunctional and/or reconstructed lower urinary tracts; • patients with renal transplants; • patients prior to arthroplasty surgeries; • patients with recurrent urinary tract infections.	Strong
Do not screen or treat asymptomatic bacteriuria in patients prior to cardiovascular surgeries.	Weak
Screen for and treat asymptomatic bacteriuria prior to urological procedures breaching the mucosa.	Strong
Screen for and treat asymptomatic bacteriuria in pregnant women with standard short course treatment or single dose fosfomycin trometamol.	Weak

3.4 Uncomplicated cystitis

*3.4.1 **Introduction***

Uncomplicated cystitis is defined as acute, sporadic or recurrent cystitis limited to non-pregnant women with no known relevant anatomical and functional abnormalities within the urinary tract or comorbidities.

*3.4.2 **Epidemiology, aetiology and pathophysiology***

Almost half of all women will experience at least one episode of cystitis during their lifetime. Nearly one in three women will have had at least one episode of cystitis by the age of 24 years [114]. Risk factors include sexual intercourse, use of spermicides, a new sexual partner, a mother with a history of UTI and a history of UTI during childhood. The majority of cases of uncomplicated cystitis are caused by *E. coli*.

*3.4.3 **Diagnostic evaluation***

3.4.3.1 Clinical diagnosis

The diagnosis of uncomplicated cystitis can be made with a high probability based on a focused history of lower urinary tract symptoms (dysuria, frequency and urgency) and the absence of vaginal discharge [115, 116]. In elderly women genitourinary symptoms are not necessarily related to cystitis [117, 118].

3.4.3.2 Differential diagnosis

Uncomplicated cystitis should be differentiated from ABU, which is considered not to be infection but rather a commensal colonisation, which should not be treated and therefore not screened for, except if it is considered a risk factor in clearly defined situations (see section 3.3).

3.4.3.3 Laboratory diagnosis

In patients presenting with typical symptoms of an uncomplicated cystitis urine analysis (i.e. urine culture, dip stick testing, etc.) leads only to a minimal increase in diagnostic accuracy [119]. However, if the diagnosis is unclear dipstick analysis can increase the likelihood of an uncomplicated cystitis diagnosis [120, 121]. Taking a urine culture is recommended in patients with atypical symptoms, as well as those who fail to respond to appropriate antimicrobial therapy [122, 123].

3.4.3.4 Summary of evidence and recommendations for the diagnostic evaluation of uncomplicated cystitis

Summary of evidence	LE
An accurate diagnosis of uncomplicated cystitis can be based on a focused history of lower urinary tract symptoms and the absence of vaginal discharge or irritation.	2b

Recommendations	Strength rating
Diagnose uncomplicated cystitis in women who have no other risk factors for complicated urinary tract infections based on: • a focused history of lower urinary tract symptoms (dysuria, frequency and urgency); • the absence of vaginal discharge.	Strong
Use urine dipstick testing for diagnosis of acute uncomplicated cystitis.	Weak
Urine cultures should be done in the following situations: • suspected acute pyelonephritis; • symptoms that do not resolve or recur within four weeks after completion of treatment; • women who present with atypical symptoms; • pregnant women.	Strong

*3.4.4 **Disease management***

Antimicrobial therapy is recommended because clinical success is significantly more likely in women treated with antimicrobials compared with placebo [124]. In female patients with mild to moderate symptoms, symptomatic therapy (e.g. Ibuprofen, phytotherapy), as an alternative to antimicrobial treatment, may be considered in consultation with individual patients [125-129]. The choice of antimicrobial therapy should be guided by [115]:

- spectrum and susceptibility patterns of the aetiological pathogens;
- efficacy for the particular indication in clinical studies;
- tolerability and adverse reactions;
- adverse ecological effects;
- costs;
- availability.

According to these principles and the available susceptibility patterns in Europe, oral treatment with fosfomycin trometamol 3 g single dose, pivmecillinam 400 mg three times a day for three to five days, and nitrofurantoin (e.g. nitrofurantoin monohydrate/macrocrystals 100 mg twice daily for five days), should be considered for first-line treatment, when available [130-133].

Alternative antimicrobials include trimethoprim alone or combined with a sulphonamide. Co-trimoxazole (160/800 mg twice daily for three days) or trimethoprim (200 mg twice daily for five days) should only be considered as drugs of first choice in areas with known resistance rates for *E. coli* of < 20% [134, 135].

Aminopenicillins are no longer suitable for empirical therapy because of worldwide high *E. coli* resistance. Aminopenicillins in combination with a beta-lactamase inhibitor such as ampicillin/sulbactam or amoxicillin/clavulanic acid and oral cephalosporins are not recommended for empirical therapy due to ecological collateral damage, but may be used in selected cases [136, 137].

Important note:
On 11th March 2019, the European Commission implemented stringent regulatory conditions regarding the use of fluoroquinolones due to their disabling and potentially long-lasting side effects [138]. This legally binding decision is applicable in all EU countries. National authorities have been urged to enforce this ruling and to take all appropriate measures to promote the correct use of this class of antibiotics. In uncomplicated cystitis a fluoroquinolone should only be used when it is considered inappropriate to use other antibacterial agents that are commonly recommended for the treatment of these infections [138].

3.4.4.1 Cystitis in pregnancy

Short courses of antimicrobial therapy can also be considered for treatment of cystitis in pregnancy [139], but not all antimicrobials are suitable during pregnancy. In general, penicillins, cephalosporins, fosfomycin, nitrofurantoin (not in case of glucose-6-phosphate dehydrogenase deficiency and during the end of pregnancy), trimethoprim (not in the first trimenon) and sulphonamides (not in the last trimenon), can be considered.

3.4.4.2 Cystitis in men

Cystitis in men without involvement of the prostate is uncommon and should be classed as a complicated infection. Therefore, treatment with antimicrobials penetrating into the prostate tissue is needed in males with symptoms of UTI. A treatment duration of at least seven days is recommended, preferably with trimethoprim-sulphamethoxazole or a fluoroquinolone if in accordance with susceptibility testing (see section 3.4.4.4) [140].

3.4.4.3 Renal insufficiency

In patients with renal insufficiency the choice of antimicrobials may be influenced by decreased renal excretion; however, most antimicrobials, have a wide therapeutic index. No adjustment of dose is necessary until glomerular filtration rate (GFR) is < 20 mL/min, with the exception of antimicrobials with nephrotoxic potential, e.g. aminoglycosides. The combination of loop diuretics (e.g. furosemide) and a cephalosporin is nephrotoxic. Nitrofurantoin is contraindicated in patients with an estimated glomerular filtration rate (eGFR) of less than 30 ml/min/1.73m2 as accumulation of the drug leads to increased side effects as well as reduced urinary tract recovery, with the risk of treatment failure [141].

3.4.4.4 Summary of evidence and recommendations for antimicrobial therapy for uncomplicated cystitis

Summary of evidence	LE
Clinical success for the treatment of uncomplicated cystitis is significantly more likely in women treated with antimicrobials than placebo.	1b
Aminopenicillins are no longer suitable for antimicrobial therapy in uncomplicated cystitis because of negative ecological effects, high resistance rates and their increased selection for extended spectrum beta-lactamase (ESBL)-producing bacteria.	3

Recommendations	Strength rating
Prescribe fosfomycin trometamol, pivmecillinam or nitrofurantoin as first-line treatment for uncomplicated cystitis in women.	Strong
Do not use aminopenicillins or fluoroquinolones to treat uncomplicated cystitis.	Strong

Table 1: Suggested regimens for antimicrobial therapy in uncomplicated cystitis

Antimicrobial	Daily dose	Duration of therapy	Comments
First-line women			
Fosfomycin trometamol	3 g SD	1 day	Recommended only in women with uncomplicated cystitis.
Nitrofurantoin macrocrystal	50-100 mg four times a day	5 days	
Nitrofurantoin monohydrate/ macrocrystals	100 mg b.i.d	5 days	
Nitrofurantoin macrocrystal prolonged release	100 mg b.i.d	5 days	
Pivmecillinam	400 mg t.i.d	3-5 days	
Alternatives			
Cephalosporins (e.g. cefadroxil)	500 mg b.i.d	3 days	Or comparable
If the local resistance pattern for E. coli is < 20%			
Trimethoprim	200 mg b.i.d	5 days	Not in the first trimenon of pregnancy
Trimethoprim-sulfamethoxazole	160/800 mg b.i.d	3 days	Not in the last trimenon of pregnancy
Treatment in men			
Trimethoprim-sulfamethoxazole	160/800 mg b.i.d	7 days	Restricted to men, fluoroquinolones can also be prescribed in accordance with local susceptibility testing.

SD = single dose; b.i.d = twice daily; t.i.d = three times daily.

3.4.5 Follow-up

Routine post-treatment urinalysis or urine cultures in asymptomatic patients are not indicated [25]. In women whose symptoms do not resolve by end of treatment, and in those whose symptoms resolve but recur within two weeks, urine culture and antimicrobial susceptibility testing should be performed [142]. For therapy in this situation, one should assume that the infecting organism is not susceptible to the agent originally used. Retreatment with a seven-day regimen using another agent should be considered [142].

3.5 Recurrent UTIs

3.5.1 Introduction

Recurrent UTIs (rUTIs) are recurrences of uncomplicated and/or complicated UTIs, with a frequency of at least three UTIs/year or two UTIs in the last six months. Although rUTIs include both lower tract infection (cystitis) and upper tract infection (pyelonephritis), repeated pyelonephritis should prompt consideration of a complicated aetiology. Recurrent UTIs negatively impact patient quality of life leading to a reduction in the quality of social and sexual relationships, self-esteem and capacity for work [143].

3.5.2 Diagnostic evaluation

Recurrent UTIs are common. Risk factors are outlined in Table 2. Initial diagnosis of rUTI should be confirmed by urine culture. An extensive routine workup including cystoscopy, imaging, etc. is not routinely recommended as the diagnostic yield is low [144]. However, it should be performed without delay in atypical cases, for example, if renal calculi, outflow obstruction, interstitial cystitis or urothelial cancer is suspected.

Table 2: Age-related associations of rUTI in women [74, 117, 145]

Young and pre-menopausal women	Post-menopausal and elderly women
Sexual intercourse	History of UTI before menopause
Use of spermicide	Urinary incontinence
A new sexual partner	Atrophic vaginitis due to oestrogen deficiency
A mother with a history of UTI	Cystocele
History of UTI during childhood	Increased post-void urine volume
Blood group antigen secretory status	Blood group antigen secretory status
	Urine catheterisation and functional status
	deterioration in elderly institutionalised women

3.5.3 Disease management and follow-up

Prevention of rUTIs includes counselling regarding avoidance of risk factors, non-antimicrobial measures and antimicrobial prophylaxis [142, 146]. These interventions should be attempted in this order. Any urological risk factor must be identified and treated. Significant residual urine should be treated optimally, including by CIC when judged to be appropriate.

3.5.3.1 Evidence Summary

A broad literature with cut-off of 31st May 2021 identified 3,604 abstracts of which 361 were selected for full text review. In total 114 systematic reviews or guidelines based on systematic literature searches and 131 original publications were selected for further analysis. A further 18 relevant publications were identified from the references of the reviewed studies. Selected studies were assigned to one of nine subgroups based on the method of prevention. An updated search with cut-off date of 1st June 2022 identified a further 316 abstracts of which 25 were selected for further analysis. The evidence question addressed was: In women with recurrent symptomatic lower urinary tract infection what interventions reduce the rate of recurrence?

3.5.3.2 Behavioural modifications

Women with rUTI should be counselled on avoidance of risks (e.g., insufficient drinking, habitual and post-coital delayed urination, wiping from front to back after defecation, douching and wearing occlusive underwear) before initiation of long-term prophylactic drug treatment, although there is limited evidence available regarding these approaches [147, 148]. An open-label RCT found that additional fluid intake of 1.5 L a day in premenopausal women with rUTI who were low-volume drinkers (< 1.5 L a day) reduced the number of cystitis episodes and antibiotic usage over a 12-month period [149]

3.5.3.3 Non-antimicrobial prophylaxis

3.5.3.3.1 Hormonal replacement

Based on the results of four meta-analyses topical oestrogen therapy (either as a creme or a pessary) shows a trend towards rUTI prevention [150-153]. All studies reported that application was superior compared to placebo but was inferior compared to antibiotics. Due to its pharmacokinetics vaginal admission has no systematic side effects, however local irritation and minor bleeding can occur. The use of oral oestrogens was not effective for rUTI prophylaxis compared to placebo, furthermore it was associated with an unfavourable systematic side effect profile. A single prospective, non-comparative study of 30 pre-menopausal women with rUTI on oral contraceptives reported a beneficial effect for additional topical oestrogen therapy [154].

3.5.3.3.2 Immunoactive prophylaxis

Several meta-analyses and systematic reviews based on nine RCTs showed that oral immunotherapy with OM-89 is an effective and safe method for the prevention of rUTIs compared to placebo at short-term follow up (< 6 months) [151, 155, 156].

A vaginal suppository containing ten strains of heat-killed uropathogenic bacteria significantly reduced the risk of rUTI compared to placebo in a meta-analysis of three small RCTs [155-157]. The preventive effect was more pronounced with booster treatment.

A systematic review of two retrospective and three prospective cohort studies concluded that MV140 may decrease the number of rUTI episodes and/or increase the probability of patients being UTI free [158]. A placebo controlled RCT of MV140 reported a significant decrease in rUTI episodes in both MV140 groups vs. placebo [159]. At 12 months follow-up 25% of women treated with placebo (95% CI, 15% to 35%) were UTI free compared with 56% (95% CI, 44% to 67%) and 58% (95% CI, 44% to 67%) of women who received three and six months of MV140 treatment, respectively. The median number of UTI episodes per patient was 3.0 (0.5 to 6.0) for the placebo group compared with 0.0 (0.0 to 1.0) in both groups receiving MV140 [159].

A comparative single-centre study of 124 women vaccinated with StroVac compared to 49 women receiving antibiotic prophylaxis with 24-month follow-up concluded that StroVac is an effective non-antibiotic prophylaxis for rUTI [160]. However, this study was not randomised or blinded resulting in a high risk of bias (selection and imprecision).

3.5.3.3.3 Prophylaxis with probiotics (*Lactobacillus* spp.)

Five meta-analyses with differing results and eleven relevant systematic reviews were identified [151, 161-174]. Two meta-analyses reported significant positive effects for rUTI prevention with effective probiotics compared to placebo [165, 167]. The contradictory results of the four meta-analyses are a result of the analysis of different Lactobacillus strains and different administration regimes, treatment durations, and patient populations. Most studies concluded that not all Lactobacillus strains are effective for vaginal flora restoration and rUTI prevention. The highest efficacy was shown with *L. rhamnosus* GR-1, *L. reuteri* B-54, *L. reuteri* RC-14, *L. casei shirota*, and *L. crispatus* CTV-05 [151, 163, 165, 167]. Although meta-analyses including all known Lactobacilli strains did not show a significant treatment benefit [151, 163, 165, 167], sensitivity analysis excluding studies using ineffective strains resulted in a positive treatment effect [165].

Of the eleven systematic reviews, seven concluded that prophylaxis with vaginal probiotics has a beneficial clinical impact for the prevention of rUTI [152, 153, 161, 164, 166, 168-171, 173]. The available data is too minimal or of low quality to allow the panel to make recommendations on the route of admission, optimal dosage, and treatment duration for probiotic prophylaxis.

3.5.3.3.4 Prophylaxis with cranberry

Seven meta-analyses and several systematic reviews were identified [151, 175-180]. A Cochrane systematic review and meta-analysis found that when compared with placebo, water or not treatment, cranberry products did not significantly reduce the occurrence of symptomatic UTI overall or in women with recurrent UTIs [175]. However, six subsequent meta-analyses concluded that consumption of cranberry-containing products may protect against UTIs in certain patient populations [151, 176-180]. The differing outcomes across the meta-analyses can be contributed to the clinical and methodological heterogeneity of the included studies [181]. A RCT of 145 women randomised to high-dose vs. low-dose cranberry proanthocyanidin extract reported no significant reduction in the number of symptomatic UTI episodes between the groups [182]. Although the efficacy of cranberry products remains unclear, the panel consensus is that clinicians may recommend them for rUTI prevention in women who are informed of the weak evidence base due to their favourable benefit to harm ratio. However, there is no clear clinical evidence regarding the appropriate dose and treatment duration.

3.5.3.3.5 Prophylaxis with D-mannose

A meta-analysis including one RCT, one randomised cross-over trial and one prospective cohort study analysed data on 390 patients and found that D-mannose was effective for rUTI prevention compared to placebo with comparable efficacy to antibiotic prophylaxis [183]. Another systematic review, concluded that D-mannose had a significant effect on UTI, but that further studies were needed to confirm these findings [161]. A further systematic review including 695 patients reported that D-Mannose improved quality of life and significantly reduced rUTIs in both catheter and non-catheter users and was effective in reducing the incidence of rUTIs and prolonging UTI-free periods [184]. However, a Cochrane systematic review including 719 patients was unable to determine if D-mannose when compared to no treatment, other supplements or antibiotics significantly reduced the number of rUTI episodes [185]. The overall quality of the evidence was low.

3.5.3.3.6 Endovesical instillation

Endovesical instillations of hyaluronic acid (HA) and chondroitin sulphate (CS) have been used for glycosaminoglycan (GAG) layer replenishment in the treatment of interstitial cystitis, overactive bladder, radiation cystitis, and for prevention of rUTI [186]. A meta-analysis (n=143) based on two RCTs and two non-RCTs found significantly decreased UTI rates per patient/year and significantly longer mean UTI recurrence times for HA and HA-CS therapy compared to control treatment [187]. In addition, subgroup analysis of the two RCTs using HA-CS reported a significantly decreased UTI rate per patient-year, significantly longer mean UTI recurrence time and a significantly better pelvic pain and urgency/frequency (PUF) total score. However, 24-h urinary frequency measured as number of voids in 3 days were not significantly improved after therapy [187].

Another meta-analysis (n=800) including two RCTs and six non-RCTs found that when compared to control treatment HA, with or without CS, was associated with a significantly lower mean UTI rate per patient-year and a significantly longer time to UTI recurrence [188]. Furthermore, HA-CS therapy was associated with significantly greater mean reductions in PUF total and symptom scores and the percentage of patients with UTI recurrence during follow-up was also lower [188].

As randomised controlled studies are available only for HA plus CS, the quality of evidence is higher for the combination than for HA alone.

3.5.3.3.7 Methenamine hippurate

A Cochrane Review from 2012 based on thirteen studies, with high levels of heterogeneity, concluded that methenamine hippurate may be effective for preventing UTI in patients without renal tract abnormalities, particularly when used for short-term prophylaxis [189]. A meta-analysis from 2021 based on six studies found that although studies showed a trend towards a benefit for methenamine hippurate in prevention of rUTIs there was no statistically significant difference between the efficacy of methenamine hippurate and any comparators [190]. A subsequent RCT including 240 women randomised (1 : 1) to receive once-daily low-dose antibiotic prophylaxis or twice-daily methenamine hippurate for twelve months reported that the incident rate of patient-reported symptomatic UTIs decreased to 1.38 episodes per person per year for the methenamine hippurate group vs. 0.89 episodes per person per year for the antibiotic group. The absolute difference was 0.49 confirming that methenamine hippurate was not inferior to antibiotic prophylaxis. The rate of adverse events was similar in both groups and a sustained benefit for both treatment arms was observed at six months follow-up [191, 192].

3.5.3.4 Antimicrobials for preventing rUTI

3.5.3.4.1 Continuous low-dose antimicrobial prophylaxis and post-coital prophylaxis

Four meta-analyses and numerous systematic reviews and guidelines were identified [153, 193-203]. All available meta-analyses conclude that antibiotic prophylaxis is the most effective approach against UTI recurrences compared with placebo or no treatment [193-195]. Antimicrobials may be given as continuous low-dose prophylaxis for longer periods, or as post-coital prophylaxis. There is no significant difference in the efficacy of the two approaches. There is no consensus about the optimal duration of continuous antimicrobial prophylaxis, with studies reporting treatment duration of three to twelve months. After discontinuation of the drug, UTIs tend to re-occur, especially among those, who have had three or more infections annually. It is mandatory to offer both continuous low-dose antimicrobial and post-coital prophylaxis after counselling, and when behavioural modifications as well as non-antimicrobial measures have been unsuccessful.

Differences in outcomes between antibiotics did not reach statistical significance. The choice of agent should be based on the local resistance patterns. Regimens include nitrofurantoin 50 mg or 100 mg once daily, fosfomycin trometamol 3 g every ten days, trimethoprim 100 mg once daily and during pregnancy cephalexin 125 mg or 250 mg or cefaclor 250 mg once daily [142, 204]. Post-coital prophylaxis should be considered in pregnant women with a history of frequent UTIs before onset of pregnancy, to reduce their risk of UTI [205].

3.5.3.4.2 Self-diagnosis and self-treatment

In patients with good compliance, self-diagnosis and self-treatment with a short course regimen of an antimicrobial agent should be considered [206]. The choice of antimicrobials is the same as for sporadic acute uncomplicated UTI (section 3.4.4.4).

3.5.4 Summary of evidence and recommendations for the diagnostic evaluation and treatment of rUTIs

Summary of evidence	LE
Extensive routine workup including cystoscopy, imaging, etc. has a low diagnostic yield for the diagnosis of rUTI.	3
Increased water intake is an effective antimicrobial-sparing strategy to prevent rUTI in premenopausal women at high risk for recurrence who drink low volumes (< 1.5 L) of fluid daily.	3
Vaginal oestrogen replacement has shown a trend towards preventing rUTI in post-menopausal women.	1b
Immunoactive prophylaxis has been shown to be more effective than placebo for in female patients with rUTIs in several randomised trials with a good safety profile.	1a
Probiotics containing L. rhamnosus GR-1, L. reuteri B-54 and RC-14, L. casei shirota, or L. crispatus CTV-05 are effective for vaginal flora restoration and have shown a trend towards prevention of rUTIs.	1b
Current scientific evidence regarding the efficacy of cranberry products in the prevention of UTIs is inconclusive.	1a
There is contradictory evidence on the efficacy of D-mannose to reduce the number of UTI episodes.	2
Based on limited evidence intravesical GAG therapy can reduce the number of UTIs per patient per year, and prolong the time interval between rUTI episodes.	2
A RCT demonstrated the non-inferiority of twice-daily methenamine hippurate to daily antibiotic prophylaxis.	1b
Both continuous low-dose antimicrobial prophylaxis and post-coital antimicrobial prophylaxis, have been shown to reduce the rate of rUTI.	1b
A prospective cohort study showed that intermittent self-start therapy is effective, safe and economical in women with rUTIs.	2b

Recommendations	Strength rating
Diagnose recurrent UTI by urine culture.	Strong
Do not perform an extensive routine workup (e.g., cystoscopy, full abdominal ultrasound) in women younger than 40 years of age with recurrent UTI and no risk factors.	Weak
Advise pre-menopausal women regarding increased fluid intake as it might reduce the risk of recurrent UTI.	Weak
Use vaginal oestrogen replacement in post-menopausal women to prevent recurrent UTI.	Strong
Use immunoactive prophylaxis to reduce recurrent UTI in all age groups.	Strong
Advise patients on the use of local or oral probiotic containing strains of proven efficacy for vaginal flora regeneration to prevent UTIs.	Weak
Advise patients on the use of cranberry products to reduce recurrent UTI episodes; however, patients should be informed that the quality of evidence underpinning this is low with contradictory findings.	Weak
Use D-mannose to reduce recurrent UTI episodes, but patients should be informed of the overall weak and contradictory evidence of its effectiveness.	Weak
Use methenamine hippurate to reduce recurrent UTI episodes in women without abnormalities of the urinary tract.	Strong
Use endovesical instillations of hyaluronic acid or a combination of hyaluronic acid and chondroitin sulphate to prevent recurrent UTIs in patients where less invasive preventive approaches have been unsuccessful. Patients should be informed that further studies are needed to confirm the results of initial trials.	Weak

Use continuous or post-coital antimicrobial prophylaxis to prevent recurrent UTI when non-antimicrobial interventions have failed. Counsel patients regarding possible side effects.	Strong
For patients with good compliance self-administered short-term antimicrobial therapy should be considered.	Strong

3.6 Uncomplicated pyelonephritis

Uncomplicated pyelonephritis is defined as pyelonephritis limited to non-pregnant, pre-menopausal women with no known relevant urological abnormalities or comorbidities.

*3.6.1 **Diagnostic evaluation***

3.6.1.1 Clinical diagnosis

Pyelonephritis is suggested by fever (> 38°C), chills, flank pain, nausea, vomiting, or costovertebral angle tenderness, with or without the typical symptoms of cystitis [207]. Pregnant women with acute pyelonephritis need special attention, as this kind of infection may not only have an adverse effect on the mother with anaemia, renal and respiratory insufficiency, but also on the unborn child with more frequent pre-term labour and birth [208].

3.6.1.2 Differential diagnosis

It is vital to differentiate as soon as possible between uncomplicated and complicated mostly obstructive pyelonephritis, as the latter can rapidly lead to urosepsis. This differential diagnosis should be made by the appropriate imaging technique (see section 3.6.1.4).

3.6.1.3 Laboratory diagnosis

Urinalysis including the assessment of white and red blood cells and nitrite, is recommended for routine diagnosis [209]. In addition, urine culture and antimicrobial susceptibility testing should be performed in all cases of pyelonephritis.

3.6.1.4 Imaging diagnosis

Evaluation of the upper urinary tract with ultrasound (US) should be performed to rule out urinary tract obstruction or renal stone disease in patients with a history of urolithiasis, renal function disturbances or a high urine pH [210]. Additional investigations, such as a contrast enhanced computed tomography (CT) scan, or excretory urography should be considered if the patient remains febrile after 72 hours of treatment, or immediately if there is deterioration in clinical status [210]. For diagnosis of complicating factors in pregnant women, US or magnetic resonance imaging (MRI) should be used preferentially to avoid radiation risk to the foetus [210].

*3.6.2 **Summary of evidence and recommendations for the diagnostic evaluation of uncomplicated pyelonephritis***

Summary of evidence	**LE**
Urine culture and antimicrobial susceptibility testing should be performed in all cases of pyelonephritis in addition to urinalysis.	4
A prospective observational cohort study found that radiologic imaging can selectively be applied in adults with febrile UTI without loss of clinically relevant information by using a simple clinical prediction rule.	2b
Additional imaging investigations, such as an unenhanced helical computed tomography should be done if the patient remains febrile after 72 hours of treatment or in patients with suspected complications e.g. sepsis.	4

Recommendations	**Strength rating**
Perform urinalysis (e.g. using the dipstick method), including the assessment of white and red blood cells and nitrite, for routine diagnosis.	Strong
Perform urine culture and antimicrobial susceptibility testing in patients with pyelonephritis.	Strong
Perform imaging of the urinary tract to exclude urgent urological disorders.	Strong

*3.6.3 **Disease management***

3.6.3.1 Outpatient treatment

Fluoroquinolones and cephalosporines are the only antimicrobial agents that can be recommended for oral empirical treatment of uncomplicated pyelonephritis [211]. However, oral cephalosporines achieve significantly lower blood and urinary concentrations than intravenous cephalosporines. Other agents such as nitrofurantoin, oral fosfomycin, and pivmecillinam should be avoided as there is insufficient data regarding their efficacy [212]. In the setting of fluoroquinolone hypersensitivity or known resistance, other acceptable choices include trimethoprim-sulfamethoxazole (160/800 mg) or an oral beta-lactam, if the uropathogen is known to be susceptible. If such agents are used in the absence of antimicrobial susceptibility results, an initial intravenous dose of a long-acting parenteral antimicrobial (e.g. ceftriaxone) should be administered. A short outpatient antibiotic course of treatment, for acute pyelonephritis, has been shown to be equivalent to longer durations of therapy in terms of clinical and microbiological success. However, this is associated with a higher recurrence rate of infection within four to six weeks and needs to be tailored to local policies and resistance patterns [213].

3.6.3.2 Inpatient treatment

Patients with uncomplicated pyelonephritis requiring hospitalisation should be treated initially with an intravenous antimicrobial regimen e.g. a fluoroquinolone, an aminoglycoside (with or without ampicillin), or an extended-spectrum cephalosporin or penicillin [214]. Ceftolozane/tazobactam achieved a clinical response rate of over 90% in patients with uncomplicated pyelonephritis [215, 216]. It also demonstrated significantly higher composite cure rates than levofloxacin among levofloxacin-resistant pathogens [217]. Ceftazidime-avibactam combination has been shown to be effective for treating ceftazidime-resistant *Enterobacterales* and *Pseudomonas aeruginosa* UTIs [218].

Novel antimicrobial agents include imipenem/cilastatin, cefiderocol, meropenem-vaborbactam and plazomicin. Imipenem/cilastatin has been investigated in a phase 2 randomised trial and showed good clinical response rates [219]. Cefatazidime-avibactam and doripenem showed similar efficacy against ceftazidime non-susceptible pathogens and may offer an alternative to carbapenems in this setting [220]. Meropenem-vaborbactam has been shown to be non-inferior to piperacillin-tazobactam in a phase 3 RCT [221]. It was also effective for treating carbapenem-resistant Enterobacterales with cure rates of 65% compared to best available treatment [222]. Once daily plazomicin was non-inferior to meropenem for the treatment of cUTIs and acute pyelonephritis caused by *Enterobacterales*, including multidrug-resistant strains [223]. Cefiderocol was non-inferior to imipenem/cilastatin for the treatment of complicated UTI in people with multidrug-resistant Gram-negative infections in a phase 2 RCT [224].

Carbapenems and novel broad spectrum antimicrobial agents should only be considered in patients with early culture results indicating the presence of multi-drug resistant organisms. The choice between these agents should be based on local resistance patterns and optimised on the basis of drug susceptibility results. In patients presenting with signs of urosepsis empiric antimicrobial coverage for ESBL-producing organisms is warranted [225]. Patients initially treated with parenteral therapy who improve clinically and can tolerate oral fluids may transition to oral antimicrobial therapy [226].

3.6.3.2.1 Summary of evidence and recommendations for the treatment of uncomplicated pyelonephritis

Summary of evidence	**LE**
Fluoroquinolones and cephalosporines are the only microbial agents that can be recommended for oral empirical treatment of uncomplicated pyelonephritis.	1b
Intravenous antimicrobial regimens for uncomplicated pyelonephritis may include a fluoroquinolone, an aminoglycoside (with or without ampicillin), or an extended-spectrum cephalosporin or penicillin.	1b
Carbapenems should only be considered in patients with early culture results indicating the presence of multi-drug resistant organisms.	4
The appropriate antimicrobial should be chosen based on local resistance patterns and optimised on the basis of drug susceptibility results.	3

Recommendations	**Strength rating**
Treat patients with uncomplicated pyelonephritis not requiring hospitalisation with short course fluoroquinolones as first-line treatment.	Strong
Treat patients with uncomplicated pyelonephritis requiring hospitalisation with an intravenous antimicrobial regimen initially.	Strong

Switch patients initially treated with parenteral therapy, who improve clinically and can tolerate oral fluids, to oral antimicrobial therapy.	Strong
Do not use nitrofurantoin, oral fosfomycin, and pivmecillinam to treat uncomplicated pyelonephritis.	Strong

Table 3: Suggested regimens for empirical oral antimicrobial therapy in uncomplicated pyelonephritis

Antimicrobial	Daily dose	Duration of therapy	Comments
Ciprofloxacin	500-750 mg b.i.d	7 days	Fluoroquinolone resistance should be less than 10%.
Levofloxacin	750 mg q.d	5 days	
Trimethoprim sulfamethoxazol	160/800 mg b.i.d	14 days	If such agents are used empirically, an initial intravenous dose of a long-acting parenteral antimicrobial (e.g. ceftriaxone) should be administered.
Cefpodoxime	200 mg b.i.d	10 days	
Ceftibuten	400 mg q.d	10 days	

b.i.d = twice daily; q.d = every day.

Table 4: Suggested regimens for empirical parenteral antimicrobial therapy in uncomplicated pyelonephritis

Antimicrobials	Daily dose	Comments
First-line treatment		
Ciprofloxacin	400 mg b.i.d	
Levofloxacin	750 mg q.d	
Cefotaxime	2 g t.i.d	Not studied as monotherapy in acute uncomplicated pyelonephritis.
Ceftriaxone	1-2 g q.d	Lower dose studied, but higher dose recommended.
Second-line treatment		
Cefepime	1-2 g b.i.d	Lower dose studied, but higher dose recommended.
Piperacillin/tazobactam	2.5-4.5 g t.i.d	
Gentamicin	5 mg/kg q.d	Not studied as monotherapy in acute uncomplicated pyelonephritis.
Amikacin	15 mg/kg q.d	
Last-line alternatives		
Imipenem/cilastatin	0.5 g t.i.d	Consider only in patients with early culture results indicating the presence of multi-drug resistant organisms.
Meropenem	1 g t.i.d	
Ceftolozane/tazobactam	1.5 g t.i.d	
Ceftazidime/avibactam	2.5 g t.i.d	
Cefiderocol	2g t.i.d	
Meropenem-vaborbactam	2g t.i.d	
Plazomicin	15mg/kg o.d	

b.i.d = twice daily; t.i.d = three times daily; q.d = every day; o.d = once daily.

In pregnant women with pyelonephritis, outpatient management with appropriate parenteral antimicrobials may also be considered, provided symptoms are mild and close follow-up is feasible [227, 228]. In more severe cases of pyelonephritis, hospitalisation and supportive care are usually required. After clinical improvement parenteral therapy can also be switched to oral therapy for a total treatment duration of seven to ten days. In men with febrile UTI, pyelonephritis, or recurrent infection, or whenever a complicating factor is suspected a minimum treatment duration of two weeks is recommended, preferably with a fluoroquinolone since prostatic involvement is frequent [229].

*3.6.4 **Follow-up***

Post-treatment urinalysis or urine cultures in asymptomatic patients post-therapy are not indicated.

3.7 Complicated UTIs

*3.7.1 **Introduction***

Complicated UTI (cUTI) occurs in an individual in whom factors related to the host (e.g. underlying diabetes or immunosuppression) or specific anatomical or functional abnormalities related to the urinary tract (e.g. obstruction, incomplete voiding due to detrusor muscle dysfunction) are believed to result in an infection that will be more difficult to eradicate than an uncomplicated infection [230-232]. New insights into the management of cUTIs also suggest to consider infections caused by multi-drug resistant uropathogens [233]. The underlying factors that are generally accepted to result in a cUTI are outlined in Table 5. The designation of cUTI encompasses a wide variety of underlying conditions that result in a remarkably heterogeneous patient population. Therefore, it is readily apparent that a universal approach to the evaluation and treatment of cUTIs is not sufficient, although there are general principles of management that can be applied to the majority of patients with cUTIs. The following recommendations are based on the Stichting Werkgroep Antibioticabeleid (SWAB) Guidelines from the Dutch Working Party on Antibiotic Policy [234].

Table 5: Common factors associated with complicated UTIs [233-236]

Obstruction at any site in the urinary tract	UTI in males
Foreign body	Pregnancy
Incomplete voiding	Diabetes mellitus
Vesicoureteral reflux	Immunosuppression
Recent history of instrumentation	Healthcare-associated infections
Isolated ESBL-producing organisms	Isolated multi-drug resistant organisms

*3.7.2 **Diagnostic evaluation***

3.7.2.1 Clinical presentation

A cUTI is associated with clinical symptoms (e.g. dysuria, urgency, frequency, flank pain, costovertebral angle tenderness, suprapubic pain and fever), although in some clinical situations the symptoms may be atypical for example, in NLUTD, CA-UTI or patients who have undergone radical cystectomy with urinary diversion. In addition, all patients with nephrostomy may have an atypical clinical presentation. Clinical presentation can vary from severe obstructive acute pyelonephritis with imminent urosepsis to a post-operative CA-UTI, which might disappear spontaneously as soon as the catheter is removed. Clinicians must also recognise that symptoms, especially lower urinary tract symptoms (LUTS), are not only caused by UTIs but also by other urological disorders, such as, for example, bladder outlet obstruction and autonomic dysfunction in patients with spinal lesions and NLUTD. Concomitant medical conditions, such as diabetes mellitus and renal failure, which can be related to urological abnormalities, are often also present in a cUTI.

3.7.2.2 Urine culture

Laboratory urine culture is the recommended method to determine the presence or absence of clinically significant bacteriuria in patients suspected of having a cUTI.

*3.7.3 **Microbiology (spectrum and antimicrobial resistance)***

A broad range of micro-organisms cause cUTIs. The spectrum is much larger than in uncomplicated UTIs and the bacteria are more likely to be resistant (especially in treatment-related cUTI) than those isolated in uncomplicated UTIs [235, 236]. *E. coli, Proteus spp., Klebsiella spp., Pseudomonas spp., Serratia spp.* and *Enterococcus spp.* are the most common species found in cultures. *Enterobacterales* predominate (60-75%), with *E. coli* as the most common pathogen; particularly if the UTI is a first infection. Otherwise, the bacterial spectrum may vary over time and from one hospital to another [237].

*3.7.4 **General principles of cUTI treatment***

Appropriate management of the urological abnormality or the underlying complicating factor is mandatory. Optimal antimicrobial therapy for cUTI depends on the severity of illness at presentation, as well as local resistance patterns and specific host factors (such as allergies). In addition, urine culture and susceptibility testing should be performed, and initial empirical therapy should be tailored and followed by (oral) administration of an appropriate antimicrobial agent on the basis of the isolated uropathogen.

3.7.4.1 Choice of antimicrobials

Considering the current resistance percentages of amoxicillin, co-amoxiclav, trimethoprim and trimethoprim-sulphamethoxazole, it can be concluded that these agents are not suitable for the empirical treatment of

pyelonephritis in a normal host and, therefore, also not for treatment of all cUTIs [238]. The same applies to ciprofloxacin and other fluoroquinolones in urological patients [238].

Patients with a UTI with systemic symptoms requiring hospitalisation should be initially treated with an intravenous antimicrobial regimen, such as an aminoglycoside with or without amoxicillin, or a second or third generation cephalosporin, or an extended-spectrum penicillin with or without an aminoglycoside [234]. The choice between these agents should be based on local resistance data, and the regimen should be tailored on the basis of susceptibility results [212]. These recommendations are not only suitable for pyelonephritis, but for all other cUTIs.

Alternative regimens for the treatment of cUTIs, particularly those caused by multidrug-resistant pathogens have been studied. Ceftolozane/tazobactam 1.5 g every eight hours demonstrated high clinical cure rates for cUTIs caused by ESBL-producing *Enterobacterales* in a pooled analysis of phase 3 clinical trials [239]. Cefiderocol (2 g) three times daily was non-inferior to imipenem-cilastatin (1 g) three times daily for the treatment of cUTI in patients with multidrug-resistant Gram-negative infections [224]. Imipenem/cilastatin plus relebactam (250 or 125 mg) was as effective as imipenem/cilastatin alone for treatment of cUTI in a phase 2 RCT [219]. Ceftazidime/avibactam has been shown to be as effective as carbapenems for the treatment of cUTI in a systematic review reporting a baseline of 25% for ESBL-producing *Enterobacterales*, but more severe adverse events were reported in the ceftazidime/avibactam group [240]. Once-daily plazomicin was shown to be non-inferior to meropenem for the treatment of cUTIs caused by *Enterobacterales,* including multidrug-resistant strains [223].

In view of the high degree of resistance, particularly among patients admitted to the department of urology, fluoroquinolones are not automatically suitable as empirical antimicrobial therapy, especially when the patient has used ciprofloxacin in the last six months [241]. Fluoroquinolones can only be recommended as empirical treatment when the patient is not seriously ill and it is considered safe to start initial oral treatment or if the patient has had an anaphylactic reaction to beta-lactam antimicrobials. Intravenous levofloxacin 750 mg once daily for five days has been shown to be non-inferior to a seven to fourteen days regimen of levofloxacin 500 mg once daily starting intravenously and switched to an oral regimen (based on mitigation of clinical symptoms) [242].

3.7.4.2 Duration of antimicrobial therapy

Treatment for seven [243] to fourteen days (for men fourteen days when prostatitis cannot be excluded) [244], is generally recommended, but the duration should be closely related to the treatment of the underlying abnormality. When the patient is hemodynamically stable and afebrile for at least 48 hours, a shorter treatment duration (e.g. seven days) may be considered in patients where a short-course treatment is desired due to relative-contraindications to the administered antibiotic [242].

*3.7.5 **Summary of evidence and recommendations for the treatment of complicated UTIs***

Summary of evidence	**LE**
Patients with a UTI with systemic symptoms requiring hospitalisation should be initially treated with an intravenous antimicrobial regimen chosen based on local resistance data and previous urine culture results from the patient, if available. The regimen should be tailored on the basis of susceptibility result.	1b
If the prevalence of fluoroquinolone resistance is thought to be < 10% and the patient has contraindications for third generation cephalosporins or an aminoglycoside, ciprofloxacin can be prescribed as an empirical treatment in women with complicated pyelonephritis.	2
In the event of hypersensitivity to penicillin a cephalosporins can still be prescribed, unless the patient has had systemic anaphylaxis in the past.	2
In patients with a cUTI with systemic symptoms, empirical treatment should cover ESBL if there is an increased likelihood of ESBL infection based on prevalence in the community, earlier collected cultures and prior antimicrobial exposure of the patient.	2
Intravenous levofloxacin 750 mg once daily for five days, is non-inferior to a seven to fourteen day regimen of levofloxacin 500 mg once daily starting intravenously and switched to an oral regimen (based on mitigation of clinical symptoms).	2

Recommendations	Strength rating
Use the combination of: • amoxicillin plus an aminoglycoside; • a second-generation cephalosporin plus an aminoglycoside; • a third-generation cephalosporin intravenously as empirical treatment of complicated UTI with systemic symptoms.	Strong
Only use ciprofloxacin provided that the local resistance percentages are < 10% when; • the entire treatment is given orally; • patients do not require hospitalisation; • patient has an anaphylaxis for beta-lactam antimicrobials.	Strong
Do not use ciprofloxacin and other fluoroquinolones for the empirical treatment of complicated UTI in patients from urology departments or when patients have used fluoroquinolones in the last six months.	Strong
Manage any urological abnormality and/or underlying complicating factors.	Strong

3.8 Catheter-associated UTIs

*3.8.1 **Introduction***

Catheter-associated UTI refers to UTIs occurring in a person whose urinary tract is currently catheterised or has been catheterised within the past 48 hours. The urinary catheter literature is problematic as many published studies use the term CA-bacteriuria without providing information on what proportion are CA-ABU and CA-UTI, and some studies use the term CA-UTI when referring to CA-ABU or CA-bacteriuria [235].

*3.8.2 **Epidemiology, aetiology and pathophysiology***

Catheter-associated UTIs are the leading cause of secondary healthcare-associated bacteraemia. Approximately 20% of hospital-acquired bacteraemias arise from the urinary tract, and the mortality associated with this condition is approximately 10% [245]. A multistate point-prevalence survey of 11,282 patients across 183 hospitals reported that UTI accounted for 12.9% of healthcare acquired infections [246]. The incidence of bacteriuria associated with indwelling catheterisation is 3-8% per day [247-251]. The duration of catheterisation is the most important risk factor for the development of a CA-UTI [252, 253]. A systematic review and meta-analysis reported an average CA-UTI incidence of 13.79/1000 hospitalised patients with a prevalence of 9.33% [254]. This study also demonstrated that patients at high risk for CA-UTI were female, had a prolonged duration of catheterisation, had diabetes and had longer hospital and intensive care unit (ICU) stays [254].

Urinary catheterisation perturbs host defence mechanisms and provides easier access of uropathogens to the bladder. Indwelling urinary catheters facilitate colonisation with uropathogens by providing a surface for the attachment of host cell binding receptors recognised by bacterial adhesins, thus enhancing microbial adhesion. In addition, the uroepithelial mucosa is damaged, exposing new binding sites for bacterial adhesins, and residual urine in the bladder is increased through pooling below the catheter bulb [255]. Catheter-associated UTIs are often polymicrobial and caused by multiple-drug resistant uropathogens.

*3.8.3 **Diagnostic evaluation***

3.8.3.1 Clinical diagnosis

Signs and systemic symptoms compatible with CA-UTI include new onset or worsening of fever, rigors, altered mental status, malaise, or lethargy with no other identified cause, flank pain, costovertebral angle tenderness, acute haematuria, pelvic discomfort and in those whose catheters have been removed dysuria, urgent or frequent urination and suprapubic pain or tenderness [234]. In the catheterised patient, the presence or absence of odorous or cloudy urine alone should not be used to differentiate CA-ABU from CA-UTI [234, 235].

3.8.3.2 Laboratory diagnosis

Microbiologically, CA-UTI is defined by microbial growth of ≥ 103 cfu/mL of one or more bacterial species in a single catheter urine specimen or in a mid-stream voided urine specimen from a patient whose urethral, suprapubic, or condom catheter has been removed within the previous 48 hours [235]. In catheterised patients, pyuria is not diagnostic for CA-UTI. The presence, absence, or degree of pyuria should not be used to differentiate CA-ABU from CA-UTI. Pyuria accompanying CA-ABU should not be interpreted as an indication for antimicrobial treatment. The absence of pyuria in a symptomatic patient suggests a diagnosis other than CA-UTI [235].

3.8.3.3 Summary of evidence table and recommendations for diagnostic evaluation of CA-UTI

Summary of evidence	LE
Patients with indwelling or suprapubic catheters become carriers of ABU, with antibiotic treatment showing no benefit.	1a
In the catheterised patient, the presence or absence of odorous or cloudy urine alone should not be used to differentiate CA-ABU from CA-UTI.	2
Microbiologically CA-UTI is defined by microbial growth of ≥ 10^3 cfu/mL of one or more bacterial species in a single catheter urine specimen or in a mid-stream voided urine specimen from a patient whose catheter has been removed within the previous 48 hours.	3

Recommendations	Strength rating
Do not carry out routine urine culture in asymptomatic catheterised patients.	Strong
Do not use pyuria as sole indicator for catheter-associated UTI.	Strong
Do not use the presence or absence of odorous or cloudy urine alone to differentiate catheter-associated asymptomatic bacteriuria from catheter-associated UTI.	Strong

3.8.4 ***Disease management***

3.8.4.1 Limiting catheterisation and appropriate catheter discontinuation

Indwelling catheters should be placed only when they are clinically indicated; for example, for management of urinary retention or where strict monitoring of fluid balance is required. Catheter restriction protocols are an important part of multi-modal interventions to reduce CA-UTI rates. Nurse-driven protocols in hospitals as well as community based multi-modal targeted infection programs have been proven to reduce CA-UTI rates [256, 257]. Adjunctive devices such as electronic reminder systems have also been shown to assist in prompt catheter removal in hospital settings (including non-ICU). A systematic review of nineteen different interventions to reduce UTI (including catheter discontinuation and limiting catheterisation), in nursing home patients reported successful CA-UTI reduction and reduced catheter usage [258]. Another report of over 2,800 patients on a surgical oncology unit found that increasing catheter bundle compliance resulted in a significant reduction in CA-UTI rates [259].

3.8.4.2 Urethral cleaning and chlorhexidine bathing

A network meta-analysis of 33 studies (6,490 patients) found no difference in the incidence of CA-UTI comparing the different urethral cleaning methods vs. disinfection [260]. The efficacy of chlorhexidine baths (either using 2% chlorhexidine-impregnated cloths or 4% chlorhexidine-based soap) in reducing CA-UTI is debatable. In a RCT of 10,783 ICU patients, no difference in CA-UTI rates were reported between chlorhexidine and control bathing groups [261]. However, a systematic review of fifteen studies involving only ICU patients reported that daily chlorhexidine bathing was associated with a significant reduction in CA-UTI (RR 0.68) [262].

3.8.4.3 Alternatives to indwelling urethral catheterisation

Alternatives include intermittent urethral catheterisation (IC) or suprapubic catheterisation. In a systematic review of patients undergoing gynaecological surgery, indwelling catheters were associated with higher rates of symptomatic UTIs compared to IC [263]. A further meta-analysis of post-partum women reported no difference in the incidence of UTI after labour between continuous catheterisation and IC [263]. A prospective cohort study of nursing home residents found that residents with a suprapubic catheter had fewer CA-UTIs and where hospitalised less, but were more likely to be colonised with multi drug resistant organisms [264].

A Cochrane Review found insufficient evidence to assess the value of different policies for replacing long-term urinary catheters on patient outcomes [98]. Another Cochrane review investigating the role of urethral (indwelling or intermittent) vs. suprapubic catheterisation in the short-term found inconclusive evidence of an effect on UTI rates [265]. For patients with NLUTD, a further systematic review found no randomised or quasi-randomised controlled trials and therefore no conclusions regarding the use of the different types of catheters could be made [266]. Therefore, based on the available literature, while there are some limited studies showing a benefit of IC or suprapubic catheterisation over urethral catheterisation for CA-UTI rates, there is insufficient evidence to recommend those approaches routinely [267].

3.8.4.4 Impregnated or coated catheters

Hydrophilic coated catheters have been found to be beneficial for reducing CA-UTI rates. A meta-analysis of seven studies investigating RCTs comparing hydrophilic coated to PVC (standard) catheters for IC found a statistically lower risk ratio (0.84) for the frequency of UTI in the hydrophilic catheter group [268]. A systematic review and practice policy statements on UTI prevention in patients with spina bifida recommended the use of single-use and hydrophilic catheters for IC [269].

Silver-alloy-impregnated catheters have not been associated with reduced CA-UTI rates. A small RCT of 54 ICU patients showed no significant difference in UTI rates between the silver-alloy impregnated group and the standard silicone foley catheter group [270]. In a cohort study of patients undergoing suprapubic catheter placement at the time of pelvic organ prolapsed surgery, a 5% difference in UTI rate at six weeks was noted, although this was not significant [271]. A systematic review of 26 trials (12,422 patients) reported that silver alloy-coated catheters were not associated with a statistically significant reduction in CA-UTI and were considerably more expensive [272]. However, the same study found that nitrofurazone-impregnated catheters reduce the risk of symptomatic CA-UTI; however, this was borderline significant (RR 0.84, 95% CI 0.71 to 0.99) [272]. A more recent RCT (214 patients) evaluating the use of nitrofurazone-infused catheters post-renal transplant found no benefit for their use [273]. Additionally, another RCT showed no benefit for the use of silver-alloy-coated indwelling catheters for reduction of UTI in 489 patients with spinal cord injury [274].

From a microbiological perspective, there may be a difference in organisms causing CA-UTI from urethral and suprapubic catheters and therefore urine culture results are important to guide therapy [267].

3.8.4.5 Antibiotic prophylaxis for catheter removal or insertion

The issue of whether antibiotic prophylaxis reduce the rate of symptomatic UTI in adults following indwelling bladder catheter removal has been the subject of multiple RCTs. A review and meta-analysis identified seven RCTs with 1,520 participants. Meta-analysis showed overall benefit for use of prophylaxis RR (95%CI) = 0.45 (0.28-0.72); ARR 5.8% (from 10.5% to 4.7%) with a number needed to treat (NNT) of 17 [214]. Results for individual trials were inconsistent with five trials including the possibility of no benefit [214]. In an affectional RCT with 172 participants undergoing laparoscopic radical prostatectomy randomised to seven days of ciprofloxacin (n=80) or no treatment (n=80) at the time of catheter removal, which occurred at a mean of nine days post-operatively, there was no difference in infective complications recorded at up to four weeks after catheter removal. More isolates obtained from the prophylaxis group (11) were resistant to ciprofloxacin compared to the no treatment group (3) [215]. With regards to catheter insertion, a systematic review and meta-analysis showed that prophylactic antibiotics reduced the rate of bacteriuria and other signs of infection, such as pyuria, fever and gram-negative isolates in patients' urine, in surgical patients who undergo bladder drainage for at least 24 hours post-operatively [275].

3.8.4.6 Antibiotic prophylaxis for intermittent self-catheterisation (ISC)

An RCT investigating the effect of antibiotic prophylaxis in patients performing ISC showed that the frequency of symptomatic antibiotic-treated UTI was reduced by 48% using prophylaxis in a cohort of 404 patients performing ISC [276]. However, resistance against the antibiotics used for UTI treatment was more frequent in urinary isolates from the prophylaxis group than in those from the control group at 9–12 months.

While the literature shows some benefit for reduction of CA-UTI by utilising antibiotics, the routine use of antibiotics for such a common procedure in the healthcare setting would result in an increased usage of antimicrobials. As highlighted in some of the RCTs this strategy is associated with increased antimicrobial resistance. Antibiotic use is the main driving force in the development of antimicrobial resistance. Current antimicrobial stewardship principles would not favour the routine use of antibiotic prophylaxis for either catheter changes or ISC even when UTIs could be prevented [267].

3.8.4.7 Antimicrobial treatment for suspected CA-UTI

A urine specimen for culture should be obtained prior to initiating antimicrobial therapy for presumed CA-UTI due to the wide spectrum of potential infecting organisms and the increased likelihood of antimicrobial resistance. The urine culture should be obtained from the freshly placed catheter prior to the initiation of antimicrobial therapy [235]. Based on the global prevalence on infections in urology (GPIU) study, the causative micro-organisms in CA-UTI are comparable with the causative micro-organisms in other cUTIs; therefore, symptomatic CA-UTIs should be treated according to the recommendations for cUTI (see section 3.7.5) [277].

Seven days is the recommended duration of antimicrobial treatment for patients with CA-UTI who have prompt resolution of symptoms, and fourteen days of treatment is recommended for those with a delayed response, regardless of whether the patient remains catheterised or not [235]. A five-day regimen of levofloxacin may be considered in patients with CA-UTI who are not severely ill. Data are insufficient to make such a recommendation about other fluoroquinolones. With the rise in fluoroquinolone resistance,

alternative antimicrobial agents should be selected where possible to start empirical therapy based on local microbiological information. A 5-day antibiotic regimen with catheter exchange has been shown in one study to be non-inferior to a 10-day regimen with catheter retention on the basis of clinical cure [278].

A three-day antimicrobial regimen may be considered for women aged ≤ 65 years who develop CA-UTI without upper urinary tract symptoms after an indwelling catheter has been removed. If an indwelling catheter has been in place for two weeks at the onset of CA-UTI and is still indicated, the catheter should be replaced to hasten resolution of symptoms and to reduce the risk of subsequent CA-bacteriuria and CA-UTI. If use of the catheter can be discontinued, a culture of a voided mid-stream urine specimen should be obtained prior to the initiation of antimicrobial therapy to help guide treatment [235]. Long-term indwelling catheters should not be changed routinely. Follow appropriate practices for catheter insertion and care [279].

3.8.4.8 Recommendations for disease management and prevention of CA-UTI

Summary of evidence	**LE**
A systematic review of nineteen different interventions to reduce UTI including catheter discontinuation and limiting catheterisation in nursing home patients reported successful CA-UTI reduction and reduced catheter usage.	1b
A meta-analysis of seven studies investigating RCTs comparing hydrophilic coated to PVC (standard) catheters for IC found a statistically lower risk ratio (0.84) for the frequency of UTI in the hydrophilic catheter group.	1a
A meta-analysis showed overall benefit for use of prophylaxis for reduction of infective complications after catheter removal; however, results from individual trials were inconsistent with five out of seven trials including the possibility of no benefit.	1a
A subsequent RCT found no benefit of antibiotic prophylaxis for reduction of infective complications at up to four weeks after catheter removal.	1b

Recommendations	**Strength rating**
Treat symptomatic catheter-associated-UTI according to the recommendations for complicated UTI (see section 3.7.5).	Strong
Take a urine culture prior to initiating antimicrobial therapy in catheterised patients in whom the catheter has been removed.	Strong
Do not treat catheter-associated asymptomatic bacteriuria in general.	Strong
Treat catheter-associated asymptomatic bacteriuria prior to traumatic urinary tract interventions (e.g. transurethral resection of the prostate).	Strong
Replace or remove the indwelling catheter before starting antimicrobial therapy.	Strong
Do not apply topical antiseptics or antimicrobials to the catheter, urethra or meatus.	Strong
Do not use prophylactic antimicrobials to prevent catheter-associated UTIs.	Strong
Do not routinely use antibiotic prophylaxis to prevent clinical UTI after urethral catheter removal.	Weak
The duration of catheterisation should be minimal.	Strong
Use hydrophilic coated catheters to reduce CA-UTI.	Strong
Do not routinely use antibiotic prophylaxis to prevent clinical UTI after urethral catheter removal or in patients performing intermittent self-catheterisation	Weak

3.9 Urosepsis

*3.9.1 **Introduction***

Patients with urosepsis should be diagnosed at an early stage, especially in the case of a cUTI. Systemic inflammatory response syndrome (SIRS), characterised by fever or hypothermia, leukocytosis or leukopenia, tachycardia and tachypnoea, has been recognised as a set of alerting symptoms [280, 281]; however, SIRS is no longer included in the recent terminology of sepsis (Table 6) [11]. Mortality is considerably increased the more severe the sepsis is.

The treatment of urosepsis involves adequate life-supporting care, appropriate and prompt antimicrobial therapy, adjunctive measures and the optimal management of urinary tract disorders [282]. Source control by decompression of any obstruction and drainage of larger abscesses in the urinary tract is essential [282]. Urologists are recommended to treat patients in collaboration with intensive care and infectious diseases specialists.

Urosepsis is seen in both community-acquired and healthcare associated infections. Nosocomial urosepsis may be reduced by measures used to prevent nosocomial infection, e.g. reduction of hospital stay, early removal of indwelling urinary catheters, avoidance of unnecessary urethral catheterisation, correct use of closed catheter systems, and attention to simple daily aseptic techniques to avoid cross-infection.

Sepsis is diagnosed when clinical evidence of infection is accompanied by signs of systemic inflammation, presence of symptoms of organ dysfunction and persistent hypotension associated with tissue anoxia (Table 6).

3.9.2 Epidemiology, aetiology and pathophysiology

Urinary tract infections can manifest from bacteriuria with limited clinical symptoms to sepsis or severe sepsis, depending on localised and potential systemic extension. It is important to note that a patient can move from an almost harmless state to severe sepsis in a very short time.

Mortality rates associated with sepsis vary depending on the organ source [283] with urinary tract sepsis generally having a lower mortality than that from other sources [284]. Sepsis is more common in men than in women [285]. In recent years, the overall incidence of sepsis arising from all sources has increased by 8.7% per year [283], but the associated mortality has decreased, which suggests improved management of patients (total in-hospital mortality rate fell from 27.8% to 17.9% from 1995 to 2000) [286]. Although the rate of sepsis due to Gram-positive and fungal organisms has increased, Gram-negative bacteria remain predominant in urosepsis [277, 287].

In urosepsis, as in other types of sepsis, the severity depends mostly upon the host response. Patients who are more likely to develop urosepsis include elderly patients, diabetics, immunosuppressed patients, such as transplant recipients and patients receiving cancer chemotherapy or corticosteroids. Urosepsis also depends on local factors, such as urinary tract calculi, obstruction at any level in the urinary tract, congenital uropathy, NLUTD, or endoscopic manoeuvres. However, all patients can be affected by bacterial species that are capable of inducing inflammation within the urinary tract.

Patients who are more likely to develop urosepsis include elderly patients, diabetics, immunosuppressed patients, such as transplant recipients and patients receiving cancer chemotherapy or corticosteroids. Urosepsis also depends on local factors, such as urinary tract calculi, obstruction at any level in the urinary tract, congenital uropathy, neurogenic bladder disorders, or endoscopic manoeuvres. However, all patients can be affected by bacterial species that are capable of inducing inflammation within the urinary tract.

3.9.3 Diagnostic evaluation

For diagnosis of systemic symptoms in sepsis either the full Sequential [Sepsis-related] Organ Failure Assessment (SOFA) score, or the quickSOFA score should be applied (Table 6). Microbiology sampling should be applied to urine, two sets of blood cultures [288], and if appropriate drainage fluids. Imaging investigations, such as sonography and CT-scan should be performed early [289].

Table 6: Definition and criteria of sepsis and septic shock [11, 280, 281]

Disorder	Definition
Sepsis	Life-threatening organ dysfunction caused by a dysregulated host response to infection. For clinical application, organ dysfunction can be represented by an increase in the Sequential [Sepsis-related] Organ Failure Assessment (SOFA) score of 2 points or more. For rapid identification a quickSOFA (qSOFA) score was developed: respiratory rate of 22/min or greater, altered mentation, or systolic blood pressure of 100 mmHg or less.
Septic shock	Septic shock should be defined as a subset of sepsis in which particularly profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mortality than with sepsis alone. Patients with septic shock can be clinically identified by a vasopressor requirement to maintain a mean arterial pressure of 65 mmHg or greater and serum lactate level greater than 2 mmol/L (>18 mg/dL) in the absence of hypovolemia.

*3.9.4 **Physiology and biochemical markers***

E. coli remains the most prevalent micro-organism. In several countries, bacterial strains can be resistant or multi-resistant and therefore difficult to treat [287]. Most commonly, the condition develops in compromised patients (e.g. those with diabetes or immunosuppression), with typical signs of generalised sepsis associated with local signs of infection.

3.9.4.1 Cytokines as markers of the septic response

Cytokines are involved in the pathogenesis of sepsis [284]. They are molecules that regulate the amplitude and duration of the host inflammatory response. They are released from various cells including monocytes, macrophages and endothelial cells, in response to various infectious stimuli. The complex balance between pro- and anti-inflammatory responses is modified in severe sepsis. An immunosuppressive phase follows the initial pro-inflammatory mechanism. Sepsis may indicate an immune system that is severely compromised and unable to eradicate pathogens or a non-regulated and excessive activation of inflammation, or both. Genetic predisposition is a probable explanation of sepsis in several patients. Mechanisms of organ failure and death in patients with sepsis remain only partially understood [284].

3.9.4.2 Biochemical markers

Procalcitonin is the inactive pro-peptide of calcitonin. Normally, levels are undetectable in healthy humans. During severe generalised infections (bacterial, parasitic and fungal) with systemic manifestations, procalcitonin levels rise [290]. In contrast, during severe viral infections or inflammatory reactions of non-infectious origin, procalcitonin levels show only a moderate or no increase. Mid-regional proadrenomedulline is another sepsis marker. Mid-regional proadrenomedullin has been shown to play a decisive role in the induction of hyperdynamic circulation during the early stages of sepsis and progression to septic shock [291]. Procalcitonin monitoring may be useful in patients likely to develop sepsis and to differentiate from a severe inflammatory status not due to bacterial infection [290, 292]. In addition, serum lactate is a marker of organ dysfunction and is associated with mortality in sepsis [293]. Serum lactate should therefore also be monitored in patients with severe infections.

*3.9.5 **Disease management***

3.9.5.1 Prevention

Septic shock is the most frequent cause of death for patients hospitalised for community-acquired and nosocomial infection (20-40%). Urosepsis treatment requires a combination of treatment including source control (obstruction of the urinary tract), adequate life-support care, and appropriate antimicrobial therapy [284, 289]. In such a situation, it is recommended that urologists collaborate with intensive care and infectious disease specialists for the best management of the patient.

3.9.5.1.1 Preventive measures of proven or probable efficacy

The most effective methods to prevent nosocomial urosepsis are the same as those used to prevent other nosocomial infections [294, 295] they include:

- Isolation of patients with multi-resistant organisms following local and national recommendations.
- Prudent use of antimicrobial agents for prophylaxis and treatment of established infections, to avoid selection of resistant strains. Antibiotic agents should be chosen according to the predominant pathogens at a given site of infection in the hospital environment.
- Reduction in hospital stay. Long inpatient periods before surgery lead to a greater incidence of nosocomial infections.
- Early removal of indwelling urethral catheters, as soon as allowed by the patient's condition. Nosocomial UTIs are promoted by bladder catheterisation as well as by ureteral stenting [296]. Antibiotic prophylaxis does not prevent stent colonisation, which appears in 100% of patients with a permanent ureteral stent and in 70% of those temporarily stented.
- Use of closed catheter drainage and minimisation of breaks in the integrity of the system, e.g. for urine sampling or bladder wash-out.
- Use of least-invasive methods to release urinary tract obstruction until the patient is stabilised.
- Attention to simple everyday techniques to assure asepsis, including the routine use of protective disposable gloves, frequent hand disinfection, and using infectious disease control measures to prevent cross-infections.

3.9.5.1.2 Appropriate peri-operative antimicrobial prophylaxis

For appropriate peri-operative antimicrobial prophylaxis see section 3.15. The potential side effects of antibiotics must be considered before their administration in a prophylactic regimen.

3.9.5.2 Treatment

Early goal-directed resuscitation was initially shown to improve survival for emergency department patients presenting with septic shock in a randomised, controlled, single-centre study [297]. However, follow-up studies in an improved emergency medicine background have not achieved positive effects with this strategy [298-300]. An individual patient data meta-analysis of the later three multicentre trials concluded that early goal-directed therapy did not result in better outcomes than usual care and was associated with higher hospitalisation costs [301].

3.9.5.2.1 Antimicrobial therapy

Initial empiric antimicrobial therapy should provide broad antimicrobial coverage against all likely causative pathogens and should be adapted on the basis of culture results, once available [282, 289]. The dosage of the antimicrobial substances is of paramount importance in patients with sepsis syndrome and should generally be high, with appropriate adjustment for renal function [282]. Antimicrobials must be administered no later than one hour after clinical assumption of sepsis [282].

3.9.5.2.2 Source control

Obstruction in the urinary tract is the most frequent urological source of urosepsis. Drainage of obstruction and abscesses, and removal of foreign bodies, such as urinary catheters or stones is therefore the most important source control strategy. These are key components of the strategy. This condition is an absolute emergency.

3.9.5.2.3 Adjunctive measures

The most important adjunctive measures in the management of sepsis are the following [282, 289]:

- fluid therapy with crystalloids, or albumin, if crystalloids are not adequately increasing blood pressure: passive leg raising-induced changes in cardiac output and in arterial pulse pressure are predictors of fluid responsiveness in adults [302];
- as vasopressors norepinephrine should be used primarily, dobutamine in myocardial dysfunction;
- hydrocortisone should be given only if fluid and vasopressors do not achieve a mean arterial pressure of ≥ 65 mmHg;
- blood products should be given to target a haemoglobin level of 7-9 g/dL;
- mechanical ventilation should be applied with a tidal volume 6 mL/kg and plateau pressure ≤ 30 cm H_2O and a high positive end-expiratory pressure;
- sedation should be given minimally, neuromuscular blocking agents should be avoided;
- glucose levels should be target at ≤ 180 mg/dL;
- deep vein thrombosis prevention should be given with low-molecular weight heparin subcutaneously;
- stress ulcer prophylaxis should be applied in patients at risk, using proton pump inhibitors;
- enteral nutrition should be started early (< 48 hours).

In conclusion, sepsis in urology remains a severe situation with a considerable mortality rate. A recent campaign, 'Surviving Sepsis Guidelines', aims to reduce mortality by 25% in the next years [282, 289, 303]. Early recognition of the symptoms may decrease the mortality by timely treatment of urinary tract disorders, e.g. obstruction, or urolithiasis. Adequate life-support measures and appropriate antimicrobial treatment provide the best conditions for improving patient survival. The prevention of sepsis is dependent on good practice to avoid nosocomial infections and using antimicrobial prophylaxis and therapy in a prudent and well-accepted manner.

3.9.5.3 Summary of evidence and recommendations for the diagnosis and treatment of urosepsis

Summary of evidence	**LE**
Initial high dose empiric antimicrobial therapy, administered within the first hour, should provide broad antimicrobial coverage against all likely causative pathogens and should be adapted on the basis of culture results, once available.	2b
Source control interventions should be implemented as soon as possible to control or eliminate diagnosed and/or suspected infectious foci.	3

Recommendations	**Strength rating**
Perform the quickSOFA score to identify patients with potential sepsis.	Strong
Take a urine culture and two sets of blood cultures before starting antimicrobial treatment.	Strong
Administer parenteral high dose broad spectrum antimicrobials within the first hour after clinical assumption of sepsis.	Strong

Adapt initial empiric antimicrobial therapy on the basis of culture results.	Strong
Initiate source control including removal of foreign bodies, decompression of obstruction and drainage of abscesses in the urinary tract.	Strong
Provide immediate adequate life-support measures.	Strong

Table 7: Suggested regimens for antimicrobial therapy for urosepsis.

Antimicrobials	Daily dose	Duration of therapy
Cefotaxime	2 g t.i.d	7-10 days Longer courses are appropriate in patients who have a slow clinical response
Ceftazidime	1-2 g t.i.d	
Ceftriaxone	1-2 g q.d	
Cefepime	2 g b.i.d	
Piperacillin/tazobactam	4.5 g t.i.d	
Ceftolozane/tazobactam	1.5 g t.i.d	
Ceftazidime/avibactam	2.5 g t.i.d	
Gentamicin*	5 mg/kg q.d	
Amikacin*	15 mg/kg q.d	
Ertapenem	1 g q.d	
Imipenem/cilastatin	0.5 g t.i.d	
Meropenem	1 g t.i.d	

** Not studied as monotherapy in urosepsis*
b.i.d = twice daily; t.i.d = three times daily; q.d = every day.

3.10 Urethritis

*3.10.1 **Introduction***

Urethritis can be of either infectious or non-infectious origin. Inflammation of the urethra presents usually with LUTS and must be distinguished from other infections of the lower urinary tract. Urethral infection is typically spread by sexual contact.

*3.10.2 **Epidemiology, aetiology and pathogenesis***

From a therapeutic and clinical point of view, gonorrhoeal urethritis (GU) caused by *Neisseria gonorrhoeae* must be differentiated from non-gonococcal urethritis (NGU). Non-gonococcal urethritis is a non-specific diagnosis that can have many infectious aetiologies. Causative pathogens include *Chlamydia trachomatis, Mycoplasma genitalium, Ureaplasma urealyticum* and *Trichomonas vaginalis.* The role of Ureaplasma spp. as urethritis causative pathogens is controversial. Recent data suggests that *U. urealyticum,* but not U. parvum is an aetiological agent in NGU [304]. The prevalence of isolated causative pathogens are: *C. trachomatis* 11-50%; *M. genitalium* 6-50%; *Ureaplasmas* 5-26%; *T. vaginalis* 1-20%; and adenoviruses 2-4% [305].

Causative agents either remain extracellularly on the epithelial layer or penetrate into the epithelium (*N. gonorrhoeae* and *C. trachomatis*) and cause pyogenic infection. Although arising from urethritis, chlamydiae and gonococci can spread further through the urogenital tract to cause epididymitis in men or cervicitis, endometritis and salpingitis in women [306].

Mucopurulent or purulent discharge, dysuria and urethral pruritus are symptoms of urethritis. However, many infections of the urethra are asymptomatic.

*3.10.3 **Evidence Summary***

A systematic search of the literature form January 2014 until February 2019 identified 488 titles of which 71 were selected for full text review. Thirteen systematic reviews or guidelines based on systematic literature searches [304-316], and seventeen original publications [317-333] were selected for further analysis. In addition, a further eleven relevant publications were identified from the references of the reviewed literature [334-344]. The evidence questions addressed were:

1. In patients with urethritis what is the best method of detecting the causative pathogen?
2. In patients with urethritis what are the best treatment strategies for clinical or microbiological cure?

3.10.4 ***Diagnostic evaluation***

In symptomatic patients the diagnosis of urethritis can be made based on the presence of any of the following criteria [305, 306]:

- Mucoid, mucopurulent, or purulent urethral discharge.
- Gram or methylene-blue stain of urethral secretions demonstrating inflammation. Five or more polymorphonuclear leucocytes (PMNL) per high power field (HPF) is the historical cut-off for the diagnosis of urethritis. A threshold of ≥ 2 PMNL/HPF was proposed recently based on better diagnostic accuracy [321, 334-336], but this was not supported by other studies [320]. Therefore, in line with the 2016 European Guideline on the management of NGU [305] the use of ≥ 5 PMNL/HPF cut-off level is recommended until the benefit of alternative cut-off levels is confirmed.
- The presence of ≥ 10 PMNL/HPF in the sediment from a spun first-void urine sample or a positive leukocyte esterase test in first-void urine.

Evidence of urethral inflammation in the Gram stain of urethral secretions with gonococci located intracellularly as Gram-negative diplococci indicates GU. Non-gonococcal urethritis is confirmed when staining of urethral secretions indicates inflammation in the absence of intracellular diplococci. Clinicians should always perform point-of-care diagnostics (e.g. Gram staining, first-void urine with microscopy, leukocyte esterase testing) if available to obtain objective evidence of urethral inflammation and to guide treatment [305, 306, 319]. Recent studies showed that processing time of point-of-care diagnostics is highly relevant in terms of patient compliance and real-life applicability [317, 318].

Men who meet the criteria for urethritis should be tested for *C. trachomatis, M. genitalium* and *N. gonorrhoea* with nucleic acid amplification tests (NAAT), even if point-of-care tests are negative for gonorrhoeae [305, 308]. The sensitivity and specificity of NAATs is better than that of any of the other tests available for the diagnosis of chlamydial and gonococcal infections [309, 337]. The performance of first-catch urine is non-inferior to urethral swabs [337]. In case of delayed treatment, if a NAAT is positive for gonorrhoea, a culture using urethral swabs should be performed before treatment to assess the antimicrobial resistance profile of the infective strain [306]. *N. gonorrhoeae* and *C. trachomatis* cultures are mainly used to evaluate treatment failures and monitor developing resistance to current treatment. Trichomonas spp. can usually be identified microscopically [306] or by NAATs [311].

Non-gonococcal urethritis is classified as persistent when symptoms do not resolve within three to four weeks following treatment. When this occurs NAATs should be performed for urethritis pathogens including *T. vaginalis* four weeks after completion of therapy [305, 322].

3.10.5 ***Disease management***

For severe urethritis empirical treatment should be started following diagnosis. If the patients symptoms are mild, delayed treatment guided by the results of NAATs is recommended. All sexual partners at risk should be assessed and treated whilst maintaining patient confidentiality [305, 325].

3.10.5.1 Gonococcal urethritis

For GU, a combination treatment using two antimicrobials with different mechanisms of action is recommended to improve treatment efficacy and to hinder increasing resistance to cephalosporins [306]. Ceftriaxone 1 g intramuscularly or intravenously with azithromycin 1 g single oral dose should be used as first-line treatment. Azithromycin is recommended because of its favourable susceptibility rates compared to other antimicrobials, good compliance with the single-dose regimen and the possibility of a C. trachomatis co-infection [306]. In case of azithromycin allergy, doxycycline can be used instead in combination with ceftriaxone or cefixime [306]. A 400 mg oral dose of cefixime is recommended as an alternative regimen to ceftriaxone; however, it has less favourable pharmacodynamics and may lead to the emergence of resistance [307, 343].

A number of alternative regimens for the treatment of GU have been studied. In a randomised, open label, non-comparative clinical study dual treatment with a combination of intramuscular gentamicin 240 mg plus oral azithromycin 2 g (n=202) single doses and a combination of oral gemifloxacin 320 mg plus oral azithromycin 2 g (n=199) single doses were associated with microbiological cure rates of 100% and 99.5%, respectively [339]. A 2014 systematic review focusing on the use of single-dose intramuscular gentamicin concluded that there is insufficient data to support or refute the efficacy and safety of this regimen in the treatment of uncomplicated gonorrhoea [313]. In three prospective single arm studies enrolling men with GU the use of extended-release azithromycin 2 g single oral dose resulted in microbiological cure rates of 83% (n=36), 93.8% (n=122) and 90.9% (n=33), respectively [329, 330, 332]. However, azithromycin monotherapy is generally not recommended because of its effect on increasing macrolide resistance rates [306]. Intramuscular spectinomycin 2 g single dose shows microbiological cure rates above 96% [340, 343] in urogenital gonorrhoeal infections; therefore, where available, it can be a valid treatment alternative. An open label, randomised trial compared oral fosfomycin trometamol 3 g

on days one, three and five (n=60) with intramuscular ceftriaxone 250 mg plus oral azithromycin 1 g single dose (n=61) in men with uncomplicated GU. In the per-protocol analysis clinical and microbiologic cure rates were 96.8% and 95.3% respectively [333].

The worldwide increase in gonorrhoeal antimicrobial resistance and the emergence of multidrug-resistant gonorrhoeal strains is a globally recognised healthcare crisis which emphasises the importance of guideline adherence [312, 324, 344].

3.10.5.2 Non-gonococcal urethritis

For NGU without an identified pathogen oral doxycycline 100 mg twice daily for seven days should be used as first-line treatment. Alternatively, single dose oral azithromycin 500 mg day one and 250 mg days two to four can be used. This regimen provides better efficacy compared to azithromycin 1 g single dose for *M. genitalium* infections, in which azithromycin 1 g single dose treatment is associated with the development of increasing macrolide resistance significantly decreasing the overall cure rate [305, 308, 314, 328]. However, a retrospective cohort study did not find significant difference between the extended and 1 g single dose azithromycin regimen regarding cure rates and the selection of macrolide resistance in *M. genitalium* urethritis [326]. If macrolide resistant *M. genitalium* is detected moxifloxacin 400 mg can be used for seven to fourteen days [305, 306, 315]. In case of failure after both azithromycin and moxifloxacin treatment, pristinamycin (registered in France) is the only antimicrobial agent with documented activity against *M. genitalium* [308, 327, 338]. Josamycin 500 mg three times a day for ten days is used in Russia, but will not eradicate macrolide-resistant strains [308].

For chlamydial urethritis azithromycin 1 g single dose and doxycycline 100 mg twice daily for seven days are both effective options [342]. A Cochrane Review found that in men with urogenital *C. trachomatis* infection regimens with azithromycin are probably less effective than doxycycline for microbiological failure, however, there might be little or no difference for clinical failure [316]. Fluoroquinolones, such as ofloxacin or levofloxacin, may be used as second-line treatment only in selected cases where the use of other agents is not possible [341].

For *U. urealyticum* infections the efficacy of doxycycline 100 mg twice daily for seven days is similar to azithromycin 1 g single dose treatment [305, 323]. For urethritis caused by *T. vaginalis* oral metronidazole or tinidazole 2 g single dose is recommended as first-line treatment. For treatment options for persistent or recurrent *T. vaginalis* infection refer to the review of Sena *et. al* [311].

In case of persistent NGU treatment should cover *M. genitalium* and *T. vaginalis* [305, 306].

*3.10.6 **Follow-up***

Patients should be followed up for control of pathogen eradication after completion of therapy only if therapeutic adherence is in question, symptoms persist or reoccurrence is suspected. Patients should be instructed to abstain from sexual intercourse for seven days after therapy is initiated, provided their symptoms have resolved and their sexual partners have been adequately treated. Reporting and source tracing should be done in accordance with national guidelines and in cooperation with specialists in venereology, whenever required. Persons who have been diagnosed with a new STD should receive testing for other STDs, including syphilis and HIV [310].

*3.10.7 **Summary of evidence and recommendations for the diagnostic evaluation and antimicrobial treatment of urethritis***

Summary of evidence	**LE**
A Gram stain of urethral discharge or a urethral smear that shows ≥ 5 leukocytes per high power field (× 1,000) and gonococci located intracellularly as Gram-negative diplococci, indicates gonococcal urethritis.	3b
Validated NAATs of first-void urine samples have better sensitivity and specificity than any of the other tests available for the diagnosis of chlamydial and gonococcal infections.	2a
For GU dual treatment with ceftriaxone and azithromycin is the most effective combination.	2a
In case of urogenital *C. trachomatis* infection in men azithromycin is probably less effective than doxycycline for microbiological failure, however, there might be little or no difference for clinical failure.	1a
In case of *U. urealyticum* infection the efficacy of doxycycline 100 mg twice for seven days is similar to azithromycin 1 g single dose treatment.	2a

Recommendations	Strength rating
Perform a Gram stain of urethral discharge or a urethral smear to preliminarily diagnose gonococcal urethritis.	Strong
Perform a validated nucleic acid amplification test (NAAT) on a first-void urine sample or urethral smear prior to empirical treatment to diagnose chlamydial and gonococcal infections.	Strong
Delay treatment until the results of the NAATs are available to guide treatment choice in patients with mild symptoms.	Strong
Perform a urethral swab culture, prior to initiation of treatment, in patients with a positive NAAT for gonorrhoea to assess the antimicrobial resistance profile of the infective strain.	Strong
Use a pathogen directed treatment based on local resistance data.	Strong
Sexual partners should be treated maintaining patient confidentiality.	Strong

Table 8: Suggested regimens for antimicrobial therapy for urethritis

Pathogen	Antimicrobial	Dosage & Duration of therapy	Alternative regimens
Gonococcal Infection	Ceftriaxone Azithromycin	1 g i.m. or i.v.*, SD 1 g p.o., SD	• Cefixime 400 mg p.o., SD plus Azithromycin 1 g p.o., SD In case of cephalosporin allergy: • Gentamicin 240 mg i.m SD plus Azithromycin 2 g p.o., SD • Gemifloxacin 320 mg p.o., SD plus Azithromycin 2 g p.o., SD • Spectinomycin 2 g i.m., SD • Fosfomycin trometamol 3 g p.o. on days 1, 3 and 5 In case of azithromycin allergy, in combination with ceftriaxone or cefixime: • Doxycycline 100 mg b.i.d, p.o., 7 days
Non-Gonococcal infection (non-identified pathogen)	Doxycycline	100 mg b.i.d, p.o., 7 days	Azithromycin 500 mg p.o., day 1, 250 mg p.o., 4 days
Chlamydia trachomatis	Azithromycin Or Doxycycline	1.0-1.5 g p.o., SD 100 mg b.i.d, p.o., for 7 days	• Levofloxacin 500 mg p.o., q.d., 7 days • Ofloxacin 200 mg p.o., b.i.d., 7 days
Mycoplasma genitalium	Azithromycin	500 mg p.o., day 1, 250 mg p.o., 4 days	In case of macrolide resistance: • Moxifloxacin 400 mg q.d., 7-14 days
Ureaplasma urealyticum	Doxycycline	100 mg b.i.d, p.o., 7 days	Azithromycin 1.0-1.5 g p.o., SD
Trichomonas vaginalis	Metronidazole Tinidazole	2 g p.o., SD 2 g p.o., SD	Metronidazole 500 mg p.o., b.i.d., 7 days
Persistent non-gonococcal urethritis			
After first-line doxycycline	Azithromycin plus Metronidazole	500 mg p.o., day 1, 250 mg p.o., 4 days 400 mg b.i.d. p.o., 5 days	If macrolide resistant *M. genitalium* is detected moxifloxacin should be substituted for azithromycin

After first-line azithromycin	Moxifloxacin plus Metronidazole	400 mg p.o. q.d., 7-14 days 400 mg b.i.d. p.o., 5 days	

SD = single dose; b.i.d = twice daily; q.d = everyday; p.o. = orally; i.m. = intramuscular; i.v. = intravenous.
** Despite the lack of RCTs there is increasing evidence that intravenous treatment with ceftriaxone is safe and effective for the treatment of gonorrhoeal infections and avoids the discomfort of an intramuscular injection for patients [345].*

3.11 Bacterial Prostatitis

*3.11.1 **Introduction***

Bacterial prostatitis is a clinical condition caused by bacterial pathogens. It is recommended that urologists use the classification suggested by the National Institute of Diabetes, Digestive and Kidney Diseases (NIDDK) of the National Institutes of Health (NIH), in which bacterial prostatitis, with confirmed or suspected infection, is distinguished from chronic pelvic pain syndrome (CPPS) (Table 9) [346-348].

Table 9: Classification of prostatitis and CPPS according to NIDDK/NIH [346-348]

Type	Name and description
I	Acute bacterial prostatitis (ABP)
II	Chronic bacterial prostatitis (CBP)
III	Chronic non-bacterial prostatitis – CPPS
IIIA	Inflammatory CPPS (white cells in semen/EPS/VB3)
IIIB	Non-inflammatory CPPS (no white cells in semen/EPS/VB3)
IV	Asymptomatic inflammatory prostatitis (histological prostatitis)

CPPS = chronic pelvic pain syndrome; EPS = expressed prostatic secretion; VB3 = voided bladder urine specimen 3 (urine following prostatic massage).

*3.11.2 **Evidence Summary***

A systematic literature search from 1980 until June 2017 was performed. One systematic review [349], six RCTs [350-355], two narrative reviews [356, 357], one prospective cohort study [358], two prospective cross-sectional studies [359, 360], and one retrospective cohort study [352], were selected from 856 references.

A retrospective study [361], investigated the potential role of unusual pathogens in prostatitis syndrome in 1,442 patients over a four-year period. An infectious aetiology was determined in 74.2% of patients; *C. trachomatis*, *T. vaginalis* and *U. urealyticum* infections were found in 37.2%, 10.5% and 5% of patients, respectively whilst *E. coli* infection was found in only 6.6% of cases. Cross sectional studies confirmed the validity of the Meares and Stamey test to determine the bacterial strain and targeted antibiotic therapies [359, 360]. The evidence levels were good, in particular those regarding information on atypical strains, epidemiology and antibiotic treatments.

A systematic review on antimicrobial therapy for CBP [349] compared multiple antibiotic regimens from eighteen selected studies enrolling a total of 2,196 patients. The role of fluoroquinolones as first line agents was confirmed with no significant differences between levofloxacin, ciprofloxacin and prulifloxacin in terms of microbiological eradication, clinical efficacy and adverse events. The efficacy of macrolides and tetracyclines on atypical pathogens was confirmed.

Randomised controlled trials on combined treatments [354, 355] indicated that the combination of plants/herbal extracts or PDE5Is with antibiotics may improve quality of life and symptoms in patients with CBP; however, the number of enrolled patients was inadequate to obtain definitive conclusions.

A review of treatment of bacterial prostatitis [356] indicated that the treatment of CBP is hampered by the lack of an active antibiotic transport mechanism into infected prostate tissue and fluids. The review underlined the potential effect of different compounds in the treatment of ABP and CBP on the basis of over 40 studies on the topic.

One RCT compared the effects of two different metronidazole regimens for the treatment of CBP caused by *T. vaginalis* [353]. Metronidazole 500 mg three times daily for fourteen days was found to be efficient for micro-organism eradication in 93.3% of patients with clinical failure in 3.33% of cases. The evidence question addressed was: In men with NIDDK/NIH Category I or II prostatitis what is the best antimicrobial treatment strategy for clinical resolution and eradication of the causative pathogen?

*3.11.3 **Epidemiology, aetiology and pathogenesis***

Prostatitis is a common diagnosis, but less than 10% of cases have proven bacterial infection [228]. *Enterobacterales*, especially *E. coli*, are the predominant pathogens in ABP [362]. In CBP, the spectrum of species is wider and may include atypical micro-organisms [356]. In patients with immune deficiency or HIV infection, prostatitis may be caused by fastidious pathogens, such as *M. tuberculosis*, *Candida spp.* and other rare pathogens, such as *Coccidioides immitis*, *Blastomyces dermatitidis,* and *Histoplasma capsulatum* [363]. The significance of identified intracellular bacteria, such as *C. trachomatis,* is uncertain [364]; however, two studies have highlighted its possible role as a causative pathogen in CBP [365, 366].

*3.11.4 **Diagnostic evaluation***

3.11.4.1 History and symptoms

Acute bacterial prostatitis usually presents abruptly with voiding symptoms and distressing but poorly localised pain. It is often associated with malaise and fever. Transrectal prostate biopsy increases the risk of ABP despite antibiotic prophylaxis and antiseptic prevention procedures [350]. Chronic bacterial prostatitis is defined by symptoms that persist for at least three months [367-369]. The predominant symptoms are pain at various locations including the perineum, scrotum, penis and inner part of the leg as well as LUTS [346-348].

3.11.4.2 Symptom questionnaires

In CBP symptoms appear to have a strong basis for use as a classification parameter [370]. Prostatitis symptom questionnaires have therefore been developed to assess severity and response to therapy [370, 371]. They include the validated Chronic Prostatitis Symptom Index (CPSI); however, its usefulness in clinical practice is uncertain [358].

3.11.4.3 Clinical findings

In ABP, the prostate may be swollen and tender on DRE. Prostatic massage should be avoided as it can induce bacteraemia and sepsis. Urine dipstick testing for nitrite and leukocytes has a positive predictive value of 95% and a negative predictive value of 70% [372]. Blood culture and complete blood count are useful in ABP. Imaging studies can detect a suspected prostatic abscess [356].

In case of longer lasting symptoms CPPS as well as other urogenital and anorectal disorders must be taken into consideration. Symptoms of CBP or CPPS can mask prostate tuberculosis. Pyospermia and hematospermia in men in endemic regions or with a history of tuberculosis should trigger investigation for urogenital tuberculosis.

3.11.4.4 Urine cultures and expressed prostatic secretion

The most important investigation in the evaluation of a patient with ABP is mid-stream urine culture [356]. In CBP, quantitative bacteriological localisation cultures and microscopy of the segmented urine and expressed prostatic secretion (EPS), as described by Meares and Stamey [373], are still important investigations to categorise clinical prostatitis [359, 360]. Accurate microbiological analysis of samples from the Meares and Stamey test may also provide useful information on the presence of atypical pathogens such as *C. trachomatis, T. vaginalis* and *U. urealiticum* [361]. The two-glass test has been shown to offer similar diagnostic sensitivity to the four-glass test [374].

3.11.4.5 Prostate biopsy

Prostate biopsies cannot be recommended as routine work-up and are not advisable in patients with untreated bacterial prostatitis due to the increased risk of sepsis.

3.11.4.6 Other tests

Transrectal US may reveal endoprostatic abscesses, calcification in the prostate, and dilatation of the seminal vesicles; however, it is unreliable as a diagnostic tool for prostatitis [375].

3.11.4.7 Additional investigations

3.11.4.7.1 Ejaculate analysis

Performing an ejaculated semen culture improves the diagnostic utility of the four-glass test [359]; however, semen cultures are more often positive than EPS cultures in men with non-bacterial prostatitis [360]. Bladder outflow and urethral obstruction should always be considered and ruled out by uroflowmetry, retrograde urethrography, or endoscopy.

3.11.4.7.2 First-void urine sample

First-void urine is the preferred specimen for the diagnosis of urogenital C. trachomatis infection in men by NAATs, since it is non-invasive and yet allows the detection of infected epithelial cells and associated *C. trachomatis* particles [376].

3.11.4.7.3 Prostate specific antigen (PSA)

Prostate specific antigen is increased in about 60% and 20% of men with ABP and CBP, respectively [357]. The PSA level decreases after antibiotic therapy (which occurs in approximately 40% of patients) and correlates with clinical and microbiological improvement [351]. Measurement of free and total PSA adds no practical diagnostic information in prostatitis [377].

3.11.4.8 Summary of evidence and recommendations for the diagnosis of bacterial prostatitis

Summary of evidence	**LE**
Urine dipstick testing for nitrite and leukocytes has a positive predictive value of 95% and a negative predictive value of 70% in patients with ABP.	3
The four-glass Meares and Stamey test is the optimum test for diagnosis of CBP. The two-glass test has been shown to offer similar diagnostic sensitivity in a comparison study.	2b
First-void urine is the preferred specimen for the diagnosis of urogenital C. trachomatis infection in men by NAATs.	2b
Transrectal ultrasound is unreliable and cannot be used as a diagnostic tool in prostatitis.	3
Semen culture sensitivity is reported to be approximately 50%; therefore, it is not routinely part of the diagnostic assessment of CBP.	3
Prostate specific antigen levels may be elevated during active prostatitis; therefore, PSA testing should be avoided as it offers no practical diagnostic information for prostatitis.	3

Recommendations	**Strength rating**
Do not perform prostatic massage in acute bacterial prostatitis (ABP).	Strong
Take a mid-stream urine dipstick to check nitrite and leukocytes in patients with clinical suspicion of ABP.	Weak
Take a mid-stream urine culture in patients with ABP symptoms to guide diagnosis and tailor antibiotic treatment.	Weak
Take a blood culture and a total blood count in patients presenting with ABP.	Weak
Perform accurate microbiological evaluation for atypical pathogens such as Chlamydia *trachomatis* or Mycoplasmata in patients with chronic bacterial prostatitis (CBP).	Weak
Perform the Meares and Stamey 2- or 4-glass test in patients with CBP.	Strong
Perform transrectal ultrasound in selected cases to rule out the presence of prostatic abscess.	Weak
Do not routinely perform microbiological analysis of the ejaculate alone to diagnose CBP.	Weak

3.11.5 ***Disease management***

3.11.5.1 Antimicrobials

Antimicrobials are life-saving in ABP and recommended in CBP. Culture-guided antibiotic treatments are the optimum standard; however, empirical therapies should be considered in all patients with ABP.

In ABP parenteral administration of high doses of bactericidal antimicrobials, such as broad-spectrum penicillins, a third-generation cephalosporin or fluoroquinolones, is recommended [378]. For initial therapy, any of these antimicrobials may be combined with an aminoglycoside [362-371, 378-382]. Ancillary measures include adequate fluid intake and urine drainage [228]. After normalisation of infection parameters, oral therapy can be substituted and continued for a total of two to four weeks [383].

Fluoroquinolones, despite the high resistance rates of uropathogens, are recommended as first-line agents in the empirical treatment of CBP because of their favourable pharmacokinetic properties [384], their generally good safety profile and antibacterial activity against Gram-negative pathogens including *P. aeruginosa* and *C. trachomatis* [349, 385]. However, increasing bacterial resistance is a concern. Azithromycin and doxycycline are active against atypical pathogens such as *C. trachomatis* and genital mycoplasmata [352, 361]. Levofloxacin did not demonstrate significant clearance of *C. trachomatis* in patients with CBP [386]. Metronidazole treatment is indicated in patients with *T. vaginalis* infections [353].

Duration of fluoroquinolone treatment must be at least fourteen days while azithromycin and doxycycline treatments should be extended to at least three to four weeks [352, 361]. In CBP antimicrobials should be given for four to six weeks after initial diagnosis [356]. If intracellular bacteria have been detected macrolides or tetracyclines should be given [349, 384, 387].

3.11.5.2 Intraprostatic injection of antimicrobials

This treatment has not been evaluated in controlled trials and should not be considered [388, 389].

3.11.5.3 Combined treatments

A combination of fluoroquinolones with various herbal extracts may attenuate clinical symptoms without increasing the rate of adverse events [354]. However, a combination of fluoroquinolones with vardenafil did not improve microbiological eradication rates or attenuated pain or voiding symptoms in comparison with fluoroquinolone treatment alone [355].

3.11.5.4 Drainage and surgery

Approximately 10% of men with ABP will experience urinary retention [390] which can be managed by urethral or suprapubic catheterisation. However, recent evidence suggests that suprapubic catheterisation can reduce the risk of development of CBP [391].

In case of prostatic abscess, both drainage and conservative treatment strategies appear feasible [392]; however, the abscess size may matter. In one study, conservative treatment was successful if the abscess cavities were < 1 cm in diameter, while larger abscesses were better treated by single aspiration or continuous drainage [393].

3.11.5.5 Summary of evidence and recommendations for the disease management of bacterial prostatitis

Summary of evidence	**LE**
The treatment regimen for ABP is based on clinical experience and a number of uncontrolled clinical studies. For systemically ill patients with ABP, parenteral antibiotic therapy is preferable. After normalisation of infection parameters, oral therapy can be substituted and continued for a total of two to four weeks.	3
The role of fluoroquinolones as first-line agents for antimicrobial therapy for CBP was confirmed in a systematic review, with no significant differences between levofloxacin, ciprofloxacin and prulifloxacin in terms of microbiological eradication, clinical efficacy and adverse events.	1a
Metronidazole 500 mg three times daily for fourteen days was found to be efficient for eradication in 93.3% of patients with T. vaginalis CBP.	1b
In patients with CBP caused by obligate intracellular pathogens, macrolides showed higher microbiological and clinical cure rates compared to fluoroquinolones.	1a
Clinicians should consider local drug-resistance patterns when choosing antibiotics.	3

Recommendations	Strength rating
Acute bacterial prostatitis	
Treat acute bacterial prostatitis according to the recommendations for complicated UTIs (see section 3.7.5).	Strong
Chronic bacterial prostatitis (CBP)	
Prescribe a fluoroquinolone (e.g. ciprofloxacin, levofloxacin) as first-line treatment for CBP.	Strong
Prescribe a macrolide (e.g. azithromycin) or a tetracycline (e.g. doxycycline) if intracellular bacteria have been identified as the causative agent of CBP.	Strong
Prescribe metronidazole in patients with T. vaginalis CBP.	Strong

Table 10: Suggested regimens for antimicrobial therapy for chronic bacterial prostatitis

Antimicrobial	Daily dose	Duration of therapy	Comments
Fluoroquinolone	Optimal oral daily dose	4-6 weeks	
Doxycycline	100 mg b.i.d	10 days	Only for *C. trachomatis* or mycoplasma infections
Azithromycin	500 mg once daily	3 weeks	Only for *C. trachomatis* infections
Metronidazole	500 mg t.i.d.	14 days	Only for *T. vaginalis* infections

b.i.d = twice daily; t.i.d = three times daily.

*3.11.6 **Follow-up***

In asymptomatic post-treatment patients routine urinalysis and/or urine culture is not mandatory as there are no validated tests of cure for bacterial prostatitis except for cessation of symptoms [356]. In patients with persistent symptoms and repeated positive microbiological results for sexually transmitted infectious pathogens, microbiological screening of the patient's partner/s is recommended. Antibiotic treatments may be repeated with a more prolonged course, higher dosage and/or different compounds [356].

3.12 Acute Infective Epididymitis

*3.12.1 **Epidemiology, Aetiology and Pathophysiology***

Epididymitis is a common condition with incidence ranging from 25 to 65 cases per 10,000 adult males per year and can be acute, chronic or recurrent [394]. Acute epididymitis is clinically characterised by pain, swelling and increased temperature of the epididymis, which may involve the testis and scrotal skin. It is generally caused by migration of pathogens from the urethra or bladder that can be identified by appropriate diagnostics in up to 90% of patients [395]. Torsion of the spermatic cord (testicular torsion) is the most important differential diagnosis in boys and young men.

The predominant pathogens isolated are *Enterobacterales* (typically *E. coli*), *C. trachomatis* and *N. gonorrhoeae* [396]. Men who have anal intercourse and those with abnormalities of the urinary tract resulting in bacteriuria are at higher risk of epididymitis caused by *Enterobacterales* [397]. The mumps virus should be considered if there are viral prodromal symptoms and salivary gland enlargement. Tuberculous epididymitis may occur, typically as chronic epididymitis, in high-risk groups such as men with immunodeficiency and those from high prevalence countries, it frequently results in a discharging scrotal sinus. *Brucella* or *Candida spp.* are rare possible pathogens.

*3.12.2 **Diagnostic Evaluation***

Culture of a mid-stream specimen of urine should be performed and any previous urine culture results should be checked. Sexually transmitted infections including *C. trachomatis* or *N. gonorrhoeae* should be detected by NAAT on first voided urine or urethral swab. A urethral swab or smear should be performed for Gram staining and culture of *N. gonorrhoeae,* when available [394, 398, 399]. Detection of these pathogens should be reported according to local procedures. All patients with probable sexually transmitted infections (STIs) should be advised to attend an appropriate clinic to be screened for other STIs. Men with *Enterobacterales* may require investigation for lower urinary tract abnormalities. If tuberculous epididymitis is suspected, three sequential early morning urine samples should be cultured for acid-fast bacilli (AFB) and sent for screening by NAAT for *M. tuberculosis* DNA [400]. If appropriate prostate secretion, ejaculate, discharge from a draining scrotal fistula, as well as fine needle aspiration and biopsy specimens should be investigated using microscopy, AFB culture and NAAT. Scrotal ultrasound is more accurate for the diagnose of acute epididymitis than urinalysis alone [401] and may also be beneficial for the exclusion of other pathologies [402].

3.12.3 ***Disease Management***

Men with suspected STI should be informed of the risks to others and advised not to have sex until free of infection. Empirical antimicrobial therapy has to be chosen with consideration of the most probable pathogen and degree of penetration into the inflamed epididymis and may need to be varied according to local pathogen sensitivities and guidance. Generally, both *C. trachomatis* and *Enterobacterales* should be covered initially and the regimen modified according to pathogen identification. Doxycycline and some specific fluoroquinolones have good clinical and microbiological cure rates in patients with suspected *C. trachomatis* or *M. genitalium* and both achieve adequate levels in inflamed male genital tissues with oral dosing. Macrolide antibiotics such as azithromycin are effective against *C. trachomatis* but have not been tested in epididymitis; however, initial pharmacokinetic studies suggest that azithromycin may effectively penetrate epididymal tissue when given in multiple doses [403]. Fluoroquinolones remain effective for oral treatment of *Enterobacterales* although resistance is increasing and local advice should be sought. Fluoroquinolones should not be considered for gonorrhoea. Single high parenteral dose of a third-generation cephalosporin is effective against *N. gonorrhoeae;* current resistance patterns and local public health recommendations should guide choice of agent.

Clinical response to antibiotics in men with severe epididymitis should be assessed after approximately three days. Men with likely or proven STI should be assessed at fourteen days to check cure and ensure tracing and treatment of contacts according to local public health recommendations.

3.12.4 ***Evidence Summary***

Relating to this chapter, four guidelines based on systematic reviews were identified [306, 398, 404, 405]. No evidence quality assessments were detailed. A high quality RCT demonstrated that a ten-day course of ciprofloxacin was superior to pivampicillin for clinical cure (80% vs. 60%) in men aged > 40 years [406]. Data from a large comparative case series suggested that young age and history of sexual activity are not sufficiently predictive of a sexually transmitted pathogen to guide antibiotic treatment in acute epididymitis [395].

Empiric antibiotic regimens from existing guidelines [306, 398, 404, 405] and panel consensus:

1. For men with acute epididymitis at low risk of gonorrhoea (e.g. no discharge) a single agent or combination of two agents of sufficient dose and duration to eradicate *C. trachomatis* and *Enterobacterales* should be used. Appropriate options are:

    A. A fluoroquinolone active against *C. trachomatis* orally once daily for ten to fourteen days*

    OR

    B. Doxycycline 200 mg initial dose by mouth and then 100 mg twice daily for ten to fourteen days* **plus** an antibiotic active against *Enterobacterales*** for ten to fourteen days*

2. For men with likely gonorrhoeal acute epididymitis a combination regimen active against Gonococcus and *C. trachomatis* must be used such as:

    A. Ceftriaxone 1000 mg intramuscularly single dose **plus** doxycycline 200 mg initial dose by mouth and then 100 mg twice daily for ten to fourteen days*

3. For non-sexually active men with acute epididymitis a single agent of sufficient dose and duration to eradicate *Enterobacterales* should be used. Appropriate option is a fluoroquinolone by mouth once daily for ten to fourteen days*

**Depending upon pathogen identification and clinical response.*
*** A parenteral option will be required for men with severe infection requiring hospitalisation.*

Surgical exploration may be required to drain abscesses or debride tissue. A comparative cohort study found that lack of separation of epididymis and testis on palpation and the presence of abscess on US may predict requirement for surgery following initial antibiotic treatment [407].

A cohort study found semen parameters may be impaired during epididymitis but recovered following successful treatment [408]. Comparative clinician cohort studies suggest adherence to guidelines for assessment and treatment of epididymitis is low, particularly by urologists compared to sexual health specialists [409] and by primary care physicians [410].

3.12.5 ***Screening***

A large cohort screening study for carriage of C. trachomatis including a randomly selected group of 5,000 men of whom 1,033 were tested showed no benefit in terms of reduction in risk of epididymitis over nine years of observation [411].

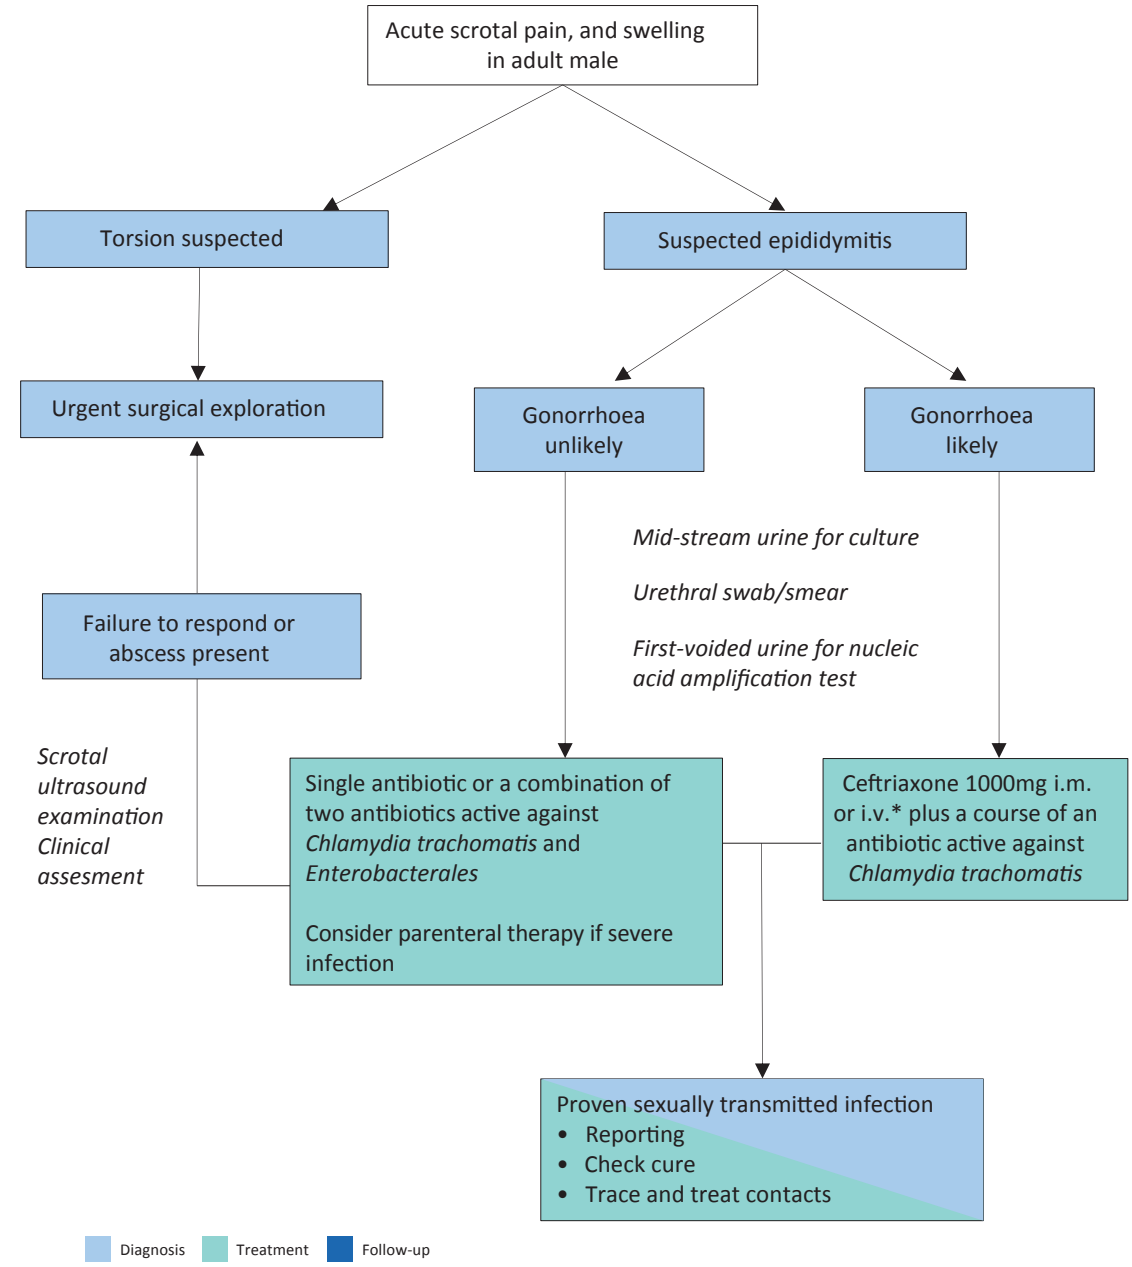
3.12.6 *Summary of evidence and recommendations for the diagnosis and treatment of acute infective epididymitis*

Summary of evidence	LE
In young sexually active patients both STIs and Enterobacterales have to be considered as aetiological agents.	3
In patients > 40 years antibiotic therapy with ciprofloxacin is superior to pivmecillinam.	1b
A negative sexual risk history does not exclude STIs in sexually active men.	3

Recommendations	Strength rating
Obtain a mid-stream urine and a first voided urine for pathogen identification by culture and nucleic acid amplification test.	Strong
Initially prescribe a single antibiotic or a combination of two antibiotics active against Chlamydia trachomatis and Enterobacterales in young sexually active men; in older men without sexual risk factors only Enterobacterales have to be considered.	Strong
If gonorrhoeal infection is likely give single dose ceftriaxone 1000 mg intramuscularly or intravenously* in addition to a course of an antibiotic active against Chlamydia trachomatis.	Strong
Adjust antibiotic agent when pathogen has been identified and adjust duration according to clinical response.	Weak
Follow national policies on reporting and tracing/treatment of contacts for sexually transmitted infections.	Strong

**Despite the lack of RCTs there is increasing evidence that intravenous treatment with ceftriaxone is safe and effective for the treatment of gonorrhoeal infections and avoids the discomfort of an intramuscular injection for patients [345].*

Figure 2: Diagnostic and treatment algorithm for men with acute epididymitis



i.m. = intramuscular; i.v. intravenously.
** Despite the lack of RCTs there is increasing evidence that intravenous treatment with ceftriaxone is safe and effective for the treatment of gonorrhoeal infections and avoids the discomfort of an intramuscular injection for patients [345].*

3.13 Fournier's Gangrene (Necrotising fasciitis of the perineum and external genitalia)

3.13.1 Epidemiology, Aetiology and Pathophysiology

Fournier's gangrene is an aggressive and frequently fatal polymicrobial soft tissue infection of the perineum, peri-anal region, and external genitalia [412]. It is an anatomical sub-category of necrotising fasciitis with which it shares a common aetiology and management pathway.

3.13.2 Diagnostic Evaluation

Typically, there is painful swelling of the scrotum or perineum with sepsis [412]. Examination shows small necrotic areas of skin with surrounding erythema and oedema. Crepitus on palpation and a foul-smelling exudate occurs with more advanced disease. Patient risk factors for occurrence and mortality include being immunocompromised, most commonly diabetes or malnutrition, recent urethral or perineal surgery, and high body mass index (BMI). In up to 40% of cases, the onset is more insidious with undiagnosed pain often resulting in delayed treatment [413]. A high index of suspicion and careful examination, particularly of obese patients, is required. Computed tomography or MRI can help define para-rectal involvement, suggesting the need for bowel diversion [412].

3.13.3 Disease Management

The degree of internal necrosis is usually vastly greater than suggested by external signs, and consequently, adequate, repeated surgical debridement with urinary diversion by suprapubic catheter is necessary to reduce mortality [412]. Consensus from case series suggests that surgical debridement should be early (< 24 hours) and complete, as delayed and/or inadequate surgery may result in higher mortality [412]. Immediate empiric parenteral antibiotic treatment should be given that covers all probable causative organisms and can penetrate inflammatory tissue. A suggested regime would comprise a broad-spectrum penicillin or third-generation cephalosporin, gentamicin and metronidazole or clindamycin [412]. This can then be refined, guided by microbiological culture.

3.13.4 Evidence Summary

A systematic literature search from 1980 to July 2017 was performed. From 640 references one RCT [414], two systematic reviews [415, 416], one narrative review [412], three registry studies [417-419], one prospective cohort study [420] and two retrospective comparative cohort studies with at least 25 patients [421, 422] were selected. The three registry studies from the United States [417-419], found mortality rates of 10%, 7.5% and 5% from 650, 1,641 and 9,249 cases, respectively. Older age, diabetes and high BMI were associated with higher risk. A prospective cohort study showed that disease-specific severity scores did predict outcome, but were not superior to generic scoring systems for critical care [420]. The evidence questions addressed were:

1. What is the best antimicrobial treatment strategy to reduce mortality?
2. What is the best debridement and reconstruction strategy to reduce mortality and aid recovery?
3. Are there any effective adjuvant treatments that improve outcome?

Concerning the evidence questions:

A. A low-quality retrospective case series [421] with 168 patients found no significant difference in mortality between patients given ≤ 10 days of parenteral antibiotics (80 patients) and those given > 10 days (88 patients).

B. A systematic review of wound closure techniques [416] found low-quality evidence from 16 case series involving 425 male patients. They recommended primary or secondary wound closure for scrotal defects ≤ 50% with the use of flaps or skin grafts for defects involving > 50% of the scrotum or with extension outside the scrotum.

C. A systematic review on the use of hyperbaric oxygen therapy [415] included three comparative case series and four other case series. All were retrospective and published prior to 2000. No consistent evidence of benefit was found; an RCT was advised. A more recent comparative case series [422] suggested benefit for use of hyperbaric oxygen therapy in 16 patients compared to 12 cases without use of such therapy in terms of reduced mortality and fewer debridements (low quality evidence). A low-quality RCT [414] with 30 patients found that use of honey-soaked dressings resulted in a shorter hospital stay (28 vs. 32 days) than dressing soaked with Edinburgh solution of lime (EUSOL). We found no evidence of benefit for use of negative-pressure (vacuum) wound therapy in Fournier's gangrene.

3.13.5 *Summary of evidence and recommendations for the disease management of Fournier's Gangrene*

Summary of evidence	LE
Immediate empiric parenteral antibiotic treatment should be given that covers all probable causative organisms and can penetrate inflammatory tissue.	3
A systematic review of wound closure techniques recommended primary or secondary wound closure for scrotal defects ≤ 50% with the use of flaps or skin grafts for defects involving > 50% of the scrotum or with extension outside the scrotum.	3
No consistent evidence of benefit for hyperbaric oxygen therapy was found.	3
A low quality RCT found that dressings soaked in honey resulted in a shorter hospital stay than dressing soaked with EUSOL.	3
No evidence of benefit for use of negative-pressure (vacuum) wound therapy in Fournier's gangrene was found.	4

Recommendations	Strength rating
Start treatment for Fournier's gangrene with broad-spectrum antibiotics on presentation, with subsequent refinement according to culture and clinical response.	Strong
Commence repeated surgical debridement for Fournier's gangrene within 24 hours of presentation.	Strong
Do not use adjunctive treatments for Fournier's gangrene except in the context of clinical trials.	Weak

Table 11: Suggested regimens for antimicrobial therapy for Fournier's Gangrene of mixed microbiological aetiology adapted from [423].

Antimicrobial	Dosage
Piperacillin-tazobactam plus Vancomycin	4.5 g every 6-8 h IV 15 mg/kg every 12 h
Imipenem-cilastatin	1 g every 6-8 h IV
Meropenem	1 g every 8 h IV
Ertapenem	1 g once daily
Gentamicin	5 mg/kg daily
Cefotaxime plus metronidazole or clindamycin	2 g every 6 h IV 500 mg every 6 h IV 600-900 mg every 8 h IV
Cefotaxime plus fosfomycin plus metronidazole	2 g every 6 h IV 5 g every 8 h IV 500 mg every 6 h IV

IV = intravenous.

3.14 Management of Human papillomavirus in men

3.14.1 *Epidemiology*

Human papilloma virus (HPV) is one of the most frequently sexually transmitted viruses encompassing both oncogenic (low- and high-risk variants) and non-oncogenic viruses. HPV 16 is the most common oncogenic variant, detected in 20% of all HPV cases [424]. A recent meta-analysis revealed a prevalence of 49% of any type of HPV and 35% of high-risk HPV in men [425]. Similar to the female genital tract, half of all HPV infections in the male genital tract are co-infections (≥ 2 HPV strains) [426].

HPV presence is dependent on study setting. In men attending urological clinics HPV was detected in 6% of urine samples [427]. A meta-analysis reported seminal HPV in 4.5-15.2% of patients resulting in seminal HPV being associated with decreased male fertility [424]. A cross sectional study of 430 men presenting for fertility treatment detected HPV in 14.9% of semen samples [428]. The presence of HPV in semen was not associated with impaired semen quality [428]. However, another systematic review reported a possible association between

HPV and altered semen parameters, and in women possible miscarriage or premature rupture of the membrane during pregnancy [429]. HPV6 and/or 11 were the most common genotypes detected in an observational study of anogenital warts, whilst HPV16 is correlated with severity of anal cytology [430]. The incidence of non-oncogenic HPV infection has been shown to be higher in men than women [431]. In males, approximately 33% of penile cancers and up to 90% of anal cancers are attributed to high-risk HPV infections, primarily with HPV16 [432]. The EAU Penial Cancer Guidelines will publish a comprehensive update in March 2022 including the results of two systematic reviews on HPV and penile cancer. Oral HPV is associated with oropharyngeal carcinomas approximately 22.4%, 4.4% and 3.5% of oral cavity, oropharynx and larynx cancers, respectively are attributed to HPV [432]. Systematic reviews have reported prevalence rates of oral HPV from 5.5-7.7%, with HPV16 present in 1-1.4% of patients [433, 434].

*3.14.2 **Risk factors***

Risk factors for HPV infection include early age of first sexual intercourse, sexual promiscuity, higher frequency of sexual intercourse, smoking and poor immune function [435-439]. Incidence and prevalence of overall HPV was considerably higher in MSM compared to heterosexuals [433, 436]. Overall, the prevalence of HPV in different sites seems to be higher in young, sexual-active adults compared to other population groups [435]. Stable sexual habits, circumcision and condom use are protective factors against HPV [425, 439-443]. Added risk factors of oral HPV infection are alcohol consumption, poor oral hygiene and sexual behaviours (oral and vaginal) [433, 435]. Positive HIV status, phimosis, and HPV status of the partner have also been associated with anogenital HPV status and decreased clearance in a number of studies [440].

*3.14.3 **Transmission***

HPV typically spreads by sustained direct skin-to-skin or mucosal contact, with vaginal, oral and anal sex being the most common transmission route [437]. In addition, HPV has been found on surfaces in medical settings and public environments raising the possibility of object-to-skin/mucosa transmission [444]. Further studies on non-sexual and non-penetrative sexual transmission are needed to understand the complexity of HPV transmission. HPV transmission may also be influenced by genotype, with a higher incidence of HPV51 and HPV52 and a high prevalence of HPV16 and HPV18 in the general and high-risk male population [437].

*3.14.4 **Clearance***

HPV time-to-clearance ranges from 1.3 to 42.1 months [445]. Clearance may be influenced by HPV genotype, patients' characteristics and affected body site [436, 440, 445]. HPV 16 has the highest incidence of high-risk HPV variants and has the lowest clearance across sites [440].

*3.14.5 **Diagnosis***

There is currently no approved test for HPV in men. Routine testing to check for HPV or HPV-related disease in men is not recommended. A physical examination to identify HPV lesions should be carried out. An acetic acid test to diagnose sub-clinical HPV lesions may be performed. If the diagnosis is uncertain or there is a suspicion of cancer a biopsy should be carried out. Intra-urethral condylomas are relatively uncommon and are usually limited to the distal urethral meatus [446, 447]. Urethrocystoscopy may be used to diagnose the presence of intra-urethral or bladder warts [447]; however, there is no high-level evidence for the use of invasive diagnostic tools for localisation of intra-urethral HPV. For detailed recommendations on the diagnosis of anogenital warts please refer to the IUSTI-European guideline for the management of anogenital warts [448].

*3.14.6 **Treatment of HPV related diseases***

Approximately 90% of HPV infections do not cause any problems and are cleared by the body within 2 years. However, treatment is required when HPV infection manifests as anogenital warts to prevent the transmission of HPV-associated anogenital infection and to minimise the discomfort caused to patients [448]. Of the treatment options available only surgical treatment has a primary clearance rate approaching 100%.

3.14.6.1 Treatments suitable for self-application

Patient-applied treatments include podophyllotoxin, salicylic acid, imiquimod, polyphenon E, 5-fluoracil and potassium hydroxide [448]. Imiquimod 5% cream showed a total clearance of external genital or perianal warts in 50% of immunocompetent patients [449] as well as in HIV positive patients successfully treated with highly active antiretroviral therapy [450]. A Cochrane review of published RCTs found imiquimod to be superior to placebo in achieving complete clearance of warts (RR: 4.03, 95% CI: 2.03–7.99) [451]. The recommended treatment schedule is imiquimod 5% cream applied to all external warts overnight 3 times each week for 16 weeks [448]. In an RCT involving 502 patients with genital and/or perianal warts sinecatechins 15% and 10% showed a complete clearance of all baseline and newly occurring warts in 57.2% and 56.3% of patients, respectively vs. 33.7% for placebo [452]. In addition, sinecatechins 10% has been shown to be associated with lower short-term recurrence rates when used as sequential therapy after laser CO2 ablative therapy [453].

Sinecatechins is applied three times daily until complete clearance, or for up to 16 weeks. Clearance rates of 36–83% for podophyllotoxin solution and 43–70% for podophyllotoxin cream have been reported [448]. A systematic review and meta-analysis confirmed the effectiveness of podophyllotoxin 0.5% solution relative to placebo (RR: 19.86, 95% CI: 3.88–101.65) [454]. Podophyllotoxin is self-applied to lesions twice daily for 3 days, followed by four rest days, for up to 4 or 5 weeks. An RCT has also shown potassium hydroxide 5% to be an effective, safe, and low-cost treatment modality for genital warts in men [455].

3.14.6.2 Physician-administered treatment

3.14.6.2 Physician-administered treatment

Physician-administered treatments included cryotherapy (79-88% clearance rate; 25-39% recurrence rate), surgical treatment (61-94% clearance rate), including excision, electrosurgery, electrocautery and laser therapy (75% clearance rate) [456, 457]. Physician-administered therapies are associated with close to 100% clearance rates, but they are also associated with high rates of recurrence as they often fail to eliminate invisible HPV-infected lesions [456, 457]. No data about the superiority of one treatment over another are available. However, among all interventions evaluated in a recent systematic review and network meta-analysis, surgical excision appeared to be the most effective treatment at minimising risk of recurrence [458].

3.14.6.3 Summary of evidence and recommendations for the treatment of anogenital warts

Summary of evidence	**LE**
A Cochrane review of published RCTs found imiquimod to be superior to placebo in achieving complete clearance of warts.	1b
In an RCT sinecatechins 15% and 10% showed a complete clearance of all baseline and newly occurring warts in 57.2% and 56.3% of patients, respectively vs. 33.7% for placebo	1b
A systematic review and meta-analysis confirmed the effectiveness of podophyllotoxin 0.5% solution relative to placebo	1b
A systematic review and meta-analysis reported that among all physician-applied therapy, surgical excision seemed to be the most effective at minimising risk of recurrence.	1a

Recommendations	**Strength rating**
Use self-administered imiquimod 5% cream applied to all external warts overnight 3 times each week for 16 weeks for the treatment of anogenital warts.	Strong
Use self-administered sinecatechins 15% or 10% applied to all external warts three times daily until complete clearance, or for up to 16 weeks for the treatment of anogenital warts.	Strong
Use self-administered podophyllotoxin 0.5% self-applied to lesions twice daily for 3 days, followed by four rest days, for up to 4 or 5 weeks for the treatment of anogenital warts.	Strong
Use cryotherapy or surgical treatment (excision, electrosurgery, electrocautery and laser therapy) to treat anogenital warts based on an informed discussion with the patient.	Strong

*3.14.7 **Circumcision for reduction of HPV prevalence***

Male circumcision is a simple surgical procedure which has been shown to reduce the incidence of sexually transmitted infections including HIV, syphilis and HSV-2 [459]. Two systematic reviews and meta-analyses, showed an inverse association between male circumcision and genital HPV prevalence in men [443, 445]. It has been suggested that male circumcision could be considered as an additional one-time preventative intervention likely to reduce the burden of HPV-related diseases in both men and women, particularly among those countries in which HPV vaccination programs and cervical screening are not available [445].

Summary of evidence	**LE**
Two systematic reviews and meta-analyses, showed an inverse association between male circumcision and genital HPV prevalence in men	1a

Recommendation	Strength rating
Discuss male circumcision with patients as an additional one-time preventative intervention for HPV-related diseases.	Strong

*3.14.8 **Therapeutic vaccination***

Three different vaccines against HPV have been licensed to date, but routine vaccination of males is currently implemented in only a few countries including Australia, Canada, the USA and Austria16. The aim of male vaccination is to reduce the rate of anal and penile cancers as well as head and neck cancers [432, 460].

A systematic review including a total of 5,294 patients reported vaccine efficacy against persisting (at least six months) anogenital HPV16 infections of 46.9% (28.6-60.8%) and against persisting oral infections of 88% (2–98%). A vaccine efficacy of 61.9% (21.4–82.8%) and 46.8% (20-77.9%) was observed against anal intraepithelial neoplasia grade 2 and 3 lesions, respectively [432]. The systematic review reported no meaningful estimates on vaccine efficacy against penile intraepithelial neoplasia grade 2 or 3, and no data were identified for anal, penile or head and neck squamous cell cancers [432].

A phase III clinical trial including 180 male patients evaluated the potential of MVA E2 recombinant vaccinia virus to treat intraepithelial lesions associated with papillomavirus infection [461]. the study showed promising results in terms of immune system stimulation against HPV lesions as well as regression in intraepithelial lesions.

Summary of evidence	LE
The role of therapeutic HPV vaccination in males in terms of effectiveness and safety is limited by the small number of relevant studies.	2
Therapeutic HPV vaccination in males is moderately effective against persistent anogenital HPV16 infection [(46.9% (28.6-60.8%)] and high-grade anal intraepithelial lesions [grade 2: 61.9% (21.4–82.8%); grade 3: 46.8% (20-77.9%)].	1b

Recommendation	Strength rating
Offer HPV vaccine to males after surgical removal of high-grade anal intraepithelial neoplasia.	Weak

*3.14.9 **Prophylactic vaccination***

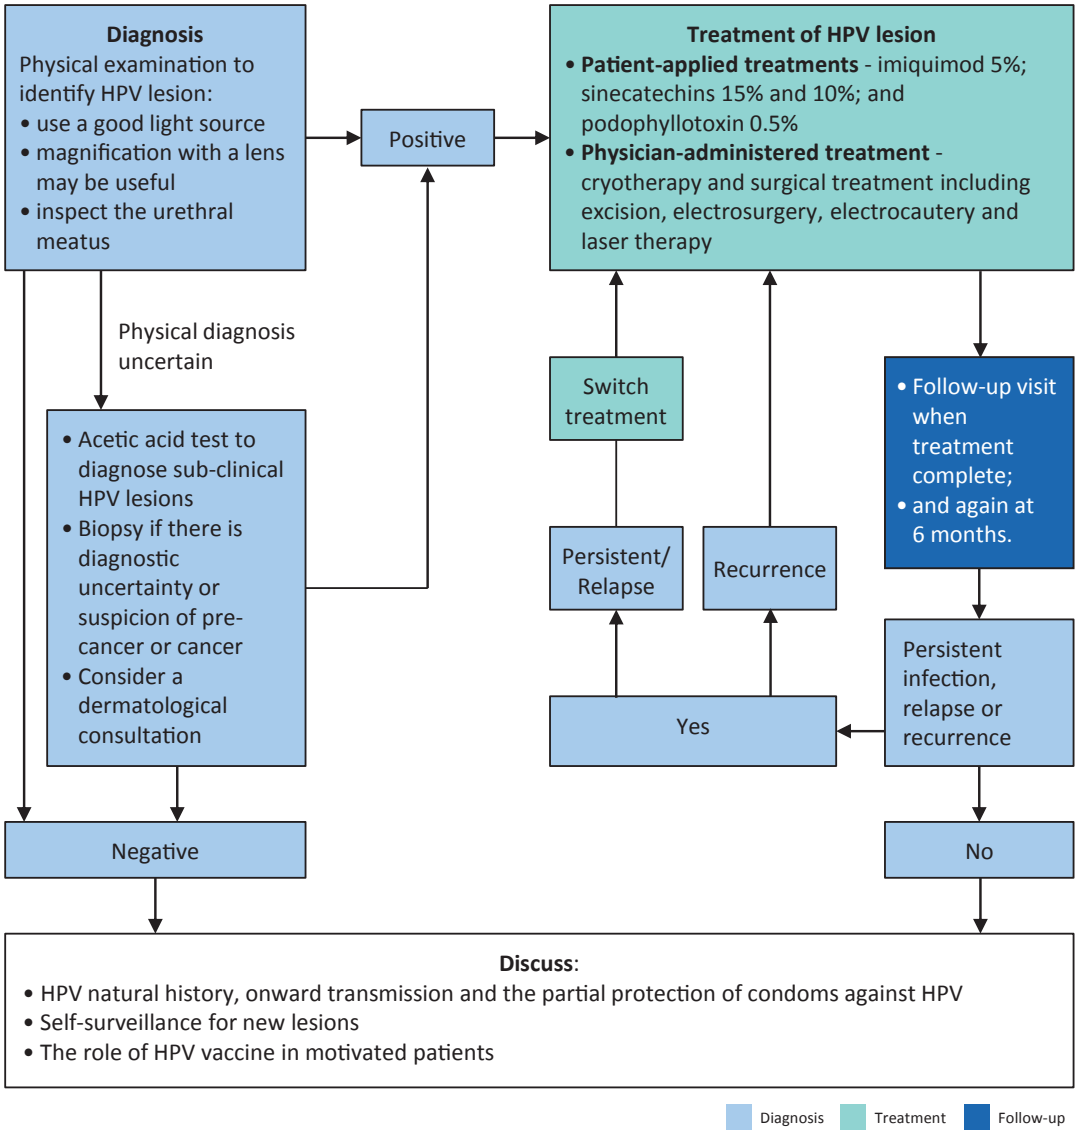
A systematic review and meta-analysis reported that vaccination is moderately effective against genital HPV-related diseases irrespective of an individual's HPV status; however, higher vaccine efficacy was observed in HPV-naïve males [432]. Supporting the early vaccination of boys with the goal of establishing optimal vaccine-induced protection before the onset of sexual activity [432]. An RCT including 1,124 demonstrated high efficacy of the quadrivalent HPV vaccine vs. placebo against HPV6/11/16/18-related persistent infections [462]. Furthermore, the vaccine elicited a robust immune response and was well tolerated with mild vaccination-related adverse events e.g. injection-site pain and swelling [462]. In addition, a Cochrane review, demonstrated that the quadrivalent HPV vaccine appears to be effective in the prevention of external genital lesions and genital warts in males [463].

Despite the fact quadrivalent HPV vaccines were approved for use in young adult males in 2010 vaccination rates have remained low at 10-15% [464]. Barriers to uptake in this patient group include lack of awareness about HPV vaccines and HPV-related diseases, concerns about vaccine safety and efficacy, economic/cost issues related to vaccine uptake, underestimation of HPV infection risks and sexual activity [464]. Health care professionals should provide easily understood and accessible communication resources regarding these issues, in order to educate young adult males and their families on the importance of HPV vaccination to reduce the incidence of certain cancers in the later life [464, 465].

Summary of evidence	LE
HPV vaccine is effective in the prevention of external genital lesions and genital warts in males.	1a
HPV vaccination is moderately effective against genital HPV-related diseases irrespective of a individual's HPV status; however, higher vaccine efficacy was observed in HPV-naïve males.	1a
A systematic review of HPV vaccination barriers among adolescent and young adult males identified a number of barriers to vaccine uptake including fear of side-effects, limited HPV awareness, financial costs and changes in sexual activity.	1b
An intervention study to evaluate whether electronic messaging can increase human papillomavirus vaccine completion and knowledge among college students concluded that intervention increased knowledge but not vaccine completion.	2b

Recommendations	Strength rating
Offer early HPV vaccination to boys with the goal of establishing optimal vaccine-induced protection before the onset of sexual activity.	Strong
Apply diverse communication strategies in order to improve HPV vaccination knowledge in young adult males.	Strong

Figure 3: Diagnostic and treatment algorithm for the management of HPV in men



3.15 Genitourinary Tuberculosis

*3.15.1 **Epidemiology, Aetiology and Pathophysiology***

An estimated 246,000 new and relapse tuberculosis (TB) cases occurred in the WHO European Region in 2019, with 49,752 of these cases occurring within the 31 countries comprising the European Union (EU)/European Economic Area (EEA) region [466]. An estimated 12.0% of incident TB cases in 2019 were co-infected with HIV. Extrapulmonary TB was notified on average for 16.6% of all incident TB cases in the Region. Eleven countries reported more than 30% of their TB cases having extrapulmonary localisation. The proportion of TB that is extrapulmonary is significantly greater among migrants than non-migrants. Genitourinary tuberculosis (GUTB) accounted for 4.6% of extrapulmonary TB cases in the EU between 1997-2017 [467]. Tuberculosis is an infectious disease caused by a group of *Mycobacterium* species called the *Mycobacterium tuberculosis* complex (MBTC) [468]. Genitourinary TB can affect all genitourinary organs and is almost always secondary due to the hematogenous spread of chronic latent TB infection (LTBI) [469]. Risk factors include primary and LTBI, diabetes, old age, low BMI, oncological comorbidities, immune suppression (including HIV), renal failure and poor socioeconomic living conditions. The risk of reactivation is estimated to be up to 15% during one's lifetime [470]. The WHO recommend either a tuberculin skin test (TST) or interferon-gamma release assay (IGRA) for the diagnosis LTBI [471].

*3.15.2 **Diagnosis***

The diagnosis of GUTB is challenging as no single diagnostic test exists. Diagnosis relies on a high suspicion of infection based on patient history; microbiological, molecular and histological testing; and imaging findings. Patients generally present with non-specific urological complaints for which no obvious cause is identified including haematuria, increased urinary frequency, difficulty voiding, abdominal, lumbar and suprapubic pain, and in female patients menstrual irregularities and pelvic pain. Patients may also present for infertility issues; however, infertility and TB will not be addressed in detail in this text.

3.15.2.1 Smear Microscopy

Smear microscopy is a simple and cost-effective way of detecting the presence of acid-fast bacilli (AFB) in urine samples, semen, tissue specimens, pus, or discharged or prostatic massage fluid, through microscopic examination using Ziehl–Neelsen or auramine staining [472, 473]. A major limitation of smear microscopy is its low sensitivity (ranging from 0-25%) in urine [474, 475].

3.15.2.2 Culture

The culture-based method (both solid and liquid media) for biological specimens is the reference standard for *M. tuberculosis* isolation from biological samples. Three midstream first-void urine samples, on consecutive days, are recommended for TB culture [473]. A disadvantage of culture-based methods is the long incubation period needed for results at least 9–10 days for positive results and 6 weeks to be considered negative as well as the need for highly equipped laboratories. In addition, studies have reported high specificities of 92–100% but low sensitivities 23.3–30% for urine culture in renal TB specimens [476, 477].

3.15.2.3 Nucleic Acid Amplification Tests

In recent years, nucleic acid amplification tests (NAATs) have been introduced in the diagnostic pathway of TB, to overcome the limits of early and rapid diagnosis and of drug susceptibility testing. In 2021 the WHO issued an update to its guidelines for the rapid diagnosis of TB in which they made a conditional recommendation that in patients with signs and symptoms of extrapulmonary TB, Xpert MTB/RIF may be used as an the initial diagnostic test [478]. Xpert MTB/RIF pooled sensitivity and specificity were 84.7% (70.8 to 93.1) and 97.3% (91.0 to 99.2) for the diagnosis of genitourinary TB [479]. The 2021 WHO guidelines also contain a number a recommendations for additional PCR testing systems as well as moderate complexity automated NAATs [478].

Note: A number of other diagnostic tests are currently under investigation by the WHO but cannot be recommended for the diagnosis of GUTB at this time.

3.15.2.4 Imaging

Imaging modalities aid in the localisation of the foci of infection in GUTB and in the assessment of the extent of the damage to the genito-urinary system. Imaging techniques for the diagnosis of GUTB have a sensitivity of approx. 90% [480]. However, the quality of the evidence available for diagnostic imaging of TB is low to very-low and further studies are required to allow the Panel to make recommendations on this topic.

Ultrasound is a cost-effective and non-invasive imaging modality that has been shown to be effective for the diagnosis of testicular, epididymal and vas deferens TB [481-485]. Ultrasound examination may also allow for the identification of parenchymal masses, cavities, mucosal thickening of the collecting system and bladder, stenosis and consecutive obstruction of the collecting system, vesicoureteral reflux, and calcifications [486]. In female GUTB patients US may identify ovarian masses, intrauterine thickening and calcifications [487].

Intravenous urography aids in the identification of renal and ureteral TB, but lacks specificity. Approximately 10-15% of patients may have normal findings on IVU [488, 489]. The most common findings on IVU are hydrocalycosis, hydronephrosis or hydroureter due to stricture, autonephrectomy and urinary calcifications [490-492].

In recent years CT and MRI have largely replaced IUV. The most common findings on CT are parenchymal scarring, hydrocalycosis, hydronephrosis or hydroureter due to stricture, and thickening of the renal pelvis, ureter and bladder walls [490-492]. In TB of the seminal vesicles and vas deferens CT imaging can show enlarged heterogeneously enhancing seminal vesicles with possible wall thickening, contraction, and intraluminal or wall calcifications [493, 494]. Prostate TB appears as a low attenuating and marginally enhancing cystic mass, which is indistinguishable from a non-TB prostatic abscess [495]. In female GUTB the fallopian tubes are most frequently affected area and present with enlargement, hydrosalpinx, pyosalpinx, and wall thickening, with calcification on CT [496].

Magnetic resonance imaging has low sensitivity for the diagnosis of GUTB in the early stages of the infection [497]. As an imaging modality MRI is useful in patients in whom CT is contraindicated, including patients with renal failure or contrast hypersensitivity reactions or those who wish to avoid exposure to radiation. Renal and ureteral abnormalities are comparable to those described for CT findings and must be distinguished from acute pyelonephritis [487, 498]. Epididymitis and testicular TB appears as a diffusely enlarged epididymis or testis with heterogeneous high T2 signal due to fibrosis and calcification [494]. Multiparametric MRI of the prostate distinguishes between the nodular or diffuse patterns of prostate TB [499].

Female GUTB has a wide range of appearances on HSG affecting the fallopian tubes, endometrium and uterus [500, 501]. Tubal obstruction is the most common finding with HSG [501]. In addition, deformity of the uterine cavity can be observed, such as a T-shaped and Dwarfed uterus, resulting from abnormal scaring and fibrosis [500]. As the disease progresses this process can potentially lead to a complete obliteration of the uterine cavity referred to as Netter syndrome [502].

*3.15.3 **Medical Treatment***

The WHO recommends a daily six month regimen for treatment of newly diagnosed extrapulmonary TB, including an intensive phase of two months with isoniazid, rifampicin, pyrazinamide, and ethambutol, followed by a continuation phase of four months with isoniazid and rifampicin [503]. For the treatment of multi-drug resistant (MDR) TB (i.e. resistance to rifampicin and isoniazid) an individualised treatment regime should be applied with at least five effective tuberculosis medicines during the intensive phase, including pyrazinamide and four core second-line tuberculosis medicines [504].

*3.15.4 **Surgical treatment***

Combination drug therapy is the first-line treatment for GUTB. However, in more than 50% of patients ablative, endoscopic or reconstructive surgery is required due to the destructive nature of the infection coupled with a delay in initial diagnosis [505-507]. In 26.9% of cases of diagnosed GUTB there is a non-functioning unilateral kidney and in 7.4%, renal failure [507].

In the largest observational study of 4,288 GUTB patient's a total of 2,364 different surgical procedures were carried out of which 948 were reconstructive [508]. In a retrospective series of 241 patients who underwent surgery for GUTB, a total of 128 reconstructive procedures were done in which 30.29% of patients had bladder augmentation [509]. A retrospective single-centre study of 128 patients reported renal units in the reconstruction group had 5.44-fold longer survival than the permanent diversion group suggesting that when feasible renal reconstruction may be better for renal function preservation [510]. Reconstructive surgery may include augmentation cystoplasty, uretero-ureterostomy, ureteroneocystostomy, ureteral reimplant, pyeloplasty, ureterocalicostomy and ileal ureter or external diversion, where indicated [511].

There is limited evidence with regard to the optimum surgical approach. Minimally invasive options, have been reported as feasible and safe strategies, comparable to open surgery [512-516]. In addition, the optimal timing for surgery is controversial. A delay of 2-6 weeks up to 9 months after the initiation of medical treatment has been proposed to allow for a reduction in active inflammation and stabilisation of the TB lesions [497].

Due to lack of high-quality evidence for surgical treatment of GUTB the Panel are unable to give a recommendation on surgical treatment at this point in time. Patients with GUTB should be assessed on an individualised bases and the decision to operate taken depending on the location, extent of disease progression and damage to the genitourinary system.

3.15.5 *Summary of evidence and recommendations for the diagnosis and treatment of GUTB*

Summary of evidence	LE
The risk of reactivation of latent TB is estimated to be 15% in an individual's lifetime.	2a
Smear microscopy for acid-fast bacilli has a low sensitivity in urine ranging from 0-25%.	2a
Studies have reported high specificities of 92–100% but low sensitivities of 23.3–30% for urine culture in renal TB specimens.	2a
Xpert MTB/RIF pooled sensitivity and specificity were 84.7% (70.8 to 93.1) and 97.3% (91.0 to 99.2) for the diagnosis of GUTB.	1b
Standard six month anti-tuberculous drug regimens are effective in all forms of TB (pulmonary and extrapulmonary).	1a
There is limited evidence with regard to the optimum surgical approach and timing of surgery in GUTB patients.	3

Recommendations	Strength rating
Diagnosis	
Take a full medical history including history of previous tuberculosis infection (pulmonary and extrapulmonary) form all patients presenting with persistent non-specific genitourinary symptoms and no identifiable cause.	Strong
Perform smear microscopy on urine, semen, tissue specimens, discharged or prostatic massage fluid using Ziehl–Neelsen (ZN) or auramine staining in patients with suspected genitourinary tuberculosis (GUTB).	Weak
Perform acid-fact bacilli culture on three midstream first-void urine samples, on three consecutive days for M. tuberculosis isolation in patients with suspected GUTB.	Strong
Use a recommended PCR test systems in addition to microbiological reference standard (MRS) in urine specimens as a diagnostic test in patients with signs and symptoms of GUTB.	Weak
Use imaging modalities in combination with culture and/or PCR to aid in the diagnosis of GUTB and to assess the location and extent of damage to the genitourinary system.	Weak
Treatment	
Use medical treatment as first-line treatment for GUTB.	Strong
Use a daily six-month regimen for treatment of newly diagnosed GUTB this should include an intensive phase of two months with isoniazid, rifampicin, pyrazinamide and ethambutol. Followed by a continuation phase of four-months with isoniazid and rifampicin.	Strong
Treat multi-drug resistant TB with an individualised treatment regime including at least five effective tuberculosis medicines during the intensive phase, including pyrazinamide and four core second-line tuberculosis medicines.	Strong

Table 12: Treatment regimens for newly diagnosed GUTB and MDR-TB [504]

Antimicrobials	Dosage
Six month regimen for treatment of newly diagnosed GUTB	
Intensive two month phase	
Isoniazid	5 mg/kg every 24 h; max daily dosage 300 mg
Rifampicin	10 mg/kg every 24 h; max daily dosage 600 mg
Pyrazinamide	25 mg/kg every 24 h; max daily dosage 2000 mg
Ethambutol	15–20 mg/kg every 24 h; max daily dosage ranging from 800 mg to 1600 mg depending on body weight
Continuation four month phase	
Isoniazid	5 mg/kg every 24 h; max daily dosage 300 mg
Rifampicin	10 mg/kg every 24 h; max daily dosage 600 mg

Treatment regimen for multi-drug resistant TB	
Treat multi-drug resistant TB with an individualised treatment regime including at least five effective tuberculosis medicines during the intensive phase, including pyrazinamide and four core second-line tuberculosis medicines*.	
Group A Fluoroquinolones	Levofloxacin, Moxifloxacin and Gatifloxacin
Group B Second-line injectables	Amikacin, Capreomycin, Kanamycin and Streptomycin**
Group C Other second-line agents	Ethionamide/ Prothionamide, Cycloserine/Terizidone, Linezolid and Clofazimine
Group D Add-on agents (not part of the core MDR-TB regime)	D1: Pyrazinamide, Ethambutol, and High-dose isoniazid D2: Bedaquiline and Delamamid D3: p-aminosalicylic acid, Imipenem-cilastatin, Meropenem, Amoxicillin-clavulanate and Thioacetazone***

** Drugs should be chosen as follows: 1 from group A, 1 from group B, and at least 2 from group C. If the minimum number of five TB medicines cannot be composed from drugs included in Groups A to C, an agent from group D2 and other agents from group D3 may be added to bring the total to five [504].*

***Streptomycin can substitute other injectable drugs if none of these agents can be used and if the strain is shown not to be resistant [504].*

****Thioacetazone should not be used if the patient is HIV seropositive [504].*

3.16 Peri-Procedural Antibiotic Prophylaxis

*3.16.1 **General Principles***

3.16.1.1 Definition of infectious complications

The European Centre for Disease Prevention and Control (ECDC) and the CDC have both presented similar definitions recommended for the evaluation of infectious complications [517, 518].

3.16.1.2 Non-antibiotic measures for asepsis

There are a number of non-antibiotic measures designed to reduce the risk of surgical site infection (SSI), many are historically part of the routine of surgery. The effectiveness of measures tested by RCTs are summarised in systematic reviews conducted by the Cochrane Wounds Group (http://wounds.cochrane.org/news/reviews). Urological surgeons and the institutions in which they work should consider and monitor maintenance of an aseptic environment to reduce risk of infection from pathogens within patients (microbiome) and from outside the patient (nosocomial/healthcare-associated). This should include use of correct methods of instrument cleaning and sterilisation, frequent and thorough cleaning of operating rooms and recovery areas and thorough disinfection of any contamination. The surgical team should prepare to perform surgery by effective hand washing [519], donning of appropriate protective clothing and maintenance of asepsis. These measures should continue as required in recovery and ward areas.

Patients should be encouraged to shower pre-operatively, but use of chlorhexidine soap does not appear to be beneficial [520]. Although evidence quality is low, any required hair removal appears best done by clipping, rather than shaving, just prior to incision [521]. Mechanical bowel preparation should not be used as evidence review suggests harm not benefit [522, 523]. There is some weak evidence that skin preparation using alcoholic solutions or chlorhexidine result in a lower rate of SSI than iodine solutions [524]. Studies on the use of plastic adherent drapes showed no evidence of benefit in reducing SSI [525].

3.16.1.3 Detection of bacteriuria prior to urological procedures

Identifying bacteriuria prior to diagnostic and therapeutic procedures aims to reduce the risk of infectious complications by controlling any pre-operative detected bacteriuria and to optimise antimicrobial coverage in conjunction with the procedure. A systematic review of the evidence identified eighteen studies comparing the diagnostic accuracy of different index tests (dipstick, automated microscopy, dipslide culture and flow cytometry), with urine culture as the reference standard [526]. The systematic review concluded that none of the alternative urinary investigations for the diagnosis of bacteriuria in adult patients prior to urological interventions can currently be recommended as an alternative to urine culture [526].

3.16.1.4 Choice of agent

Urologists should have knowledge of local pathogen prevalence for each type of procedure, their antibiotic susceptibility profiles and virulence in order to establish written local guidelines. These guidelines should cover the five modalities identified by the ECDC following a systematic review of the literature [527]. The agent

should ideally not be one that may be required for treatment of infection. When risk of skin wound infection is low or absent, an aminoglycoside (gentamicin) should provide cover against likely uropathogens provided the eGFR is > 20 mL/min; second generation cephalosporins are an alternative [528]. Recent urine culture results including presence of any multi-resistant organisms, drug allergy, history of *C. difficile* associated diarrhoea, recent antibiotic exposure, evidence of symptomatic infection pre-procedure and serum creatinine should be checked. The panel have decided not to make recommendations for specific agents for particular procedures as there is considerable variation in Europe and worldwide regarding bacterial pathogens, their susceptibility and availability of antibiotic agents.

*3.16.2 **Specific procedures and evidence question***

An updated literature search from February 2017 (cut-off of last update) to June 2021 identified RCTs, systematic reviews and meta-analyses that investigated the benefits and harms of using antibiotic prophylaxis prior to specific urological procedures. The available evidence enabled the panel to make recommendations concerning urodynamics, cystoscopy, stone procedures (extracorporeal shockwave lithotripsy [ESWL], ureteroscopy and percutaneous nephrolithotomy [PCNL]), transurethral resection of the prostate (TURP) and transurethral resection of the bladder (TURB). For nephrectomy and prostatectomy the scientific evidence was too weak to allow the panel to make recommendations either for or against antibiotic prophylaxis. The general evidence question was: Does antibiotic prophylaxis reduce the rate of post-operative symptomatic UTI in patients undergoing each named procedure?

3.16.2.1 Urodynamics

The literature search identified one systematic review for antibiotic prophylaxis in women only [529]. This included 3 RCTs (n=325 patients) with the authors reporting that prophylactic antibiotics reduced the risk of bacteriuria but not clinical UTI after urodynamics [529]. A previous Cochrane review identified nine RCTs enrolling 973 patients with overall low quality and high or unclear risks of bias [530]. The outcome of clinical UTI was reported in four trials with no benefit found for antibiotic prophylaxis vs. placebo [RR (95%CI) 0.73 (0.52-1.03)]. A meta-analysis of nine trials showed that use of antibiotics reduced the rate of post-procedural bacteriuria [RR (95%CI) 0.35 (0.22-0.56)] [530].

3.16.2.2 Cystoscopy

Three systematic reviews and meta-analyses [531-533] and one additional RCT [534] on cystoscopy for stent removal were identified. Garcia-Perdomo *et al.*, included seven RCTs with a total of 3,038 participants. The outcome of symptomatic UTI was measured by five trials of moderate overall quality and meta-analysis showed a benefit for using antibiotic prophylaxis [RR (95%CI) 0.53 (0.31 – 0.90)]; ARR 1.3% (from 2.8% to 1.5%) with a NNT of 74 [532]. This benefit was not seen if only the two trials with low risk of bias were used in the meta-analysis. Carey *et al.*, included seven RCTs with 5,107 participants. Six trials were included in meta-analysis of the outcome of symptomatic bacteriuria which found benefit for use of antibiotic prophylaxis [RR (95%CI) 0.34 (0.27 – 0.47)]; ARR 3.4% (from 6% to 2.6%) with NNT of 28 [531]. Zeng *et al.*, included twenty RCTs and two quasi-RCTs with a total of 7,711 participants. The outcome of symptomatic UTI was measured by eleven RCTs of low overall quality and meta-analysis showed a possible benefit for using antibiotic prophylaxis [RR (95% CI) 0.49 (0.28 – 0.86)] [533]. For systemic UTI, antibiotic prophylaxis showed no effect compared with placebo or no treatment in five RCTs [RR (95% CI) 1.12 (0.38 - 3.32)]. However, prophylactic antibiotics may increase bacterial resistance [(RR (95% CI) 1.73 (1.04 – 2.87)].

Given the low absolute risk of post-procedural UTI in well-resourced countries, the high number of procedures being performed, and the high risk of contributing to increasing antimicrobial resistance the panel consensus was to strongly recommend not to use antibiotic prophylaxis in patients undergoing urethrocystoscopy (flexible or rigid).

3.16.2.3 Interventions for urinary stone treatment

3.16.2.3.1 Extracorporeal shockwave lithotripsy

For patients without bacteriuria undergoing ESWL two systematic reviews and meta-analyses were identified with latest search dates of November 2011 and October 2012, respectively [535, 536] and two further trials [537]. Lu *et al.*, included nine RCTs with a total of 1,364 patients and found no evidence of benefit in terms of reducing the rate of post-procedural fever or bacteriuria [535]. Mrkobrada *et al.*, included eight RCTs with a total of 940 participants and found no evidence of benefit for antibiotic prophylaxis to reduce rate of fever or trial-defined infection [536]. A RCT with 274 patients and severe risk of bias found no reduction in fever at up to one week post-procedure using a single dose of levofloxacin 500 mg and no difference in the rate of bacteriuria [537]. Another RCT (n=600) again with severe risk of bias found no difference in UTI and positive urine culture rates at two weeks post-procedure using 200 mg ofloxacin post-operatively for 3-days vs. placebo [538].

For patients with bacteriuria or deemed at high risk of complications one RCT comparing the use of ofloxacin or trimethoprim-sulphamethoxazole for three days prior and four days subsequent to ESWL in 56 patients with ureteric stents was identified [539]. They found no difference in rate of clinical UTI at seven days (no events) and no difference in post-ESWL bacteriuria.

3.16.2.3.2 Ureteroscopy

One updated systematic review and meta-analysis with last search date of June 2017 was identified and included eleven RCTs with 4,591 patients [540]. The meta-analysis found that post-operative pyuria and bacteriuria rates were significantly lower in patients who received pre-operative antibiotic prophylaxis pyuria (OR: 0.42, 95% CI 0.25–0.69 and OR: 0.25, 95% CI 0.11–0.58, respectively). Five studies assessed post-operative febrile UTI (fUTI) and found no difference in the rate of fUTIs between patients who did or did not receive antibiotic prophylaxis (OR: 0.82, 95% CI 0.40– 1.67; p=0.59). However, a significantly higher risk of post-operative fever in the pre-operative antibiotic prophylaxis group (OR: 1.75, 95% CI 1.22–2.50; p=0.002) was reported. A subgroup analysis on the type of pre-operative antibiotic prophylaxis found no difference between a single dose of oral vs. intravenous antibiotics [540].

A RCT comparing different ciprofloxacin-based antibiotic prophylaxis regimens on the incidence of SIRS after URS found there was no difference in the incidences of SIRS between the regimens including the zero-dose regime [541]. However, there was a greater risk of SIRS in patients who did not receive antibiotic prophylaxis when the stone size was > 200 mm^2 [541]. Another RCT comparing the use of two oral doses of 3g Fosfomycin tromethamine before surgery to standard of care did not find any difference in the incidence of infections, bacteriuria or fever [542].

Panel discussion considered that despite low quality evidence suggesting no benefit in reducing risk of clinical UTI, clinicians and patients would prefer to use prophylaxis to prevent kidney infection or sepsis. Ideally this should be examined in a robustly designed clinical study.

3.16.2.3.3 Percutaneous neprolithotomy (PNL)

The largest systematic review and meta-analysis performed, latest search date April 2019, included 1,549 patients in thirteen comparative studies on antibiotic prophylaxis strategies for PNL [543]. Compared with a single dose before surgery pre-operative antibiotic prophylaxis significantly reduced post-operative sepsis and fever (OR 0.31, 95%CI 0.20-0.50 and OR 0.26, 95%CI 0.14-0.48, respectively) [543]. Similarly, the rate of positive pelvic urine and positive stones culture were reduced when pre-operative prophylaxis was given. There was no difference in sepsis rates between patients receiving or not receiving post-operative prophylaxis; however, patients who received post-operative antibiotic prophylaxis had more fever [543].

Four RCTs with overall low risk of bias comparing different antibiotic regimes in PNL were identified [544-547]. Seyrek *et al.*, compared the rate of SIRS following PNL in 191 patients receiving either a combination of sulbactam/ampicillin or cefuroxime. There was no difference in SIRS or urosepsis rates [544]. Tuzel *et al.*, investigated single dose ceftriaxone versus ceftriaxone and subsequently an oral third-generation cephalosporin until after nephrostomy catheter withdrawal at mean (SD) of 3 (1) days in 73 participants undergoing PNL. They found no difference in rate of infectious complications between the two antibiotic regimens [545]. Taken *et al.*, compared the administration of 1g ceftriaxone and 1g cefazoline both administered 30 minutes before surgery and continued till nephrostomy removal. They found no difference in terms of SRIS or sepsis between groups [547]. Omar *et al.*, compared ciprofloxacin 200 mg IV vs. 2 mg cefotaxime 30 minutes before and 12hours after surgery and found a higher rate of fever in the cefotaxime group [546]. However, these results remain limited by the high risk of bias and the lack of data regarding post-operative infection. These studies give moderate evidence that a single dose of a suitable agent was adequate for prophylaxis against clinical infection after PNL.

3.16.2.4 Transurethral resection of the prostate

A systematic review of 39 RCTs with search date up to 2009 was identified [548]. The update search to February 2017 did not reveal any further relevant studies. Of the 39 RCTs reviewed by Dahm *et al.*, six trials involving 1,666 men addressed the risk of septic episodes, 17 trials reported procedure related fever and 39 investigated bacteriuria. Use of prophylactic antibiotics compared to placebo showed a relative risk reduction (95% CI) for septic episode of 0.51 (0.27-0.96) with ARR of 2% (3.4% - 1.4%) and a NNT of 50. The risk reduction (95% CI) for fever was 0.64 (0.55-0.75) and 0.37 (0.32-0.41) for bacteriuria.

3.16.2.5 Transurethral resection of the bladder

One systematic review which included seven trials with a total of 1,725 participants was identified [549]. Antimicrobial prophylaxis showed no significant effect on post-operative UTIs [OR (95% CI) 1.55 (0.73 - 3.31)] and asymptomatic bacteriuria [OR (95% CI) 0.43 (0.18 – 1.04)] [549]. The review did not attempt sub-group analysis according to presence of risk factors for post-operative infection such as tumour size. Risk factors for development of post-operative UTIs were evaluated only by three of the included studies and most of the parameters were analysed by no more than one study.

A RCT (n=100) comparing oral fosfomycin 3g (the night before surgery) vs. intravenous cefoxitin 2g (30 min pre- and 24 hrs post-surgery) on post-operative UTIs found that a single oral administration of fosfomycin was non-inferior to intravenous administration of cefoxitin in the prevention of post-TURB UTI, even in patients considered at higher risk [550].

Panel discussion concluded that a weak recommendation to use antibiotic prophylaxis for patients undergoing TURB who had a high risk of suffering post-operative sepsis would be appropriate.

3.16.2.6 Midurethral slings

One systematic review and meta-analysis identified one study assessing the role of pre-operative antibiotics for midurethral sling surgery alone [551]. The study was halted due to low rate of infectious outcomes seen at the first scheduled interim analysis. The study enrolled 29 women in the antibiotic prophylaxis (cefazolin) group and 30 in the placebo group with a total follow-up of six months. No statistically significant difference between the cefazolin and placebo groups, with respect to wound infections [1 (3.3%) and 0 (0%)] or bacteriuria [3 (10%) and 1 (3.5%)] was found [551].

3.16.2.7 Renal tumour ablation

One systematic review publication date 2018 included 6,952 patients across 51 studies [552]. Infectious complications were reported in 74 patients including fever (60.8%), abscess (21.6%) and UTI (8.1%). Prophylactic antibiotic use was reported in 5.4% of patients but it was not possible to study its association to infectious complications due to lack of reporting.

3.16.2.8 Prostate biopsy

3.16.2.8.1 Transperineal prostate biopsy

A total of eight randomised studies including 1,596 patients compared the impact of biopsy route on infectious complications. Infectious complications were significantly higher following transrectal biopsy (48 events among 789 men) compared to transperineal biopsy (22 events among 807 men), [RR (95% CIs) 2.48 (1.47 to 4.2) [553, 554]. In addition, a systematic review including 165 studies with 162,577 patients described sepsis rates of 0.1% and 0.9% for transperineal and transrectal biopsies, respectively [555]. Finally, a population-based study from the UK (n=73,630) showed lower re-admission rates for sepsis in patients who had transperineal versus transrectal biopsies (1.0% vs, 1.4%, respectively) [556]. The available evidence demonstrates that the transrectal approach should be abandoned in favour of the transperineal approach despite any possible logistical challenges.

A systematic review and meta-analysis of eight non-RCTs reported no significant differences between patients receiving or not receiving antibiotic prophylaxis in terms of post-biopsy infection (0.11% vs. 0.31%) and sepsis (0.13% vs. 0.09%), for the transperineal approach [557]. This is in line with another systematic review and meta-analysis of 112 individual patient cohorts which also showed no significant difference in the number of patients experiencing post-transperineal biopsy infection with 1.35% of 29,880 patients receiving antibiotic prophylaxis and 1.22% of 4,772 not receiving antibiotic prophylaxis (p=0.8) [558]. In addition, two recently published RCTs have reported comparably low post-biopsy infection rates for transperineal biopsy regardless of whether antibiotic prophylaxis was administered or not [559, 560].

There is a growing body of evidence to suggest that antibiotic prophylaxis may not be required for transperineal biopsy; however, the Panel have chosen to wait until a number of ongoing RCTs report their study findings before making a recommendation on this.

3.16.2.8.2 Transrectal prostate biopsy

An updated meta-analysis of eleven RCTs including 2,237 men showed that use of a rectal povidone-iodine preparation before biopsy, in addition to antimicrobial prophylaxis, resulted in a significantly lower rate of infectious complications [RR (95% CIs) 0.47 (0.36 to 0.61) [553, 561-563]. Single RCTs showed no evidence of benefit for perineal skin disinfection [564], but reported an advantage for rectal povidone-iodine preparation before biopsy compared to after biopsy [565].

A meta-analysis of four RCTs including 671 men evaluated the use of rectal preparation by enema before transrectal biopsy. No significant advantage was found regarding infectious complications [RR (95% CIs) 0.96 (0.64 to 1.54) [553].

An updated meta-analysis of 29 RCTs with 4,127 patients found no evidence that use of peri-prostatic injection of local anaesthesia resulted in more infectious complications than no injection [RR (95% CIs) 1.08 (0.80 to 1.49)] [553, 554, 566, 567]. An updated meta-analysis of 10 RCTs including 2,342 patients found that extended biopsy templates showed comparable infectious complications to standard templates [RR (95% CIs) 0.82 (0.55 to 1.24)] [553, 568]. Additional meta-analyses found no difference in infections complications regarding needle guide type (disposable vs. reusable), needle type (coaxial vs. non-coaxial), needle size (large vs. small), and number of injections for peri-prostatic nerve block (standard vs. extended) [553].

A meta-analysis of eleven studies with 1,753 patients showed significantly reduced infections after transrectal prostate biopsy when using antimicrobial prophylaxis as compared to placebo/control [RR (95% CIs) 0.56 (0.40 to 0.77)] [569].

Fluoroquinolones have been traditionally used for antibiotic prophylaxis in this setting; however, overuse and misuse of fluoroquinolones has resulted in an increase in fluoroquinolone resistance. In addition, the European Commission has implemented stringent regulatory conditions regarding the use of fluoroquinolones resulting in the suspension of the indication for peri-operative antibiotic prophylaxis including prostate biopsy [138].

A systematic review and meta-analysis on antibiotic prophylaxis for the prevention of infectious complications following prostate biopsy concluded that in countries where fluoroquinolones are allowed as antibiotic prophylaxis, a minimum of a full one-day administration is recommended [569]. An updated meta-analysis of eight RCTs with 2,939 patients confirmed that targeted therapy (antibiotic guidance based on rectal swab microbiology) in case of fluoroquinolone resistance is associated with reduced infectious complications [RR (95% CIs) 0.54 (0.40 to 0.72)] [569]. In addition, an updated meta-analysis of ten RCTs with 2,787 patients comparing augmented prophylaxis (combination of two or more different classes of antibiotics) to standard prophylaxis showed augmented prophylaxis to be superior [RR (95% CIs) 0.44 (0.32 to 0.59)] [569, 570]. In countries where use of fluoroquinolones are suspended cephalosporins or aminoglycosides can be used as individual agents with comparable infectious complications based on meta-analysis of two RCTs [569]. An updated meta-analysis of four RCTs compared fosfomycin trometamol to fluoroquinolones [RR (95% CIs) 0.62 (0.37 to 1.06)] [569, 571]. Although initial RCTs suggested fosfomycin trometamol to be superior the latest Swedish study, which aimed to recruit 3,448 patients, was discontinued after 42 patients due to the unusually high number of hospitalisations in the fosfomycin trometamol group [571]. Therefore, routine general use should be critically assessed due to the relevant infectious complications also reported in non-randomised studies [572]. Of note the indication of fosfomycin trometamol for prostate biopsy has been withdrawn in Germany as the manufacturers did not submit the necessary pharmacokinetic data in support of this indication. Urologists are advised to check their local guidance in relation to the use of fosfomycin trometamol for prostate biopsy. Another possibility is the use of augmented prophylaxis without fluoroquinolones, although no standard combination has been established to date. Finally, targeted prophylaxis based on rectal swap/stool culture is plausible, but no RCTs are available on non-fluoroquinolones. See figure 1 for prostate biopsy workflow to reduce infections complications.

3.16.3 Summary of evidence and recommendations for peri-procedural antibiotic prophylaxis

Summary of evidence	**LE**
The outcome of clinical UTI was reported in four out of eleven RCTs with no benefit found for antibiotic prophylaxis vs. placebo in patients following filling and voiding cystometry.	1b
A meta-analysis of five trials of moderate quality showed a benefit for using antibiotic prophylaxis for the reduction of symptomatic UTI in patients undergoing cystoscopy. However, this benefit was not seen if only the two trials with low risk of bias were used in the meta-analysis.	1a
Two meta-analyses found no benefit for antibiotic prophylaxis following ESWL in terms of reducing the rate of post-procedural fever and bacteriuria or trial-defined infection in patients without bacteriuria.	1a
Two meta-analyses found no evidence of benefit for antibiotic prophylaxis prior to ureteroscopy in reducing the rate of clinical UTI; however, the rate of bacteriuria was reduced.	1a
A meta-analysis of five RCTs demonstrated a moderate level of evidence that antibiotic prophylaxis was associated with a statistically significant reduction in the risk of post-procedural UTI following PNL.	1a
Two RCTs concluded that a single dose of a suitable agent was adequate for prophylaxis against clinical infection after PNL.	1b

A systematic review of 39 RCTs concluded that antibiotic prophylaxis reduced the rate of infectious complications in men undergoing TURP.	1b
A systematic review of two RCTs found no benefit for antibiotic prophylaxis in patients undergoing TURB.	1b
A meta-analysis of eight studies including 1,596 patients showed significantly reduced infectious complications in patients undergoing transperineal biopsy as compared to transrectal biopsy.	1a
A meta-analysis of eight non-RCTS reported comparable rates of post-biopsy infections in patients undergoing transperineal biopsy irrespective if antibiotic prophylaxis was given or not.	1a
A meta-analysis of eleven RCTs including 2,237 men showed that use of a rectal povidone-iodine preparation before transrectal biopsy, in addition to antimicrobial prophylaxis, resulted in a significantly lower rate of infectious complications.	1a
A meta-analysis on eleven studies with 1,753 patients showed significantly reduced infections after transrectal biopsy when using antimicrobial prophylaxis as compared to placebo/control.	1a

Recommendations	**Strength rating**
Do not use antibiotic prophylaxis to reduce the rate of symptomatic urinary infection following: • urodynamics; • cystoscopy; • extracorporeal shockwave lithotripsy.	Strong
Use antibiotic prophylaxis to reduce the rate of symptomatic urinary infection following ureteroscopy.	Weak
Use single dose antibiotic prophylaxis to reduce the rate of clinical urinary infection following percutaneous nephrolithotomy.	Strong
Use antibiotic prophylaxis to reduce infectious complications in men undergoing transurethral resection of the prostate.	Strong
Use antibiotic prophylaxis to reduce infectious complications in high-risk patients undergoing transurethral resection of the bladder.	Weak
Perform prostate biopsy using the transperineal approach due to the lower risk of infectious complications.	Strong
Use routine surgical disinfection of the perineal skin for transperineal biopsy.	Strong
Use rectal cleansing with povidone-iodine in men prior to transrectal prostate biopsy.	Strong
Do not use fluoroquinolones for prostate biopsy in line with the European Commission final decision on EMEA/H/A-31/1452.	Strong
Use either target prophylaxis based on rectal swab or stool culture; augmented prophylaxis (two or more different classes of antibiotics); or alternative antibiotics (e.g. fosfomycin trometamol*, cephalosporin, aminoglycoside) for antibiotic prophylaxis for transrectal biopsy.	Weak

**Of note the indication of fosfomycin trometamol for prostate biopsy has been withdrawn in Germany as the manufacturers did not submit the necessary pharmacokinetic data in support of this indication. Urologists are advised to check their local guidance in relation to the use of fosfomycin trometamol for prostate biopsy.*

Table 13: Suggested regimens for antimicrobial prophylaxis prior to urological procedures

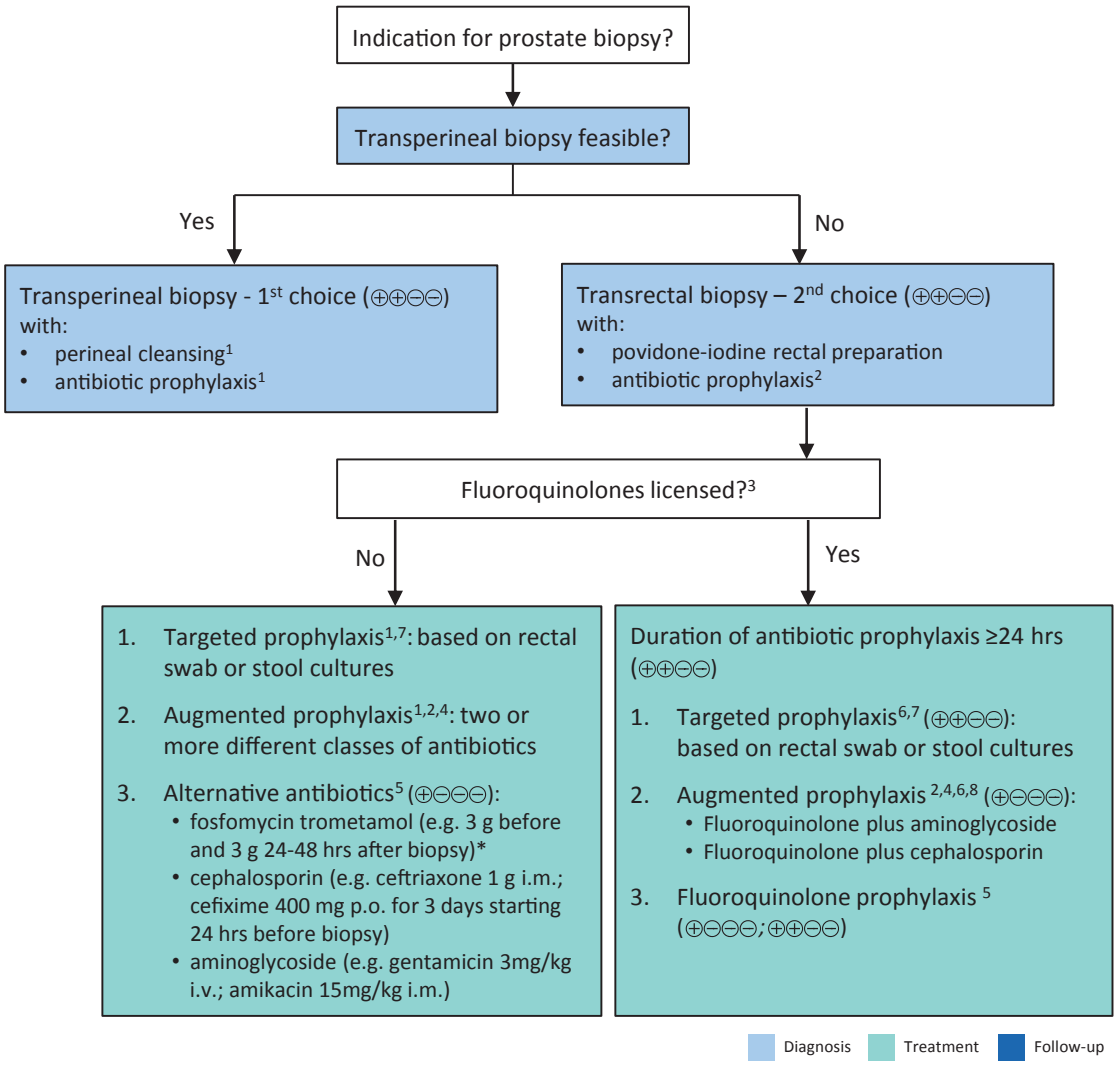
As stated in section 3.14.1.4 the panel has decided not to make recommendations for specific agents for particular procedures, those listed below represent possible choices only. Urologists should choose a specific antimicrobial based on their knowledge of local pathogen prevalence for each type of procedure, their antibiotic susceptibility profiles and virulence.

Procedure	Prophylaxis recommended	Antimicrobial
Urodynamics	No	N/A
Cystoscopy	No	
Extracorporeal shockwave lithotripsy	No	
Ureteroscopy	Yes	Trimethoprim Trimethoprim-sulphamethoxazole Cephalosporin group 2 or 3 Aminopenicillin plus a beta-lactamase inhibitor
Percutaneous nephrolithotomy	Yes (single dose)	
Transurethral resection of the prostate	Yes	
Transurethral resection of the bladder	Yes, in patients who have a high risk of suffering post-operative sepsis.	
Transrectal prostate biopsy	Yes	1. Targeted prophylaxis - based on rectal swab or stool culture. 2. Augmented prophylaxis - two or more different classes of antibiotics*. 2. Alternative antibiotics • fosfomycin trometamol** (e.g. 3 g before and 3 g 24-48 hrs after biopsy) • cephalosporin (e.g. ceftriaxone 1 g i.m.; cefixime 400 mg p.o. for 3 days starting 24 hrs before biopsy) • aminoglycoside (e.g. gentamicin 3mg/kg i.v.; amikacin 15mg/kg i.m.)

** Note option 2 is against antibiotic stewardship programmes*

*** Of note the indication of fosfomycin trometamol for prostate biopsy has been withdrawn in Germany as the manufacturers did not submit the necessary pharmacokinetic data in support of this indication. Urologists are advised to check their local guidance in relation to the use of fosfomycin trometamol for prostate biopsy.*

Figure 4: Prostate biopsy workflow to reduce infectious complications



1. *Two systematic reviews including non-RCTs and two RCTs describe comparable rates of post-biopsy infection in patients with and without antibiotic prophylaxis.*
2. *Be informed about local antimicrobial resistance.*
3. *Banned by European Commission due to side effects.*
4. *Contradicts principles of Antimicrobial Stewardship.*
5. *Fosfomycin trometamol (4 RCTs), cephalosporins (2 RCTs), aminoglycosides (2 RCTs).*
6. *Only one RCT comparing targeted and augmented prophylaxis.*
7. *Originally introduced to use alternative antibiotics in case of fluoroquinolone resistance.*
8. *Various schemes: fluoroquinolone plus aminoglycoside (4 RCTs); and fluoroquinolone plus cephalosporin (1 RCT).*
9. *Significantly inferior to targeted and augmented prophylaxis.*

GRADE Working Group grades of evidence. High certainty: (⊕⊕⊕⊕)very confident that the true effect lies close to that of the estimate of the effect. Moderate certainty: (⊕⊕⊕○)moderately confident in the effect estimate: the true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different. Low certainty: (⊕⊕○○) confidence in the effect estimate is limited: the true effect may be substantially different from the estimate of the effect. Very low certainty: (⊕○○○) very little confidence in the effect estimate: the true effect is likely to be substantially different from the estimate of effect. Figure reproduced from Pilatz et al., [573] with permission from Elsevier.

** Of note the indication of fosfomycin trometamol for prostate biopsy has been withdrawn in Germany as the manufacturers did not submit the necessary pharmacokinetic data in support of this indication. Urologists are advised to check their local guidance in relation to the use of fosfomycin trometamol for prostate biopsy*

5. CONFLICT OF INTEREST

All members of the EAU Urological Infections Guidelines Panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is publicly accessible through the EAU website: http://www.uroweb. org/guidelines/. These Guidelines were developed with the financial support of the EAU. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance, travel and meeting expenses. No honoraria or other reimbursements have been provided.

6. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Paris 2024. ISBN 978-94-92671-23-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, The Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

EAU Guidelines on Urological Trauma

N.D. Kitrey (Chair), F. Campos-Juanatey, P. Hallscheidt, E. Mayer, E. Serafetinidis, D.M. Sharma, M. Waterloos
Guidelines Associates: H. Mahmud, K. Zimmermann
Guidelines Office: N. Schouten

European Association of Urology

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aim and objectives

The European Association of Urology (EAU) Guidelines Panel for Urological Trauma have prepared these guidelines in order to assist medical professionals in the management of urological trauma in adults. Paediatric trauma is addressed in the EAU Paediatric Urology Guidelines [1].

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions – also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Urological Trauma Guidelines Panel consists of an international group of urologists and an interventional radiologist, all with particular expertise in urological trauma. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU Website Uroweb: http://uroweb.org/guideline/urological-trauma/?type=panel.

1.3 Available publications

A quick reference document, the Pocket Guidelines, is available in print and on the EAU Website. This is an abridged version which may require consultation together with the full text version. A number of translated versions, alongside several scientific publications in European Urology, the Associations scientific journal, are also available [2-5]. All documents can be viewed through the EAU website: http://uroweb.org/guideline/urological-trauma/.

1.4 Publication history

The Urological Trauma Guidelines were first published in 2003. All sections of the 2023 Urological Trauma Guidelines have been fully updated. The next update of the Urological Trauma Guidelines will be published in 2025.

2. METHODS

2.1 Evidence sources

For the 2023 Urological Trauma Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the Urological Trauma Guidelines was performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between May 1st, 2021, and April 29th, 2022. A total of 1,236 unique records were identified, retrieved and screened for relevance. A detailed search strategy is available online: http://uroweb.org/guideline/urological-trauma/?type=appendices-publications. The majority of identified publications were comprised of case reports and retrospective case series. The lack of high-powered randomised controlled trials (RCTs) makes it difficult to draw meaningful conclusions. The panel recognises this critical limitation.

Recommendation within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences [6, 7]. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [8];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention.

Strong recommendations typically indicate a high degree of evidence quality and/or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [9].

Additional information can be found in the general Methodology section of this print, and online at the EAU website; http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Peer review

The Urological trauma Guidelines was peer reviewed prior to publication in 2019.

3. EPIDEMIOLOGY, CLASSIFICATION & GENERAL MANAGEMNET PRINCIPALS

3.1 Definition and Epidemiology

Trauma is defined as a physical injury or a wound to living tissue caused by an extrinsic agent. Worldwide, there are over four million injury-related deaths ever year which constitute nearly 8% of all deaths [10]. About 25% of them are violence related. For young people (5 - 29 years old), three of the top five causes of death are injury-related (road traffic injuries, homicide, and suicide). Tens of millions more people suffer non-fatal injuries each year which lead to acute care visits, hospitalizations, and often result in temporary or permanent disability and the need for long-term physical and mental health care and rehabilitation. Twice as many males than females are killed each year because of injuries and violence [10].

Trauma is therefore a serious public health problem with significant social and economic costs. Considerable variation exists in the causes and the effects of traumatic injuries between geographical areas, as well as between low, middle, and high-income countries with about 90% of injury-related deaths occur in low- and middle-income countries [10].

3.2 Classification of trauma

Traumatic injuries are classified by the World Health Organization (WHO) into intentional (either interpersonal violence related, war-related or self-inflicted injuries), and unintentional injuries (mainly road traffic accidents/injury, falls, and other domestic accidents). Intentional trauma accounts for approximately half of the trauma-related deaths worldwide [11]. A specific type of unintentional injury is iatrogenic injury which occurs during therapeutic or diagnostic procedures by healthcare personnel. Traumatic insults are classified according to the basic mechanism of the injury into penetrating, when an object pierces the skin, and blunt injuries. Penetrating trauma is further classified according to the velocity of the projectile into:

1. high-velocity projectiles (e.g. rifle bullets - 800-1,000 m/sec);
2. medium-velocity projectiles (e.g. handgun bullets - 200-300 m/sec);
3. low-velocity items (e.g. knife stab).

High-velocity weapons inflict greater damage due to a temporary expansive cavitation that causes destruction in a much larger area than the projectile tract itself. In lower velocity injuries, the damage is usually confined to the projectile tract. Blast injury is a complex cause of trauma which includes blunt and penetrating trauma and burns.

The most commonly used classification grading system is the AAST (American Association for the Surgery of Trauma) injury scoring scale [12]. It is useful for managing renal trauma, but for the other urological organs, the injuries are commonly described by their anatomical site and severity (partial/complete).

3.3 General management principals

*3.3.1 **The Initial evaluation***

The initial emergency assessment of a trauma patient is beyond the focus of these guidelines. It is usually carried out by emergency medicine and trauma specialised personnel following advanced trauma life support (ATLS) principles. Detailed further assessment involves cross-sectional imaging, laboratory analysis and specialist surgical input. The management of individual organ injury will follow in the sections below. Tetanus vaccine status should be assessed for all penetrating injuries.

3.3.2 ***Polytrauma managed in major trauma centres leads to improved survival***

Urological trauma is often associated with significant injuries in the polytraumatised patient [13]. Lessons from civilian trauma networks, military conflict, and mass casualty events have led to many advances in trauma care [14-16]. These include the widespread acceptance of damage control principles and trauma centralisation to major trauma centres staffed by dedicated trauma teams. The re-organisation of care to these centres has been shown to reduce mortality by 25% and length of stay by four days [14]. Urologists increasingly understand their role in the context of polytrauma with the ultimate aims of improving survivability and decreasing morbidity in these patients.

3.3.3 ***Damage control***

Damage control is a life-saving strategy for severely injured patients that recognises the consequences of the lethal triad of trauma - hypothermia, coagulopathy, and acidosis [17-19]. The first of a three phased approach consists of rapid control of haemorrhage and wound contamination. The second phase involves resuscitation in the intensive care unit (ICU), with the goal of restoring normal temperature, coagulation, and tissue oxygenation. The final stage involves definitive surgery when more time-consuming reconstructive procedures are performed in the stabilised patient [20]. Urological intervention needs to be mindful of the phase of management. Temporary abbreviated measures followed by later definitive surgery are required. Complex reconstructive procedures, including organ preservation, are not undertaken. The decision to enter damage control mode is taken by the lead trauma clinician following team discussion.

Urological examples include haemodynamically unstable patients due to suspected renal haemorrhage or pelvic fracture with associated urethral or bladder injury. The options of abdominal packing and temporary urinary drainage by ureteric, bladder or urethral catheterisation are valuable adjuncts to care.

3.3.4 ***Mass casualty events and Triage***

A mass casualty event is one in which the number of injured people and the severity of their injuries exceed the capacity of the facility and staff [21]. Triage, communication, and preparedness are important components for a successful response.

Triage after mass casualty events involves difficult moral and ethical considerations. Disaster triage requires differentiation of the few critically injured individuals who can be saved by immediate intervention from the many others with non-life-threatening injuries for whom treatment can be delayed and from those whose injuries are so severe that survival is unlikely in the circumstances [22, 23].

3.3.5 ***The role of thromboprophylaxis and bed rest***

Trauma patients are at high risk of deep venous thrombosis (DVT). Concerns about secondary haemorrhage result in prolonged post-injury bed rest DVT which effectively compounds this risk. Established prophylaxis measures reduce thrombosis and are recommended following systemic review [24]. However, the strength of evidence is not high and as yet there is no evidence to suggest that mortality or pulmonary embolism risk is reduced [25]. Compression stockings and low molecular weight heparins are favoured. The risk of secondary haemorrhage in isolated renal trauma is low and the practice of strict bed rest has waned in patients who are able to mobilise [26].

3.3.6 ***Antibiotic stewardship***

Single shot antibiotic doses are common in major trauma. The indication for continuing antibiotics is governed by injury grade, associated injuries and the need for intervention. Patients with urinary extravasation tend to be kept on antibiotics but there is no evidence base for this. Antibiotics should be avoided in lesser trauma e.g. Grade 1-3 renal trauma, and regular review should be undertaken for those continued on antibiotics.

3.3.7 ***Urinary catheterisation***

Prolonged catheterisation is required in all forms of bladder and urethral injury. Catheterisation is not necessary in stable patients with low-grade renal injury. Patients with heavy haematuria, who require monitoring or ureteric stenting, benefit from catheterisation. This can be removed once haematuria lightens and there is an improvement in the clinical situation. The shortest possible period of catheterisation is advised.

4. UROGENITAL TRAUMA GUIDELINES

4.1 Renal Trauma

4.1.1 Epidemiology, aetiology and pathophysiology

Renal trauma is present in up to 5% of all trauma cases [27]. It is most common in young males and has an overall population incidence of 4.9 per 100,000 [28]. Most injuries can be managed non-operatively with successful organ preservation [29, 30].

Blunt injuries result from road traffic accidents/injury, falls, sporting injuries, and assault [31]. The kidney and/or hilar structures are directly crushed as a result. Less commonly, sudden deceleration may result in an avulsion injury affecting the vascular structures of the hilum or the ureteropelvic junction (UPJ).

Penetrating injuries are due to stab and gunshot wounds. They tend to be more severe and less predictable than blunt trauma. The prevalence is higher in urban settings [32]. Penetrating injury produces direct tissue disruption of the parenchyma, vascular pedicles, or collecting system. High-velocity bullets or fragments have the potential for greatest parenchymal destruction and are most often associated with multiple-organ injuries [33].

The most commonly used classification system is that of the AAST [12]. It is validated and predicts morbidity and the need for intervention [34, 35]. This remains the most useful of urological trauma classifications; however, the majority of Grade 1-4 injuries are now managed conservatively and debate has centred around updating the classification of high-grade injury i.e. identifying the injuries most likely to benefit from early angiographic embolisation, repair or nephrectomy [29, 36].

Table 4.1.1: Extract of the AAST renal injury grading scale [37]

Grade*	Type of injury	Description of injury
1	Haematoma and/or Contusion	Subcapsular non-expanding haematoma or parenchymal contusion without parenchymal laceration.
2	Haematoma	Non-expanding perirenal haematoma confined to Gerota fascia.
	Laceration	Renal parenchymal laceration ≤ 1 cm depth without urinary extravasation.
3	Laceration	Renal parenchymal laceration ≤ 1 cm depth without collecting system rupture or urinary extravasation. Any injury in the presence of a kidney vascular injury or active bleeding contained within Gerota fascia.
4	Laceration	Parenchymal laceration extending into urinary collecting system with urinary extravasation. Renal pelvis laceration and/or complete ureteropelvic disruption.
	Vascular	Segmental renal vein or artery injury. Active bleeding beyond Gerota fascia into the retroperitoneum or peritoneum. Segmental or complete kidney infarction(s) due to vessel thrombosis without active bleeding.
5	Laceration	Shattered kidney with loss of identifiable parenchymal renal anatomy.
	Vascular	Main renal artery or vein laceration or avulsion of renal hilum. Devascularised kidney with active bleeding.

**Advance one grade for bilateral injuries up to Grade 3.*

Note: The AAST renal injury scale was updated in 2018 and is presented in Table 4.1.1; however, all references included in this text are based on the AAST 1989 renal injury scale. The 2018 injury scale does not outperform the previous grading system in predicting bleeding and the need for treatment intervention and does not impact on the validity of the current recommendations [38].

4.1.2 Evaluation

The evaluation of stable patients with suspected renal trauma is now based on a trauma protocol computed tomography (CT) scan, often performed prior to involvement of a urologist [39, 40]. It is important to consider all parameters in the evaluation of the patient and to understand the indications for scanning when these are not absolute. Indicators of injury include a direct blow to the flank or rapid deceleration event (fall, high-speed road traffic accidents). Special consideration should be given to pre-existing renal disease [41] or the injured solitary kidney [42]. Pre-existing abnormality e.g. hydronephrosis makes injury more likely following trauma [43].

Vital signs should be recorded throughout the initial evaluation and give the most reliable indication of the urgency of the situation. Physical examination may reveal flank bruising, stab wounds, or bullet entry or exit wounds and abdominal tenderness.

Urinalysis, haematocrit and baseline creatinine are required. Haematuria (visible or non-visible) is the key finding. However, major injury such as disruption of the UPJ, pedicle injuries, segmental arterial thrombosis and stab wounds may not have haematuria [44, 45]. Haematuria that is out of proportion to the history of trauma may suggest pre-existing pathology [46]. Urine dipstick quickly evaluates for haematuria, but false-negative results can range from 3-10% [47]. An increased creatinine level usually reflects pre-existing renal pathology.

*4.1.3 **Imaging: criteria for radiographic assessment***

The goals of imaging are to grade the renal injury, document pre-existing renal pathology, demonstrate presence of the contralateral kidney and identify injuries to other organs. Haemodynamic status will determine the initial imaging pathway with unstable patients potentially requiring immediate intervention. The majority of patients with moderate to major trauma will have had a CT scan performed soon after presentation. In patients who have not had any imaging the indications for renal imaging are [31, 48-51]:

- visible haematuria;
- non-visible haematuria and one episode of hypotension;
- a history of rapid deceleration injury and/or significant associated injuries;
- penetrating trauma;
- clinical signs suggesting renal trauma e.g. flank pain, abrasions, fractured ribs, abdominal distension and/or a mass and tenderness.

4.1.3.1 Computed tomography

Computed tomography is the imaging modality of choice in stable patients. It is quick, widely available, and can accurately identify grade of renal injury [52], establish the presence of the contralateral kidney and demonstrate concurrent injuries to other organs. It is ideally performed as a three-phase study [53]:

1. The arterial phase assesses vascular injury and presence of active extravasation of contrast.
2. The nephrographic phase optimally demonstrates parenchymal contusions and lacerations.
3. The delayed phase imaging (five minutes) identifies collecting system/ureteric injury.

In practice, trauma patients usually undergo standardised whole-body imaging protocols and delayed phase imaging of the renal tract is not routinely performed. If there is suspicion that renal injuries have not been fully evaluated, delayed phase imaging is recommended. The rates of contrast-induced nephropathy seen in trauma patients is low [54].

4.1.3.2 Ultrasonography (US)

In the primary survey of a critically injured patient, FAST (Focused Assessment Sonography in Trauma) is used to identify hemoperitoneum as the cause of haemorrhage and hypovolemia. However, it is not routinely used for the assessment of solid organ injury as it is insensitive, operator dependant, does not define the injury well, and is inferior to CT. It is an option for follow-up [55-57].

4.1.3.3 Other imaging modalities

4.1.3.3.1 Intravenous pyelography (IVP)

Intravenous pyelography and radionuclide scans and magnetic resonance imaging (MRI) do not have a significant role in the trauma setting. The quality of one shot IVP is generally poor. Palpation of the contralateral (unaffected) kidney is a pragmatic surrogate of function [18].

The diagnostic accuracy of MRI in renal trauma is similar to that of CT [58, 59]. However, the logistical challenges of MRI make this modality impractical in acute trauma.

*4.1.4 **Disease management***

4.1.4.1 Non-operative management

The non-operative management of renal trauma can be viewed as a “package of care”; a stepwise approach starting with conservative treatment, followed by minimally invasive and/or surgical exploration, if necessary. It should be noted that an algorithm for “package of care” will vary in different centres according to available interventions; however, the importance of escalation in treatment interventions should be emphasised [29]. This approach has likely resulted in the rate of nephrectomy for high-grade renal injuries decreasing over time [60].

4.1.4.1.1 Blunt renal injuries

Haemodynamic stability is the primary criterion for the management of all renal injuries. Non-operative management has become the treatment of choice for most cases. In stable patients, this means a period of bed rest, serial blood tests, regular observation and re-imaging as indicated [26]. Primary conservative management is associated with a lower rate of nephrectomies, and no increase in immediate or long-term morbidity [61].

Grade 1-3 injuries are managed non-operatively [62, 63]. Grade 4 injuries are also mostly treated conservatively, but the requirement for subsequent intervention is higher [64]. Persistent urinary extravasation from an otherwise viable kidney after blunt trauma usually responds to stent placement and/or percutaneous drainage [65].

Grade 5 injuries often present with haemodynamic instability and major associated injuries. There is thus a higher rate of exploration and nephrectomy [66, 67]. However, several studies now support expectant management in patients with Grade 4 and 5 injuries [29, 30, 68-72]. Similarly, unilateral main arterial injuries or arterial thrombosis are normally managed non-operatively in haemodynamically stable patients with surgical repair reserved for bilateral artery injuries or injuries involving a solitary functional kidney [73]. Pre-hospital prolonged warm ischaemia usually results in irreparable damage and renal loss.

One study designed a nomogram to predict the need for an intervention to stop bleeding in high-grade renal trauma. Factors which increased risk of intervention were a haematoma size of > 12 cm, penetrating trauma, vascular contrast extravasation, pararenal haematoma extension, concomitant injuries, and shock [74].

4.1.4.1.2 Penetrating renal injuries

Penetrating abdominal wounds have traditionally been managed surgically. However, selective non-operative management of penetrating abdominal wounds is now accepted following detailed assessment in stable patients [64, 75-77].

For renal injuries, the site of the wound, haemodynamic stability, and diagnostic imaging are the main determinants for intervention. The majority of low-grade stab wounds posterior to the anterior axillary line can be managed non-operatively in stable patients [78]. Grade 3 or higher injuries due to stab wounds in stable patients can be managed expectantly but warrant closer observation as the clinical course is more unpredictable and associated with a higher rate of delayed intervention [78, 79]. High-grade injuries, concomitant abdominal injuries and gunshot wounds are most likely to fail non-operative management [77]. A gunshot wound is an independent risk factor for nephrectomy in grade IV and V traumatic renal injuries, compared with stab wounds [80]. Overall, non-operative management of penetrating injuries in selected stable patients is associated with a successful outcome in up to 50% of stab wounds and up to 40% of gunshot wounds [30, 81-84].

4.1.4.1.3 Selective angioembolisation

Selective angioembolisation (AE) has a key role in the non-operative management of blunt renal trauma in haemodynamically stable patients [85]. Currently there are no validated criteria to identify patients who require AE and its use in renal trauma remains variable. Accepted CT findings indicating the need for AE are active extravasation of contrast, arteriovenous fistula (AVF) and pseudo-aneurysm [86]. The presence of both active extravasation of contrast and a large haematoma (> 25 mm depth) predict the need for AE with good accuracy [86, 87].

Angioembolisation has been utilised in the non-operative management of all grades of renal injury; however, it is likely to be most beneficial in the setting of high-grade renal trauma (AAST > 3) [88-90]. Non-operative management of high-grade renal trauma, where AE is included in the management algorithm, can be successful in up to 94.9% of Grade 3, 89% of Grade 4 and 76% of Grade 5 injuries [85, 88, 91-93]. Increasing grade of renal injury is associated with increased risk of failed AE and need for repeat intervention [94]. Gross haematuria, haemodynamic instability, Grade 5 trauma and urinary extravasation are significant predictors of AE failure [95].

Repeat embolisation prevents nephrectomy in 67% of patients. Open surgery after failed embolisation usually results in nephrectomy [94, 96]. Despite concerns regarding parenchymal infarction and the use of iodinated contrast media, AE does not appear to affect the occurrence or outcome of acute kidney injury following renal trauma [97]. For high-grade injuries, AE has also been shown to have a high success rate and to provide the greatest protection of renal function, with no difference in renal function after long-term follow-up [98]. In severe polytrauma or high operative risk, the main artery may be embolised, either as a definitive treatment or as a step to a more controlled nephrectomy.

The evidence supporting AE in penetrating renal trauma is sparse. One study found that AE is three times more likely to fail in penetrating trauma [75]. However, AE has been used successfully to treat acute haemorrhage, AVF and pseudo-aneurysms resulting from penetrating renal trauma [99].

4.1.4.1.4 Ureteral stenting and urinary catheterisation

In the management of high-grade renal trauma with collecting system injuries, ureteral stenting in asymptomatic patients has proven no clear benefits. Current evidence suggests intervention (ureteral stenting, nephrostomy or perirenal drainage) only when patients develop symptoms (flank pain, fever, leucocytosis) related with persistent urinary leaks [65, 100].

Catheterisation is not necessary in stable patients with low-grade injury. Patients with severe visible haematuria, who require monitoring or stenting, benefit from catheterisation. A longer period of catheterisation is required if a stent is placed. Once the haematuria lightens and the patient is mobile, the catheter should be removed.

4.1.4.1.5 Repeat imaging (early)

Computed tomography scans should be performed on patients with fever, unexplained decreased haematocrit, or significant flank pain. Repeat imaging is also recommended in high-grade injury and in penetrating trauma two to four days after trauma to minimise the risk of missed complications. Repeat imaging can be safely omitted for patients with Grade 1-3 injuries as long as they remain clinically well [101, 102].

4.1.4.2 Surgical management

4.1.4.2.1 Indications for renal exploration

A non- or transient- response to initial fluid resuscitation is a strong indication for exploration [75, 76]. There is a trend towards ongoing resuscitation and AE [103]. Exploration is influenced by aetiology and grade of injury, transfusion requirements, the need to explore associated abdominal injuries, and the discovery of an expanding or pulsatile peri-renal haematoma at laparotomy [104]. Haemodynamic instable grade 5 vascular injuries are an indication for exploration [91, 105].

4.1.4.2.2 Operative findings and reconstruction

The overall exploration rate for blunt trauma is low [106]. The goals of exploration following renal trauma are vascular control and renal salvage. Most series recommend the transperitoneal approach for surgery [107, 108]. Entering the retroperitoneum and leaving the confined haematoma undisturbed within the perinephric fascia is recommended; temporarily packing the fossa tightly with laparotomy pads can salvage the kidney in instances of intra-operative haemorrhage [109]. Access to the pedicle is obtained either through the posterior parietal peritoneum, which is incised over the aorta, just medial to the inferior mesenteric vein or by bluntly dissecting along the plane of the psoas muscle fascia, adjacent to the great vessels, and directly placing a vascular clamp on the hilum [109].

Stable haematomas detected during exploration for associated injuries should not be opened. Central or expanding haematomas indicate injuries of the renal pedicle, aorta, or vena cava and are potentially life-threatening and warrant further exploration [110].

Feasibility of renal reconstruction should be judged during the operation. The overall rate of patients who undergo a nephrectomy during exploration is approximately 30% [111]. Other intra-abdominal injuries also increase the likelihood of nephrectomy [112]. Mortality is associated with overall severity of the injury and not often a consequence of the renal injury itself [113]. High velocity gunshot injuries make reconstruction difficult and nephrectomy is usually required [114].

Renorrhaphy is the most common reconstructive technique. Partial nephrectomy is required when non-viable tissue is detected. Watertight closure of the collecting system is desirable, although closing the parenchyma over the injured collecting system is acceptable.

The use of haemostatic agents and sealants in reconstruction is helpful [115]. In all cases, drainage of the ipsilateral retroperitoneum is recommended.

The repair of vascular injuries is seldom, if ever, effective [116]. Repair should be attempted in patients with a solitary kidney or bilateral injuries [117]. Nephrectomy for main artery injury has outcomes similar to those of vascular repair and does not worsen post-treatment renal function in the short-term. Bleeding or dissection of the main renal artery may also be managed with a stent.

4.1.5 ***Follow-up***

The risk of complications relates to aetiology, injury grade, and mode of management [118, 119]. Follow-up includes physical examination, urinalysis, diagnostic imaging, blood pressure measurement and serum creatinine [66]. Potential complications are primarily identified by imaging; however, follow-up imaging is not recommended in low-grade uncomplicated injury. Ultrasound can be used to define the post-injury anatomy avoiding further ionising radiation. Nuclear scans are useful for documenting functional recovery following renal injury and reconstruction [120]. Annual blood pressure monitoring is recommended to exclude renovascular hypertension [121].

4.1.5.1 Complications

Early (≤ 1 month) complications include bleeding, infection, perinephric abscess, sepsis, urinary fistula, hypertension, urinary extravasation, and urinoma. Delayed complications include bleeding, calculus formation, chronic pyelonephritis, hypertension, AVF, hydronephrosis and pseudo-aneurysms. Bleeding may be life-threatening with elective angiographic embolisation the preferred treatment [122]. Perinephric abscess formation is initially managed by percutaneous drainage [106].

Hypertension is rare [123, 124]. It may occur acutely because of external compression from peri-renal haematoma (Page kidney), chronically due to compressive scar formation, or as a result of renal artery thrombosis, segmental arterial thrombosis, renal artery stenosis (Goldblatt kidney), or AVF. Arteriography may be required. Treatment, including medical management, excision of the ischaemic parenchymal segment, vascular reconstruction, or nephrectomy, is indicated if hypertension persists [121].

Arteriovenous fistulae usually present with delayed onset of significant haematuria, most often after penetrating trauma. Percutaneous embolisation is often effective for symptomatic AVF, but larger fistulae may require surgery [125]. The development of pseudo-aneurysm is a rare complication following blunt trauma.

*4.1.6 **Iatrogenic renal injuries***

Iatrogenic renal trauma needs to be recognised and managed promptly to minimise morbidity and mortality. The most common causes of iatrogenic renal injuries are percutaneous access to kidney, stone surgery, cancer surgery (laparoscopic and open) and transplantation [3]. The diagnosis and management follow the same principles as outlined previously.

*4.1.7 **Summary of evidence and recommendations for evaluation and management of renal trauma***

Summary of evidence	**LE**
Vital signs on admission give the most reliable indication of the urgency of the situation.	3
Special consideration should be given to patients with a solitary kidney and pre-existing renal disease.	4
Haematuria is a key finding following renal trauma; although, it may not be present in certain situations.	3
A multiphase CT scan is the best method for the diagnosis and staging of renal injuries in haemodynamically stable patients.	3
Haemodynamic stability is the primary criterion for selecting patients for non-operative management.	3
Ureteric stenting in stable asymptomatic Grade 4 renal injuries is not necessary.	3
Selective angioembolisation is effective in patients with active bleeding from renal injury, without other indications for immediate abdominal operation.	3
Renal reconstruction should be attempted if haemorrhage is controlled and there is sufficient viable renal parenchyma.	3
Iatrogenic renal injuries are procedure-dependent (1.8-15%); the most common injuries are vascular.	3
Limited literature exists with regard to long-term consequences of renal trauma. Current follow-up includes physical examination, urinalysis, diagnostic imaging, serum creatinine, as well as annual blood pressure monitoring to diagnose renovascular hypertension.	4

Recommendations	Strength rating
Evaluation	
Assess haemodynamic stability upon admission.	Strong
Record past renal surgery, and known pre-existing renal abnormalities (ureteropelvic junction obstruction, solitary kidney, urolithiasis).	Strong
Test for haematuria in a patient with suspected renal injury.	Strong
Perform a multiphase computed tomography (CT) scan in trauma patients with: • visible haematuria; • non-visible haematuria and one episode of hypotension; • a history of rapid deceleration injury and/or significant associated injuries; • penetrating trauma; • clinical signs suggesting renal trauma e.g. flank pain, abrasions, fractured ribs, abdominal distension and/or a mass and tenderness.	Strong
Management	
Manage stable patients with blunt renal trauma non-operatively with close monitoring and re-imaging as required.	Strong
Manage isolated Grade 1-4 stab and low-velocity gunshot wounds in stable patients non-operatively.	Strong
Use selective angioembolisation for active renal bleeding if there are no other indications for immediate surgical exploration.	Strong
Insert urinary system drainage (ureteral stenting, nephrostomy) or perirenal drainage in cases of persistent or symptomatic urinary leak.	Strong
Proceed with renal exploration in the presence of: • persistent haemodynamic instability; • Grade 5 vascular or penetrating injury; • expanding or pulsatile peri-renal haematoma.	Strong
Attempt renal reconstruction if haemorrhage is controlled and there is sufficient viable renal parenchyma.	Weak
Repeat imaging in high-grade and penetrating injuries and in cases of fever, worsening flank pain, or falling haematocrit.	Strong
Follow-up approximately three months after major renal injury with urinalysis, individualised radiological investigation eg.: nuclear scintigraphy, CT or ultrasound, blood pressure measurement and renal function tests. Longer term annual follow-up for blood pressure is recommended.	Weak

4.2 Ureteral Trauma

*4.2.1 **Incidence***

Trauma to the ureters is relatively rare as they are protected by their small size, mobility, posterior location, and the adjacent musculoskeletal and visceral structures. Iatrogenic injury during open, laparoscopic and endoscopic surgery is responsible for the majority of cases [126]. The injury is often missed intra-operatively and may result in significant morbidity [127].

*4.2.2 **Epidemiology, aetiology, and pathophysiology***

Overall, ureteral trauma accounts for 1-2.5% of urinary tract trauma [126, 128-130], Penetrating external ureteral trauma, mostly by gunshot wounds, is the commonest form in most modern series, [126, 128, 131]. Higher rates of ureteral injury are seen in modern combat injuries [127]. About one-third of cases of external trauma to the ureters are caused by blunt trauma, mostly road traffic accidents [129, 130].

Ureteral injury should be suspected in all cases of penetrating abdominal injury, although it occurs in just 2-3% of cases [126]. It should also be suspected in blunt trauma with significant deceleration as pelvi-ureteral disruption can result. [126]. The distribution of external ureteral injuries along the ureter varies between series, but it is commonest in the upper ureter [128-130].

The incidence of urological iatrogenic trauma has decreased in the last twenty years due to improvements in technique, instrument technology, training methods and subspecialisation [131, 132].

Iatrogenic ureteral trauma can result from:
- ligation with a suture,
- rushing by a surgical instrument,
- partial or complete transection by unintended scalpel incision,
- thermal injury,
- or ischaemia from devascularisation [131, 133, 134].

Injury usually involves the lower ureter [126, 131, 133, 135]. Gynaecological operations are the most common cause of significant iatrogenic trauma (Table 4.2.1). It also occurs in colorectal operations, (resection of the distal colon) and vascular surgery (aortic aneurysm repair) [136, 137]. There has been a significant decrease in the rate of ureteral injury during robot-assisted procedures [138] and colorectal surgery [42]. However, minimally invasive techniques have not further reduced the rate of ureteral injuries in gynaecological surgery [139-141].

Ureteroscopy is a common cause of iatrogenic ureteric trauma contributing up to 71.6% in some series [142]. The post-ureteroscopic lesion scale (PULS) aims to standardise intra-operative traumatic findings during ureteroscopy [143]. Predictors for high grade ureteric injury include male gender, longer operative times, and ureteral access sheath (UAS) insertion times [142].

A smaller proximal ureter diameter seen in CT scanning and a predictor for high-grade ureteral injury during ureteral access sheath (UAS) placement [144]. A small RCT using pre-operative silodosin 8 mg for three days significantly reduced Grade 2 or higher ureteral injuries due to UAS insertion [145].

Risk factors for iatrogenic trauma include conditions that alter the normal anatomy, e.g., advanced malignancy, prior surgery or irradiation, diverticulitis, endometriosis, anatomical abnormalities, and major haemorrhage [131, 136, 146, 147]. Occult ureteral injury occurs more often than reported and not all injuries are diagnosed intra-operatively [127].

Table 4.2.1: Incidence of ureteral injury in various procedures

Procedure	Percentage %
Gynaecological [135, 148-150]	
Emergency caesarean delivery	0.01-0.06
Vaginal hysterectomy	0.02-0.5
Abdominal hysterectomy	0.03-2.0
Laparoscopic hysterectomy	0.13-6.0
Urogynaecological (anti-incontinence/prolapse)	1.7-4.3
Colorectal [134, 138, 148, 151, 152]	0.15-10
Ureteroscopy [132]	

Mucosal abrasion	0.3-4.1
Ureteral perforation	0.2-2.0
Intussusception/avulsion	0-0.3
Post-chemotherapy lymph node dissection for non-seminoma germ cell tumours	0.02
Radical prostatectomy [154]	
Open retropubic	0.05-1.6
Robot-assisted	0.05-0.4

*4.2.3 **Diagnosis***

The diagnosis of ureteral trauma is challenging; therefore, a high index of suspicion should be maintained. In penetrating external trauma, it is best identified intra-operatively during laparotomy [155]. The diagnosis is delayed in most cases of blunt trauma and iatrogenic trauma [131, 135, 156].

4.2.3.1 Clinical diagnosis

External ureteral trauma usually accompanies severe abdominal and pelvic injuries. Penetrating trauma is usually associated with vascular and intestinal injuries, while blunt trauma is associated with damage to the pelvic bones and lumbosacral spinal injuries [129, 130]. Haematuria is an unreliable and poor indicator of ureteral injury, as it is present in only 50-75% of patients [126, 131, 157].

Iatrogenic injury may be noticed during the primary procedure, when intravenous dye (e.g. indigo carmine) is injected to exclude ureteral injury. Early recognition facilitates immediate repair and provides a better outcome [146, 155]. However, it is usually presenting later in the same admission, with the untoward sequelae of ureteral injury - upper tract obstruction, sepsis, abdominal distension, and when it is discovered by subsequent evidence of upper tract obstruction, urinary fistulae formation or sepsis. The following clinical signs are characteristic of delayed diagnosis - flank pain, urinary incontinence, vaginal or drain urinary leakage, haematuria, fever, and uraemia or urinoma. The complication rate increases with delayed diagnosis [126, 156, 158].

4.2.3.2 Radiological diagnosis

Multi-phase CT is the mainstay imaging technique for trauma patients. Generally, it is widely available and allows for multi-phasic assessment of all of the structures in the pelvis and abdomen. Computed tomography urography (CTU) is the examination of choice when ureteral injuries are suspected [159, 160]. Extravasation of contrast medium in the delayed phase is the hallmark sign of injury. However, hydronephrosis, ascites, urinoma or mild ureteral dilation are often the only signs. In unclear cases, a retrograde or antegrade urography is the best method for confirmation [131]. Intravenous pyelography, especially one-shot IVP, is unreliable in diagnosis, as it is negative in up to 60% of patients [126, 131].

*4.2.4 **Prevention of iatrogenic trauma***

The prevention of iatrogenic trauma to the ureters depends upon the visual identification of the ureters and careful intra-operative dissection in their proximity [131, 133, 134]. The use of prophylactic pre-operative ureteral stent insertion assists in visualisation and palpation can be used in cases of higher complexity [37, 161]. It is probably makes it easier to detect ureteral injury intra-operatively [133]; however, it is not associated with a decrease in the likelihood of ureteric injury [152]. Apart from its evident disadvantages (potential complications, increased surgical time and cost), a stent may alter the location of the ureter and diminish its flexibility [133, 151]. A retrograde instillation of indocyanine green in the ureters has been shown to safely allow their identification and preservation in complex robotic-assisted colorectal surgeries [162, 163].

*4.2.5 **Management***

Management of ureteral trauma depends on many factors including the aetiology, severity, and location of the injury. Immediate diagnosis of a ligation injury during an operation can be managed by de-ligation and stent placement. Partial injuries can be repaired immediately with a stent or urinary diversion via a nephrostomy tube. Stenting is helpful because it provides canalisation and may decrease the risk of stricture [131, 164, 165]. Immediate repair of complete ureteral injury is advisable as it significantly decreases the need for secondary or tertiary procedures compared to delayed repair [164]. The ureter is mobilised on both ends and a spatulated end-to-end anastomosis is performed. Primary repair by uretero-ureterostomy or ureteric re-implantation can be safely performed laparoscopically at the time of the iatrogenic injury, with good medium-term results [166]. In cases of unstable trauma patients, a 'damage control' approach is preferred with ligation of the ureter, diversion of the urine (e.g. via a nephrostomy), and a later delayed definitive repair [167]. A national trauma

database study reported that the majority of blunt low- and high-severity traumatic ureteric injuries in both stable and unstable patients were treated by nephrostomy or stenting [168]. Exploratory laparotomy for associated traumatic injuries was a predictor for immediate ureteral reconstruction [168]. Injuries that are diagnosed late are usually managed first by placement of a nephrostomy tube or stent [131].

Endo-urological treatment of delayed-diagnosed ureteral injuries by internal stenting, with or without dilatation, is the first step in most cases. It is performed either retrogradely or antegradely via a percutaneous nephrostomy, and it has a variable success rate of 14-19% [169-171]. An open or robot-assisted laparoscopic surgical repair is necessary in case of failure [172]. The basic principles for any surgical repair of a ureteral injury are outlined in Table 4.2.2. Wide debridement is highly recommended for gunshot wound injuries due to the 'blast effect' of the injury.

4.2.5.1 Proximal and mid-ureteral injury

Injuries shorter than 2-3 cm can usually be managed by a primary uretero-ureterostomy [126]. When this approach is not feasible, a ureterocalicostomy should be considered. In case of a large extra-renal pelvis and a stricture at the UPJ, a pelvic spiral flap (Culp de Weerd) is an option [173]. In extensive ureteral loss, a transureteroureterostomy is a valid option. The proximal stump of the ureter is transposed across the midline and anastomosed to the contralateral ureter. The reported stenosis rate is 4% and re-intervention or revision occurs in 10% of cases [174].

4.2.5.2 Distal ureteral injury

Distal injuries are best managed by ureteral re-implantation (ureteroneocystostomy) because the primary trauma jeopardises the blood supply to the distal ureter. The question of refluxing vs. non-refluxing ureteral re-implantation remains unresolved in the literature. The risk for clinically significant reflux should be weighed against the risk for ureteral obstruction.

A psoas hitch between the bladder and the ipsilateral psoas tendon is usually needed to bridge the gap and to protect the anastomosis from tension. The contralateral superior vesical pedicle may be divided to improve bladder mobility. The reported success rate is very high (97%) [174]. In extensive mid-lower ureteral injury, the large gap can be bridged with a tabularised L-shaped bladder flap (Boari flap). It is a time-consuming operation and unsuited to the acute setting. The success rate is reported to be 81-88% [175].

4.2.5.3 Long segment ureteral injury

A longer ureteral injury can be replaced using a segment of the intestines, usually the ileum (ileal interposition graft). This should be avoided in patients with impaired renal function or known intestinal disease. Follow-up includes serum chemistry to diagnose hyperchloremic metabolic acidosis [176]. The long-term complications include anastomotic stricture (3%) and fistulae (6%) [177]. Another option is downward nephropexy and a long Boari flap. In cases of extensive ureteral loss or after multiple attempts at ureteral repair, the kidney can be relocated to the pelvis (auto-transplantation). The renal vessels are anastomosed to the iliac vessels and a ureteral re-implantation is performed [178, 179].

Buccal mucosa ureteroplasty is an option for long segment ureteral injury, especially after a previous failed reconstruction, as an alternative to auto-transplantation. The overall success rate is 90%, but experience is limited [180].

4.2.5.4 Permanent urinary diversion/nephrectomy

Following early or late repairs, up to 38% of patients develop secondary ureteric strictures requiring interventions [181] or palliative management by indwelling ureteric catheter or nephrostomy tube [164, 182]. Moreover, in some series up to 10% of failed repairs have evidence of renal parenchyma or function loss, leading to nephrectomy [164, 181].

Table 4.2.2: Principles of surgical repair of ureteral injury

Debridement of necrotic tissue
Spatulation of ureteral ends
Watertight tension-free mucosa-to-mucosa anastomosis using absorbable sutures
Internal stenting

4.2.6 *Summary of evidence and recommendations for the management of ureteral trauma*

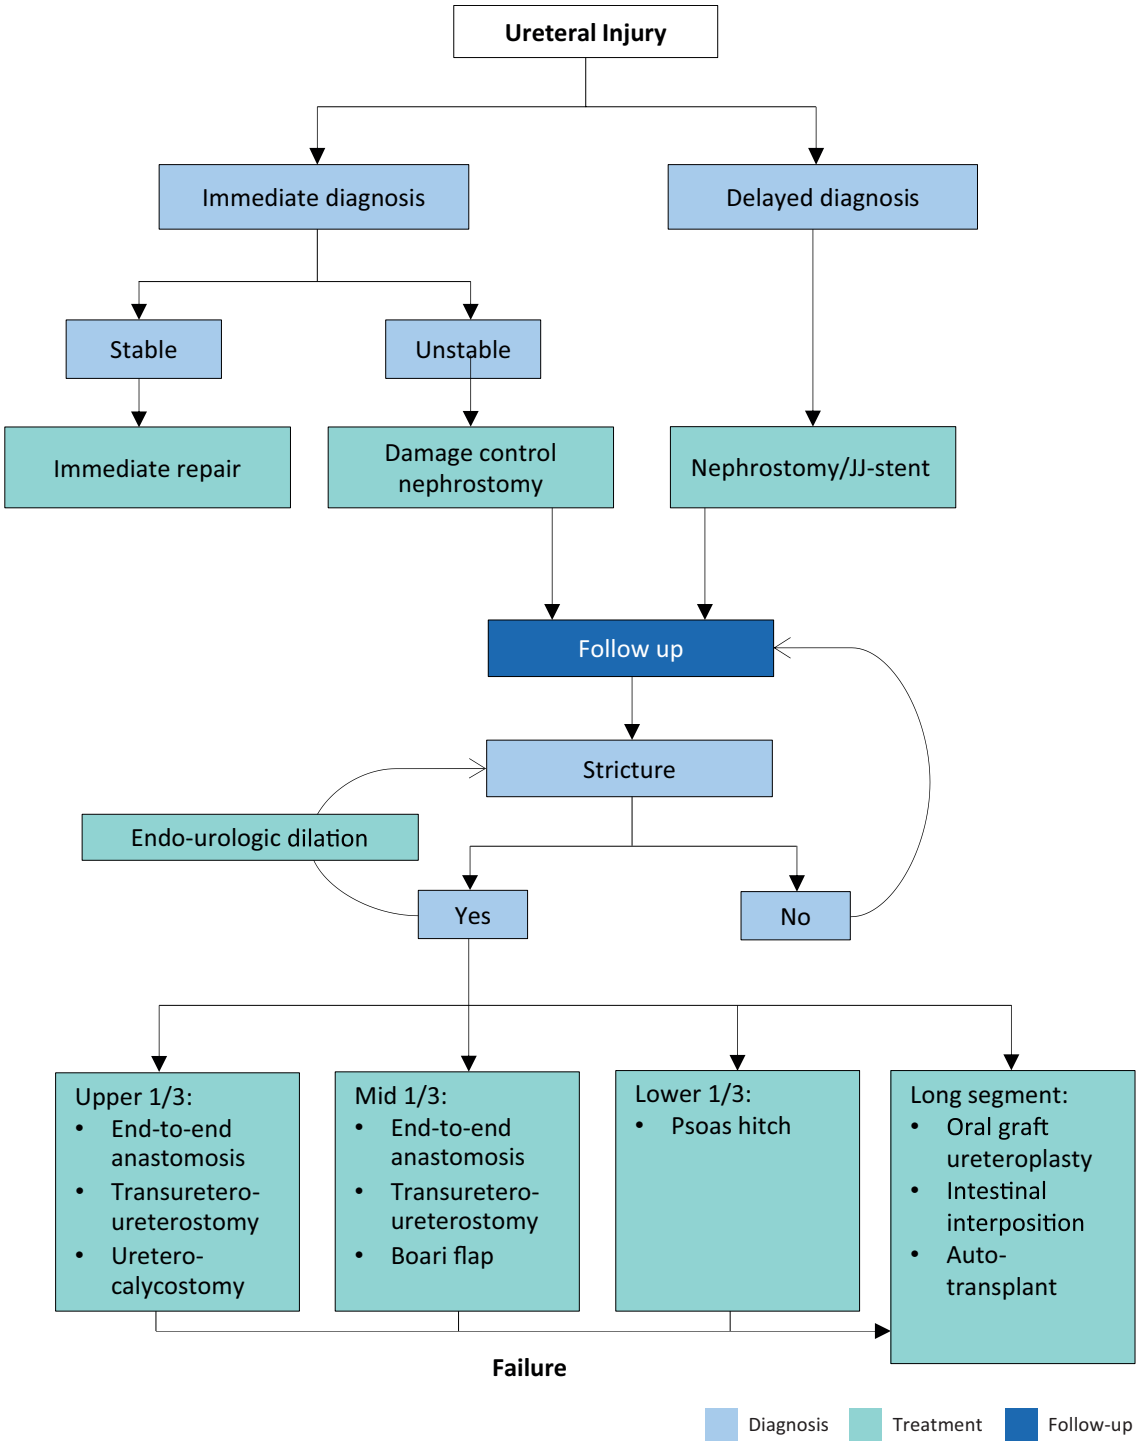
Summary of evidence	LE
Iatrogenic ureteral trauma is the most common cause of ureteral injury.	3
Gunshot wounds account for the majority of penetrating ureteral injuries, while road traffic accidents account for most blunt injuries.	3
Ureteral trauma usually accompanies severe abdominal and pelvic injuries.	3
Haematuria is an unreliable and poor indicator of ureteral injury.	3
Pre-operative prophylactic stents do not prevent ureteral injury; however, they may assist in its detection.	2
Endo-urological treatment of small ureteral fistulae and strictures is safe and effective.	3
Major ureteral injury requires ureteral reconstruction following temporary urinary diversion.	3

Recommendations	Strength rating
Visually identify the ureters to prevent ureteral trauma during complex abdominal and pelvic surgery.	Strong
Beware of concomitant ureteral injury in all abdominal penetrating trauma, and in deceleration-type blunt trauma.	Strong
Use pre-operative prophylactic stents in high-risk cases.	Strong
Repair iatrogenic ureteral injuries recognised during surgery immediately.	Strong
Treat iatrogenic ureteral injuries with delayed diagnosis by nephrostomy tube/JJ stent urinary diversion.	Strong
Manage ureteral strictures by ureteral reconstruction according to the location and length of the affected segment.	Strong

4.2.7 *Treatment algorithms*

Management of ureteral injuries

Figure 4.2.1: Management of ureteral injuries



4.3 Bladder Trauma

4.3.1 *Classification*

Bladder trauma is primarily classified according to the location of the injury: **intraperitoneal**, **extraperitoneal**, and **combined** intra-extraperitoneal [183], as it guides further management [184]. Bladder trauma is categorised by aetiology: **non-iatrogenic** (blunt and penetrating) and **iatrogenic** (external and internal).

4.3.2 *Epidemiology, aetiology, and pathophysiology*

Road traffic accidents (Motor vehicle accidents) are the most common cause of blunt bladder injury, followed by falls and other accidents. The main mechanisms are pelvic crush and blows to the lower abdomen [129, 183, 185]. Most patients with blunt bladder injury have associated pelvic fractures (60-90%) and other

intra-abdominal injuries (44-68.5%) [186, 187]. Pelvic fractures are associated with bladder injury in about 3% of cases [129, 188]; however, this can be as high as 26.5% in cases of severe pelvic injury [189]. Bladder injury is associated with urethral injury in 5-20% of cases [184, 187, 190].

The incidence of extraperitoneal (22.4-61.1%), and intraperitoneal (38.9-65.8%) injuries varies among series [191]. **Extraperitoneal injury** is almost always associated with pelvic fractures [185, 187]. It is usually caused by distortion of the pelvic ring, with shearing of the anterolateral bladder wall near the bladder base (at its fascial attachments), or by a contrecoup at the opposite side. The highest risk of bladder injury was found in disruptions of the pelvic circle with displacement > 1 cm, diastasis of the pubic symphysis > 1 cm, and pubic rami fractures [129, 184]. Occasionally, the bladder is directly perforated by a sharp bony fragment [184].

Intraperitoneal injury is caused by a sudden rise in intravesical pressure of a distended bladder, secondary to a blow to the pelvis or lower abdomen. The bladder dome is the weakest point of the bladder and ruptures usually occur there [184]. Penetrating injuries, mainly gunshot wounds, are rare except in conflict zones and violent urban areas [183, 192, 193]. Improvised explosive devices are the main cause of combat related bladder injuries in asymmetric warfare [194].

4.3.2.1 Iatrogenic bladder trauma (IBT)

The bladder is the urological organ that is most commonly affected by iatrogenic injury [195]. Table 4.3.1 shows the incidence of IBT during various procedures. **External IBT** occurs most often during obstetric and gynaecological procedures, followed by urological and general surgical operations [195]. Main risk factors are previous surgery, inflammation and malignancy [195]. Bladder perforations occur in up to 4.9% of mid-urethral sling operations for stress urinary incontinence in women. This rate is significantly lower in the obturator route compared to the retropubic route [196].

Internal IBT mainly occurs during transurethral resection of the bladder (TURB). Reported risk factors are larger tumours, older age, pre-treated bladders (previous TURB, intravesical instillations) and location at the bladder dome [197, 198]. Tumours at the lateral wall pose a risk factor because of the obturator jerk [199, 200]. Extraperitoneal perforations are more frequent than intraperitoneal perforations [198, 201], and perforations requiring intervention are rare (0.16-0.57%) [197].

Table 4.3.1: Incidence of iatrogenic bladder trauma during various procedures

Procedure	Percentage (%)
Obstetrics & Gynaecology	
Laparoscopic/Robotic radical hysterectomy (malignant) [202]	4.19-4.59
Abdominal radical hysterectomy (malignant) [202]	2.37
Hysterectomy laparoscopic/abdominal/vaginal (benign) [141, 203]	0.1-2.5
Caesarean delivery [204]	0.08-0.94
General surgery	
Abdominal cytoreductive surgery [205]	4.5
Rectal procedures [206]	0.27-0.41
Small/large bowel procedures [206]	0.12-0.14
Laparoscopic inguinal hernia repair [207]	0.04-0.14
Urology specific	
Transurethral resection of the bladder [208, 209]	3.5-58
Retropubic male sling [210]	8.0-19
Mid-urethral sling (retropubic route) [196, 211]	4.91-5.5
Transvaginal mesh surgery [212]	2.84
Pubovaginal sling [211]	2.8
Laparoscopic sacrocolpopexy [213]	1.9
Mid-urethral sling (transobturator route) [211]	1.61
Burch colposuspension [211, 214]	1.0-1.2
Native tissue colporrhaphy [212]	0.53

*4.3.3 **Diagnostic evaluation***

The principal sign of bladder injury is visible haematuria [184, 185]. Absolute indications for bladder imaging include: visible haematuria and a pelvic fracture [184] or non-visible haematuria combined with high-risk pelvic fracture (disruption of the pelvic circle with displacement > 1 cm or diastasis of the pubic symphysis > 1 cm) or posterior urethral injury [184]. Bladder trauma should also be suspected in patients with blunt urethral trauma and high Injury Severity Score (ISS) [215]. In the absence of these absolute indications, further imaging is based on clinical signs and symptoms including [184, 185, 192, 216]:

- inability to void or inadequate urine output;
- abdominal tenderness or distension due to urinary ascites, or signs of urinary ascites in abdominal imaging;
- uraemia and elevated creatinine level due to intraperitoneal re-absorption;
- entry/exit wounds at lower abdomen, perineum, or buttocks in penetrating injuries.

Intra-operative signs of external iatrogenic bladder injury include: extravasation of urine, visible laceration, visible bladder catheter, and blood and/or gas in the urine bag during laparoscopy [204]. Direct inspection is the most reliable method of assessing bladder integrity [195]. Retrograde bladder filling (with or without instillation of dye e.g., methylene blue) helps to detect smaller lesions [217, 218]. If bladder perforation is close to the trigone, the ureteric orifices should be inspected [195, 204].

Internal bladder injury is recognised by cystoscopic identification of fatty tissue, dark space, or bowel [208]. It may also be detected by the inability to distend the bladder, low return of irrigation fluid, or abdominal distension [219].

Post-operatively, missed bladder trauma is diagnosed by haematuria, abdominal pain, abdominal distension, ileus, peritonitis, sepsis, urine leakage from the wound, decreased urinary output, or increased serum creatinine [195, 204]. An IBT during hysterectomy or caesarean delivery can result in vesicovaginal or vesicouterine fistulae [204, 220].

4.3.3.1 Cystography

Cystography is the preferred diagnostic modality for non-iatrogenic bladder injury and for a suspected IBT in the post-operative setting [220, 221]. Both plain and CT cystography have a comparable sensitivity (90-95%) and specificity (100%) [185, 222]. However, CT cystography is superior in the identification of bony fragments in the bladder and bladder neck injuries, as well as concomitant abdominal injuries [184, 187].

Cystography must be performed using retrograde filling of the bladder with a minimum volume of 300-350 mL of dilute contrast material [221, 223]. Passive bladder filling by clamping the urinary catheter during the excretory phase of CT or IVP is not sufficient to exclude bladder injury [185]. Intraperitoneal extravasation is visualised by free contrast medium in the abdomen outlining bowel loops or abdominal viscera [224]. Extraperitoneal bladder injury is typically diagnosed by flame-shaped areas of contrast extravasation in the peri-vesical soft tissues. Contrast medium in the vagina is a sign of vesicovaginal fistula [220].

4.3.3.2 Cystoscopy

Cystoscopy is the preferred method for detection of intra-operative bladder injuries as it may directly visualise the laceration and can localise the lesion in relation to the position of the trigone and ureteral orifices [224]. A lack of bladder distension during cystoscopy suggests a large perforation. Cystoscopy is recommended to detect perforation of the bladder (or urethra) following retropubic sub-urethral sling operations [196, 214]. Routine intra-operative cystoscopy during other gynaecologic procedures is not recommended [225], although the threshold to perform it should be low in any suspected bladder injury.

*4.3.4 **Prevention***

The risk of bladder injury is reduced by emptying the bladder by urethral catheterisation in every procedure where the bladder is at risk [217, 226]. Furthermore, the catheter's balloon can aid in identification of the bladder [217]. During TURB for tumours at the lateral wall, the incidence of internal IBT can be reduced by obturator nerve block or adequate muscle relaxation [200]. There is conflicting evidence whether bipolar TURB can reduce the risk for an obturator jerk [199, 200]. The use of combat pelvic protection systems reduces the risk of bladder and other genitourinary injuries due to the blast mechanism of improvised explosive devices [194, 227].

*4.3.5 **Disease management***

4.3.5.1 Conservative management

Conservative treatment, which comprises of clinical observation, continuous bladder drainage and antibiotic prophylaxis [198], is the standard treatment for an uncomplicated extraperitoneal injury due to blunt [184, 187, 190] or iatrogenic trauma [198].

Conservative treatment can also be chosen for uncomplicated intraperitoneal injury after TURB or other operations, but only in the absence of peritonitis and ileus [209, 224]. Placement of an intraperitoneal drain is advocated, especially when the lesion is larger [219, 228]. Penetrating extraperitoneal bladder injuries (only if minor and isolated) can also be managed conservatively [191, 216, 229].

4.3.5.2 Surgical management

Bladder closure is performed with absorbable sutures [191, 195]. There is no evidence that two-layer is superior to watertight single-layer closure [187, 191].

4.3.5.2.1 Blunt non-iatrogenic trauma

Most extraperitoneal ruptures can be treated conservatively; however, bladder neck involvement, bone fragments in the bladder wall, concomitant rectal or vaginal injury or entrapment of the bladder wall necessitate surgical intervention [184, 230]. There is an increasing trend to treat pelvic ring fractures with open stabilisation and internal fixation with osteosynthesis material. During this procedure, an extraperitoneal rupture should be sutured concomitantly in order to reduce the risk of infection [231]. Likewise, an extraperitoneal rupture should be sutured during surgical exploration for other injuries, in order to decrease the risk of complications and to reduce recovery time [190]. In case of extraperitoneal injury with pelvic fractures treated by internal fixation, there is conflicting evidence about the need to repair the bladder in order to reduce the risk of infection [231, 232].

Intraperitoneal ruptures should always be managed by surgical repair [184, 187] because intraperitoneal urine extravasation can lead to peritonitis, intra-abdominal sepsis and death [186]. Abdominal organs should be inspected for possible associated injuries and urinomas must be drained if detected. Laparoscopic suturing of the intraperitoneal rupture is also possible [185].

4.3.5.2.2 Penetrating non-iatrogenic trauma

Penetrating bladder injury is managed by emergency exploration, debridement of devitalised bladder wall and primary bladder repair [192, 193]. A midline exploratory cystotomy is advised to inspect the bladder wall and the distal ureters [191, 192]. In gunshot wounds, there is a strong association with intestinal and rectal injuries, usually requiring faecal diversion [192, 216]. Most gunshot wounds are associated with two transmural injuries (entry and exit wounds) and the bladder should be carefully checked for these two lesions [192]. As the penetrating agent (bullet, knife) is not sterile, antibiotic treatment is advised [193]. In selected patients (haemodynamically stable without associated injuries), penetrating well-contained extraperitoneal bladder injuries probably can be safely managed non-operatively [233].

4.3.5.2.3 Iatrogenic bladder trauma

Perforations lacerations intra-operatively are primarily closed [234]. Bladder injuries not recognised during surgery or internal IBT should be managed according to their location. The standard of care for intraperitoneal injuries is surgical exploration and repair [224]. If surgical exploration is performed after TURB, the bowel must be inspected to rule out concomitant injury [197]. For extraperitoneal injuries, exploration is only needed for perforations complicated by symptomatic extravesical collections. It requires drainage of the collection, with or without closure of the perforation [235]. If bladder perforation is encountered during mid-urethral sling or transvaginal mesh procedures, sling re-insertion and urethral catheterisation (two to seven days) should be performed [236].

*4.3.6 **Follow-up***

Continuous bladder drainage is required to prevent elevated intravesical pressure and to allow the bladder to heal [195, 237]. Conservatively treated bladder injuries (traumatic or external IBT) are followed up by cystography to rule out extravasation and ensure proper bladder healing [184]. The first cystography is planned approximately ten days after injury [191]. In case of ongoing leakage, cystoscopy should be performed to rule out bony fragments in the bladder, and a second cystography is warranted one week later [184].

After operative repair of a simple injury in a healthy patient, the catheter can be removed after five to ten days without cystography [237, 238]. In cases of complex injury (trigone involvement, ureteric re-implantation) or risk factors of impaired wound healing (e.g., steroids, malnutrition) cystography is advised [191, 237]. For conservatively treated internal IBT, catheter drainage, lasting five to seven days, is proposed [198, 201].

4.3.7 Summary of evidence and recommendations for bladder injury

Summary of evidence	LE
The combination of pelvic fracture and visible haematuria is highly suggestive of bladder injury.	3
Cystography is the preferred diagnostic modality for non-iatrogenic bladder injury and for suspected IBT in the post-operative setting.	3
Cystography must be performed using retrograde filling of the bladder with a minimum volume of 300-350 mL of dilute contrast material. Passive bladder filling by clamping the urinary catheter during the excretory phase of CT or IVP is not sufficient to exclude bladder injury.	3
The risk of bladder perforation during mid-urethral sling operations for stress urinary incontinence is lower for the obturator route compared to the retropubic route.	1a
Conservative treatment, which comprises of clinical observation, continuous bladder drainage and antibiotic prophylaxis, is the standard treatment for an uncomplicated extraperitoneal injury due to blunt trauma.	3
In extraperitoneal bladder injury with either bladder neck involvement, bone fragments in the bladder wall, concomitant rectal or vaginal injury, or entrapment of the bladder wall, surgical intervention is necessary in order to decrease the risk of complications and to reduce recovery time.	3
Intraperitoneal bladder trauma is managed by surgical repair because intraperitoneal urine extravasation can lead to peritonitis, intra-abdominal sepsis, and death.	3
Conservative treatment is suitable for uncomplicated intraperitoneal injury during endo-urological procedures, in the absence of peritonitis and ileus.	3
In cases of complex injury (trigone involvement, ureteric re-implantation) or risk factors of impaired wound healing (e.g., steroids, malnutrition) cystography is advised after bladder repair.	2a

Recommendations	Strength rating
Perform cystography in the presence of visible haematuria and pelvic fracture.	Strong
Perform cystography in case of suspected iatrogenic bladder injury in the post-operative setting.	Strong
Perform cystography with active retrograde filling of the bladder with dilute contrast (300-350 mL).	Strong
Perform cystoscopy to rule out bladder injury during retropubic sub-urethral sling procedures.	Strong
Manage uncomplicated blunt extraperitoneal bladder injuries conservatively.	Weak
Manage blunt extraperitoneal bladder injuries operatively in cases of bladder neck involvement and/or associated injuries that require surgical intervention.	Strong
Manage blunt intraperitoneal injuries by surgical exploration and repair.	Strong
Manage small uncomplicated intraperitoneal bladder injuries during endoscopic procedures conservatively.	Weak
Perform cystography to assess bladder wall healing after repair of a complex injury or in case of risk factors for wound healing.	Strong

4.4 Urethral Trauma

4.4.1 Epidemiology, aetiology and pathophysiology

4.4.1.1 Anterior male urethral injury

The bulbar urethra is the most common site affected by blunt trauma. In bulbar injuries, the bulb is compressed against the pubic symphysis, resulting in rupture of the urethra at the site of compression [239]. Possible mechanisms are straddle injuries or kicks to the perineum. A penile fracture can be complicated by a urethral injury in approximately 15% of cases [240, 241]. **Penetrating** anterior injuries are rare and are usually caused by gunshot wounds, stab wounds, dog bites, impalement, or penile amputations [239]. Depending on the affected segment, penetrating injuries are usually associated with penile, testicular and/or pelvic injuries [242]. Insertion of **foreign bodies** is another rare cause of anterior injury. It is usually a result of autoerotic stimulation or may be associated with psychiatric disorders [243].

Iatrogenic injury is the most common type of urethral trauma [244]. The incidence of male urethral injury during transurethral catheterisation is 13.4 per 1,000 catheters inserted [245]. Injuries can occur due to creation of a false passage by the tip of the catheter or inadvertent inflation of the anchoring balloon in the urethra [245]. The importance of catheter insertion training programmes [246, 247] and the implementation of difficult urinary catheterisation protocols [248], to prevent urethral injury during transurethral catheterisation, have been demonstrated. Preliminary data suggests that guidewire led catheter insertion, or use of a safety valve for balloon inflation may prevent urethral trauma in difficult catheterisation cases [249, 250]. A SR of the use of hydrophilic coated catheters, in patients performing intermittent catheterization, showed no clear benefit [251].

During penile prosthesis insertion, the risk of urethral perforation is 0.1-4%. Proximal urethral injuries are more common than distal ones [252].

4.4.1.2 Posterior male urethral injuries

Blunt posterior urethral injuries are almost exclusively related to pelvic fractures and the risk increases with fracture configuration severity [253]. These injuries are referred to as pelvic fracture urethral injuries (PFUI) [239], and are mainly caused by road traffic accidents [254]. Pelvic fracture urethral injuries are divided into partial or complete ruptures [253, 254]. In complete ruptures, there is a gap between the disrupted ends of the urethra, which fills up with scar tissue. There is no urethral wall in the scarred space and any lumen represents a fistulous tract between the urethral stumps [255]. Injuries of the bladder neck and prostate are rare and mostly occur at the anterior midline of both the bladder neck and prostatic urethra [256]. It is highly uncommon to find a complete transection of the bladder neck or an avulsion of the anterior part of the prostate [256]. Concomitant injuries to the head, thorax, abdomen and/or spine are frequent (up to 66%) [254].

Penetrating injuries of the pelvis, perineum, or buttocks (mainly gunshot wounds) can also damage the posterior urethra but are extremely rare in the civilian setting [253]. There is a high probability of associated injuries (approx. 90%), mainly intra-abdominal [192].

The associated injuries which occur with both blunt and penetrating posterior urethral injuries can be life-threatening, and if so, will govern the patient's assessment and treatment [254]. Delayed morbidities of posterior urethral injuries include strictures, incontinence and erectile dysfunction, all of which may have a detrimental effect on the patient's quality of life [257]. The pooled estimate for the proportion of patients with erectile dysfunction following PIFU is 34% [258].

Iatrogenic injury has been reported with transanal total mesorectal excision in 1-11% of cases. This injury is usually partial and located at the membranous urethra [259].

4.4.1.3 Female urethral injuries

Birth related injuries to the female urethra are rare and consist of minor (peri)urethral lacerations during vaginal delivery. Pelvic fractures are the main cause of **blunt** trauma [260]; however, PFUIs in females are rare and less common than in males [253]. This is usually attributed to the flexibility provided by the vagina and the greater inherent elasticity of the female urethra [260], it may also be the result of less severe and more frequent stable pelvic fractures in females [184, 254]. In unstable pelvic fractures in females, a high suspicion for a urethral injury should be maintained [260]. Female urethral injuries are classified into two types: longitudinal or partial (most frequent) injuries and transverse or complete injuries [260]. Concomitant bladder or vaginal injury is possible; therefore, females are at risk of developing urinary incontinence and urethrovaginal fistula [254, 260].

Insertion of a synthetic sub-urethral sling for the treatment of female stress urinary incontinence is complicated by an intra-operative urethral injury in 0.2-2.5% of cases [261] and is an important cause of **iatrogenic** urethral injury.

*4.4.2 **Evaluation***

4.4.2.1 Clinical signs

Blood at the meatus is the cardinal sign, but the absence of it doesn't rule out a urethral injury [184, 254]. Inability to void (with a palpable distended bladder) is another classic sign and is often associated with a complete rupture [254, 255]. Haematuria and pain on urination may be present in incomplete ruptures. Urinary extravasation and bleeding may result in scrotal, penile and/or perineal swelling and ecchymosis, depending on the location and extent of the trauma. The presentation of these clinical symptoms may be delayed (> 1 hour) [255].

Rectal examination should always be done to exclude an associated rectal injury (up to 5% of cases) and may reveal a 'high-riding' prostate, which is an unreliable finding [184, 255]. Failure to detect a rectal injury can cause significant morbidity and even mortality. A rectal injury is suggested by blood on the examining finger and/or a palpable laceration [184]. Another sign of urethral injury is difficulty or inability to pass a urethral catheter [184, 255].

A female urethral injury should be suspected from the combination of a (unstable) pelvic fracture with blood at the vaginal introitus, vaginal laceration, haematuria, urethrorrhagia, labial swelling, urinary retention, or difficulties passing a urethral catheter [184, 257]. Vaginal examination is indicated to assess vaginal lacerations [184, 257].

4.4.2.2 Urethrography

Retrograde urethrography (RUG) is the standard in the early evaluation of a male urethral injury [184, 262] and is conducted by injecting 20-30 mL of contrast material while occluding the meatus. Films should be taken in a 30° oblique position. In patients with PFUI, it is important to move the X-ray beam to the 30° angle rather than the patient [254]. In an unstable patient, RUG should be postponed until the patient has been stabilised [184, 192].

During RUG, any extravasation outside the urethra is pathognomonic for urethral injury [255]. A typical image for incomplete rupture shows extravasation from the urethra which occurs while the bladder is still filling. A complete rupture is suggested by massive extravasation without bladder filling [254]. Although RUG is able to reliably identify the site of injury (anterior vs. posterior), the distinction between a complete and partial rupture is not always clear [254, 263]. Therefore, any proposed classification system based on RUG is not reliable [254, 263]. In females, the short urethra and vulvar oedema makes adequate urethrography nearly impossible [264].

Prior to deferred treatment, a combination of RUG and antegrade cysto-urethrography is the standard to evaluate site and extent of the urethral stenosis, and to evaluate the competence of the bladder neck [254].

4.4.2.3 Cysto-urethroscopy

Flexible cysto-urethroscopy is a valuable alternative to diagnose an acute urethral injury and may distinguish between complete and partial rupture [262]. Flexible cysto-urethroscopy is preferred to RUG in suspected penile fracture-associated urethral injury as RUG is associated with a high false-negative rate [265, 266]. In females, where the short urethra often precludes adequate radiological visualisation, cysto-urethroscopy and vaginoscopy are the diagnostic modalities of choice [184, 260]. If, prior to deferred treatment, the competence of the bladder neck is not clear upon antegrade cysto-urethrography, a suprapubic cystoscopy is advised [254].

4.4.2.4 Ultrasound and magnetic resonance imaging

In the acute phase, US scanning is used for guiding the placement of a suprapubic catheter [254]. In complex PFUIs, MRI before deferred treatment provides valuable additional information, which can help to determine the most appropriate surgical strategy [267]. This information includes a better estimation of the length of the distraction defect, degree of prostatic displacement and presence/absence of a false passage [267].

*4.4.3 **Disease Management***

4.4.3.1 Male anterior urethral injuries

4.4.3.1.1 Immediate exploration and urethral reconstruction

This is indicated for penile fracture related injuries [268] and non-life-threatening penetrating injuries [257]. Small lacerations can be repaired by simple closure [241]. Complete ruptures without extensive tissue loss are treated with anastomotic repair [241, 242]. Only 2% of cases will develop a urethral stricture after immediate urethral reconstruction for penile fracture [268]. In the case of longer defects or apparent infection (particularly bite wounds), a staged repair with urethral marsupialisation is needed [262]. Penetrating injuries require peri- and post-operative antibiotic treatment [269].

Immediate urethroplasty has been performed in blunt injuries. The long term-outcomes (patency rate, potency rate) of patients treated with immediate urethroplasty is similar to these initially treated with suprapubic diversion and delayed urethroplasty [270]. The main advantage of performing immediate urethroplasty is that this strategy significantly reduces the time to spontaneous voiding from two to six months to three weeks on average [270, 271]. Spongiosal contusion and haematoma during immediate urethroplasty will make the operation technically more demanding; therefore, immediate urethroplasty should be performed by a dedicated urethral surgeon [271].

Perforation of the distal urethra during penile prosthesis insertion needs to be repaired over a catheter; in this instance the initial procedure should be abandoned [272].

4.4.3.1.2 Urinary diversion

Blunt anterior urethral injuries are associated with spongiosal contusion. Evaluation of the limits of urethral debridement in the acute phase might be difficult and as a consequence, it is reasonable to start with urinary diversion only [262].

If urinary diversion is performed, the therapeutic options are suprapubic diversion or a trial of early endoscopic re-alignment with transurethral catheterisation [262]; there is conflicting evidence as to which intervention is superior [270, 271, 273]. A retrospective case series of 44 patients comparing early realignment versus suprapubic tube placement, shows no difference in stricture formation [274].

Urinary diversion is maintained for one to two weeks for partial ruptures and three weeks for complete ruptures [262, 273]. A review of 49 Chinese studies (1,015 patients), reported a 57% (range: 0 - 100%) success rate for endoscopic re-alignment of blunt anterior injuries [270]. The wide range in success rate most likely reflects a mix of partial and complete ruptures which was not further specified in the review. For complete ruptures, urinary diversion on its own is unlikely to result in a successful outcome (0 - 25% patency rate) [271, 273].

Transurethral or suprapubic urinary diversion are treatment options for iatrogenic or life-threatening penetrating injuries [257, 275]. Minor iatrogenic urethral injuries and urethral contusions do not require urinary diversion [3].

4.4.3.2 Male posterior urethral injuries

4.4.3.2.1 Emergency room management

As these injuries are usually associated with other severe injuries, resuscitation and immediate treatment of life-threatening injuries have absolute priority [254]. Penetrating injuries especially have a very high likelihood of associated injuries requiring immediate exploration [192, 276]. There is no urgency to treat the urethral injury and urinary diversion is not essential during the first hours after trauma [255]; however, it is preferable to establish early urinary diversion to:

- monitor urinary output, since this is a valuable sign of the haemodynamic condition and the renal function of the patient;
- treat symptomatic retention if the patient is still conscious;
- minimise urinary extravasation and its secondary effects, such as infection and fibrosis [254].

Insertion of a suprapubic catheter is an accepted practice in urgent situations [255, 276]. However, insertion of a suprapubic catheter is not without risk, especially in the unstable trauma patient where the bladder is often displaced by a pelvic haematoma or because of poor bladder filling due to haemodynamic shock or concomitant bladder injury. In these circumstances, an attempt at urethral catheterisation can be carried out by experienced personnel. It is extremely unlikely that the gentle passage of a urethral catheter will do any additional damage [254]. If there is any difficulty, a suprapubic catheter should be placed under US guidance or under direct vision, for example, during laparotomy for associated injuries [254]. Suprapubic catheter placement does not increase the risk of infectious complications in patients undergoing internal fixation to stabilise a pelvic fracture [277]. Therefore, the assertion that suprapubic catheter placement would increase the risk of orthopaedic hardware infection and subsequent explantation is not justified [277].

4.4.3.2.2 Early urethral management (less than six weeks after injury)

For partial injuries, urinary diversion (suprapubic or transurethral) is sufficient as these injuries can heal without significant scarring or obstruction [255, 257]. A complete injury will not heal, and formation of an obliterated segment is inevitable in case of suprapubic diversion alone [255, 257]. To avoid this obliteration and a long period of suprapubic diversion followed by deferred urethroplasty, the urethral ends can be sutured (urethroplasty) or approximated over a transurethral catheter (re-alignment).

4.4.3.2.2.1 Early re-alignment

Early re-alignment can be performed when a stable patient is on the operating table for other surgery or as a stand-alone procedure in the absence of concomitant injuries [192, 278]. In a partial injury, re-alignment, and transurethral catheterisation avoids extravasation of urine in the surrounding tissues reducing the inflammatory response. In complete injuries, the aim of re-alignment is to correct severe distraction injuries rather than to prevent a stricture [257, 279].

Re-alignment can be done by an open or endoscopic technique [279, 280]. The open technique is associated with longer operation times, more blood loss and longer hospital stays; as such, endoscopic re-alignment is now preferred [270]. Using a flexible/rigid cystoscope and biplanar fluoroscopy, a guidewire is placed inside the bladder under direct visual control, over this, a catheter is placed. If necessary, two cystoscopes can be used: one retrograde (per urethra) and one antegrade (suprapubic route through the bladder neck) [254]. The duration of catheterisation is three weeks for partial and six weeks for complete ruptures with voiding urethrography upon catheter removal [254]. It is important to avoid traction on the balloon catheter as it can damage the remaining sphincter mechanism at the bladder neck [254].

With contemporary endoscopic re-alignment procedures, stricture formation is reduced to 44-49% [279, 280] compared to a 89-94% stricture rate with suprapubic diversion [280, 281]. There is no evidence that early re-alignment increases the risk of urinary incontinence (4.7-5.8%) or erectile dysfunction (16.7-20.5%) [280, 281].

Another potential benefit of early re-alignment is that when a stricture occurs it will be shorter and therefore, easier to treat. For short, non-obliterative strictures following re-alignment, direct vision urethrotomy can be performed. Approximately 50% of strictures after endoscopic re-alignment can be treated endoscopically [279]. However, repetitive endoscopic procedures in case of stricture formation might delay the time to definitive cure and can increase the incidence of adverse events (false passage, abscess formation) [282, 283]. In light of this, repetitive endoscopic treatments after failed re-alignment are not recommended; instead, urethroplasty must be performed.

A retrospective review found a shorter stricture length after early (open) re-alignment and as a consequence, a tendency for less complex manoeuvres to be needed to allow for a tension-free anastomosis during urethroplasty [284]. On the other hand, another retrospective review, reported an equal stricture length and no greater facilitation of urethroplasty after failed endoscopic re-alignment compared to suprapubic diversion only [282]. The proposed benefit is thus highly questionable. Furthermore, there is conflicting evidence as to whether failed early re-alignment jeopardises the success of definitive urethroplasty [254].

Differences between series in the rates of incontinence, impotence and re-stricture can be explained by differences in patient selection (severe vs. less severe trauma), a mix of partial and complete ruptures, and differences in follow-up duration. Furthermore, these differences make the comparison with other techniques difficult, especially with urethroplasty [184, 279].

4.4.3.2.2.2 Early urethroplasty

Immediate urethroplasty within 48 hours after injury is difficult because of poor visualisation and the inability to accurately assess the degree of urethral disruption, due to extensive swelling and ecchymosis, which may result in extensive unjustified urethral debridement. Another problem is the risk of severe bleeding (average 3 L) following entry into the pelvic haematoma [254]. In addition, with high rates of impotence (23%), incontinence (14%) and strictures (54%), urethroplasty within 48-hours is not indicated [254].

Early urethroplasty can be performed after two days and up to six weeks after the initial injury, if associated injuries have been stabilised, the distraction defect is short, the perineum is soft and the patient is able to lie down in the lithotomy position [285, 286]. This avoids a long period of suprapubic diversion with its discomfort and complications [285, 286]. As the results (complications, stricture recurrence, incontinence, and impotence) are equivalent to delayed urethroplasty [286-288], early urethroplasty might be an option for patients fulfilling the above-mentioned criteria.

Lacerations (blunt or penetrating) at the bladder neck and prostatic urethra are a specific entity: they will never heal spontaneously, will cause local cavitation (presenting a source of infection) and compromise the intrinsic sphincter mechanism (with increased risk of urinary incontinence) [256]. They must be reconstructed as soon as possible [257, 263, 276]. For penetrating injuries with severe lesions to the prostate, prostatectomy (bladder neck sparing) must be performed [276].

4.4.3.2.3 Deferred management (greater than three months after injury)

The standard treatment remains deferred urethroplasty [13, 14]. In the case of a complete rupture, treated with an initial period of three months suprapubic diversion, obliteration of the posterior urethra is almost inevitable [255]. Endoscopic treatment of a complete obliteration is not successful [254]. After at least three months of suprapubic diversion, the pelvic haematoma is nearly always resolved, the prostate has descended into a more normal position, the scar tissue has stabilised [285] and the patient is clinically stable and able to lie down in the lithotomy position [262, 285]. Associated life-threatening injuries often preclude early management of penetrating membranous urethral injuries. In those cases, suprapubic diversion with delayed urethroplasty is also advised [17, 25, 27]. Perineal anastomotic repair is the surgical technique of choice, but a combined abdominoperineal approach is necessary in rare cases of concomitant bladder neck injury or recto-urethral fistula [289].

An extensive overview of deferred urethroplasty can be found in the Urethral Strictures Guidelines [290].

4.4.3.2.4 Iatrogenic posterior injuries

Urethral defects during transanal total mesorectal excision were repaired by direct suture repair via a transperineal approach in a small case series (n=32). Despite direct repair, 26% developed complications including urethral stricture, urethral dehiscence, recto-urethral fistula, and recto-perineal fistula. No evidence on other strategies is available [259].

4.4.3.3 Female urethral injuries

Emergency room management of PFUIs in females is the same as in males (section 4.4.3.2.1); however, subsequent management differs. Treatment options are [260]:

- **Early realignment:** This is associated with a high stricture and fistula rate.
- **Early repair (less than or equal to seven days):** Complication rate is the lowest with early repair; therefore, this strategy is preferred once the patient is haemodynamically stable [257, 260].
- **Delayed repair (greater than seven days):** Delayed repair often requires complex abdominal or combined abdominal-vaginal reconstruction with elevated risk of urinary incontinence and vaginal stenosis.

The approach (vaginal, abdominal or combined) for early repair depends on the location of the injury [260]. Proximal and mid-urethral disruptions require immediate exploration and primary repair using the retropubic and transvaginal routes, respectively, with primary suturing of the urethral ends or urethral laceration. Concomitant vaginal lacerations are repaired (two-layer closure) trans vaginally at the same time [260]. Distal urethral injuries can be left hypospadiac since they do not disrupt the sphincter mechanism, but a concomitant vaginal laceration must be closed [184, 264]. In case of urethral injury during synthetic sub-urethral sling insertion, immediate repair is warranted with abandonment of sling insertion [261].

Table 4.4.1: Complication rates for different treatment strategies for PFUIs in females [260]

Type of repair	Stricture (%)	Fistula (%)	Incontinence (%)	Vaginal stenosis (%)	Need for permanent urinary diversion (%)
Early realignment	59	13	0	0	0
Early repair	3	6	9	0	3
Delayed repair	3	4	31	4	7

4.4.4 Summary of evidence and recommendations for the evaluation and management of urethral trauma

Summary of evidence	LE
Implementing training programmes on urinary catheter insertion for personnel involved with urethral catheterisation significantly improves the rate of catheter-related complications.	2b
In males, a urethral injury is detected as contrast extravasation during urethrography or as a mucosal laceration during cysto-urethroscopy.	3
As opposed to cysto-urethroscopy, voiding cysto-urethrography will miss a female urethral injury in approximately 50% of cases.	3
Transurethral or suprapubic urinary diversion are the treatment options for iatrogenic injuries.	3
With urinary diversion (suprapubic or transurethral catheter) satisfactory urethral luminal re-canalisation may occur after partial blunt anterior urethral ruptures.	3
Complete blunt anterior urethral ruptures are unlikely to be cured by urinary diversion alone, whereas immediate urethroplasty has an equal success rate compared to delayed urethroplasty. The main advantage of immediate urethroplasty is to reduce the time to spontaneous voiding.	3
If PFUIs are associated with life-threatening injuries, urethral management has no priority and urinary diversion with either urethral or suprapubic catheterisation is sufficient initially.	3
With early endoscopic re-alignment the stricture rate is reduced to 44-49% without increased risk of incontinence or erectile dysfunction.	3
Repetitive endoscopic treatments after failed re-alignment delay the time to definitive cure and increase the incidence of adverse events.	3
For partial posterior injuries, urinary diversion (suprapubic or transurethral) is sufficient as these injuries might heal without significant scarring or obstruction.	3

Immediate urethroplasty (< 48 hours) in male PFUI is associated with a higher risk of bleeding, stricture, incontinence, and impotence rates compared to delayed urethroplasty.	3
In selected patients for male PFUI, early urethroplasty (two days to six weeks) is associated with similar stricture, incontinence and impotence rates compared to delayed urethroplasty.	3
Suprapubic diversion with delayed urethroplasty in male PFUI with complete urethral disruption is associated with an 86% stricture free success rate and with no significant impact on erectile function and urinary continence.	2a
Early repair in female PFUI has the lowest complication rate.	3

Recommendations	**Strength rating**
Provide appropriate training to reduce the risk of traumatic catheterisation.	Strong
Evaluate male urethral injuries with flexible cysto-urethroscopy and/or retrograde urethrography.	Strong
Evaluate female urethral injuries with cysto-urethroscopy and vaginoscopy.	Strong
Treat iatrogenic anterior urethral injuries by transurethral or suprapubic urinary diversion.	Strong
Treat partial blunt anterior urethral injuries by suprapubic or urethral catheterisation.	Strong
Treat complete blunt anterior urethral injuries by immediate urethroplasty, if surgical expertise is available, otherwise perform suprapubic diversion with delayed urethroplasty.	Weak
Treat pelvic fracture urethral injuries (PFUIs) in haemodynamically unstable patients by transurethral or suprapubic catheterisation initially.	Strong
Perform early endoscopic re-alignment in male PFUIs when feasible.	Weak
Do not repeat endoscopic treatments after failed re-alignment for male PFUI.	Strong
Treat partial posterior urethral injuries initially by suprapubic or transurethral catheter.	Strong
Do not perform immediate urethroplasty (< 48 hours) in male PFUIs.	Strong
Perform early urethroplasty (two days to six weeks) for male PFUIs with complete disruption in selected patients (stable, short gap, soft perineum, lithotomy position possible).	Weak
Manage complete posterior urethral disruption in male PFUIs with suprapubic diversion and deferred (at least three months) urethroplasty.	Strong
Perform early repair (within seven days) for female PFUIs (not delayed repair or early re-alignment).	Strong

Management of anterior and posterior urethral injuries in men

Figure 4.4.1: Management of anterior urethral injuries in men

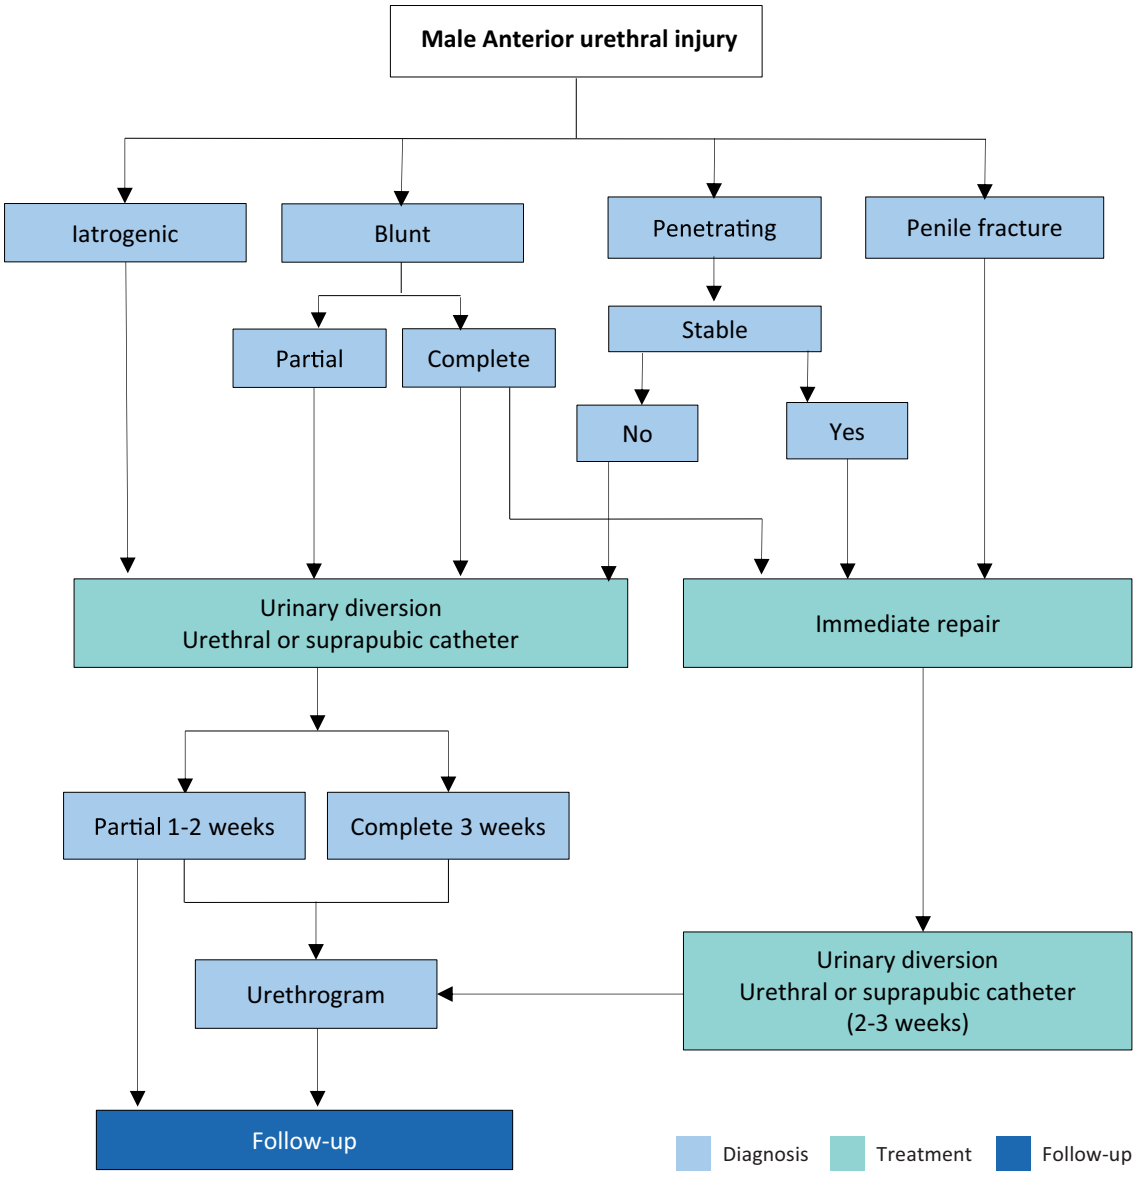

Figure 4.4.2: Management of posterior urethral injuries in men

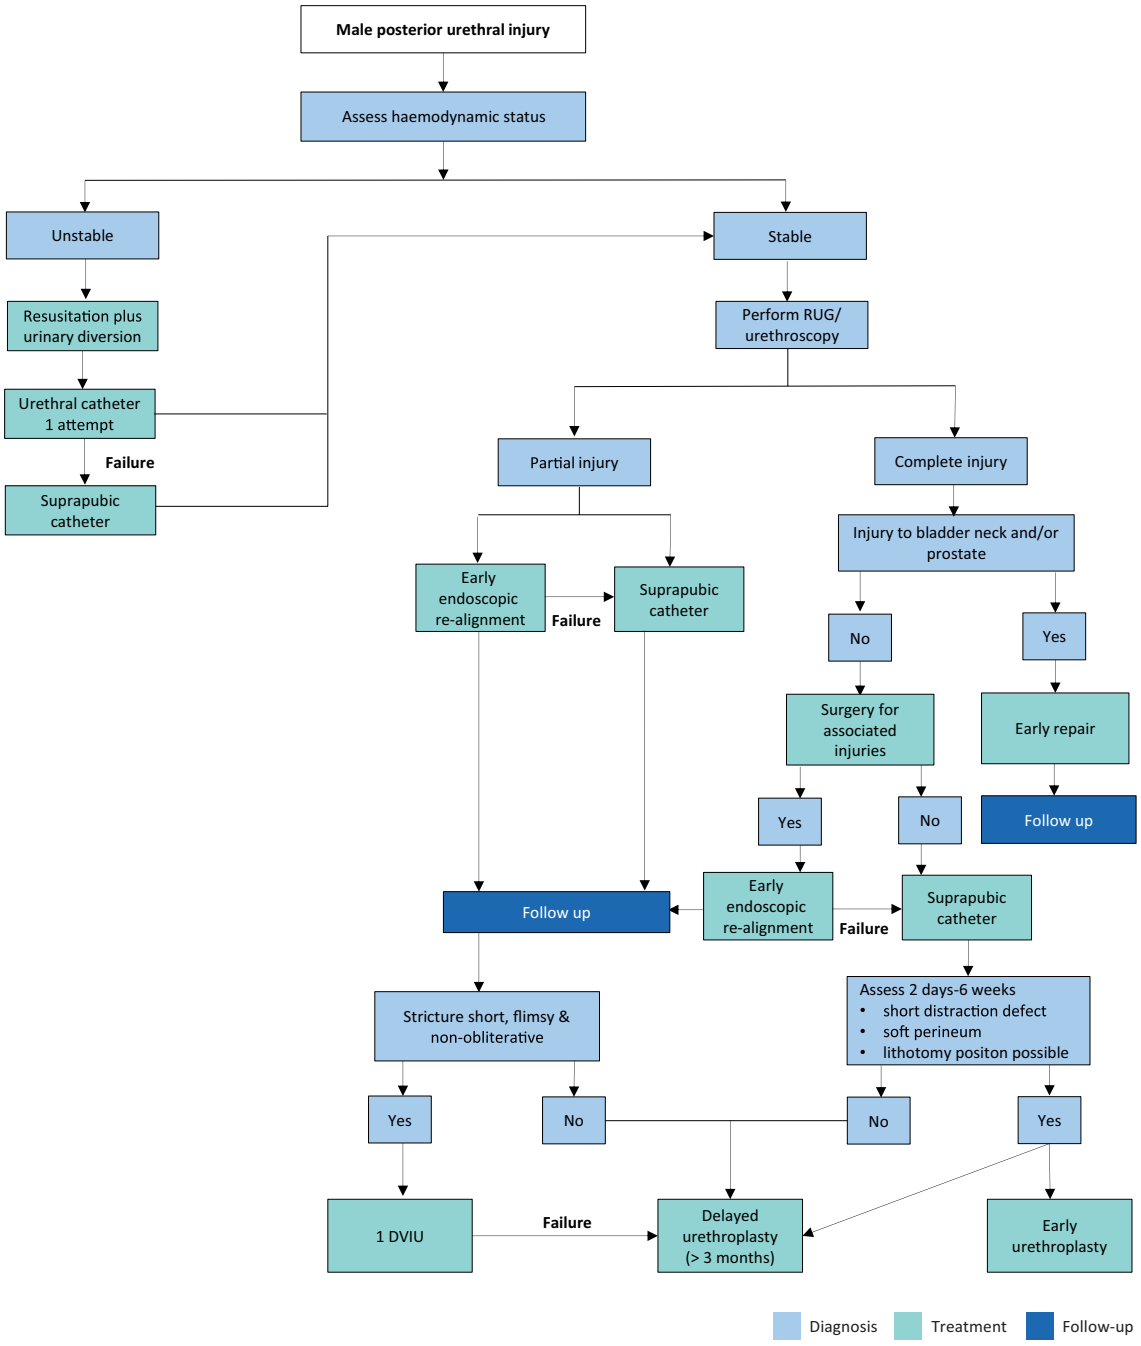

RUG = retrograde urethrography; DVIU = direct visual internal urethrotomy.

4.5 Genital Trauma

4.5.1 Epidemiology, aetiology and pathophysiology

Of all urological injuries, 33-66% involve the external genitalia [291]. Genital trauma is much more common in males than in females, especially between the ages of 15 and 40 years. This is due to anatomical differences, increased frequency of road traffic accidents and increased participation in physical sports, war and crime [292]. The risk of associated injuries to neighbouring organs (bladder, urethra, vagina, rectum, and bowel), after blunt trauma is higher in females than in males.

Genital trauma is commonly caused by blunt injuries (80%). In males, blunt genital trauma frequently occurs unilaterally with approximately 1% presenting as bilateral scrotal or testicular injuries [293]. Any kind of contact sport, without the use of protective aids, may be associated with genital trauma. Off-road cycling, motor biking (especially on motorbikes with a dominant petrol tank), rugby, football and hockey are all activities associated with blunt testicular trauma [294-297]. Penetrating injuries are most commonly caused by firearms (75.8%) with the majority requiring surgical intervention [298, 299].

Accidents during sexual intercourse can also cause genital trauma; men of younger age are the most affected. The major pathologies are penile fractures, strangulation, necrosis, and assorted injuries from various sexual practices [300, 301].

The most important presentation of blunt penile trauma is penile fracture. The most common causes are sexual intercourse, forced flexion (taqaandan), masturbation and rolling over in 46%, 21%, 18% and 8.2%, respectively [302]. It has also been reported that penile fracture patients have a significantly higher rate of substance abuse [303]. The usual mechanism of injury is when the penis slips out of the vagina and strikes against the symphysis pubis or perineum. Sixty per cent of cases occur during consensual intercourse [304], with penile fracture more likely in certain positions [305]. Penile fracture is caused by rupture of the cavernosal tunica albuginea and may be associated with subcutaneous haematoma and lesions of the corpus spongiosum or urethra in 10-22% [306-308]. Genital injury is prevalent (42%) after sexual abuse [309].

Although animal bites are common, bites injuring the external genitalia are rare. Wounds are usually minor but have a risk of wound infection.

Gunshot injuries to the external genitalia are relatively uncommon and are usually not life-threatening; however, they can have a significant impact on quality of life. About 40-60% of all penetrating genito-urinary lesions involve the external genitalia [310, 311], 35% of these are gunshot wounds [293]. In a series of wartime injuries, the majority were caused by improvised explosive devices and other explosive ordinance, while smaller numbers of injuries were due to gunshot injuries [312]. In both males and females, penetrating injuries affect multiple organs in 70% of patients. In males, penetrating scrotal injuries affect both testes in 30% of cases compared with 1% in blunt injuries [293, 313]. Self-mutilation of the external genitalia has also been reported in psychotic patients and transsexuals [314]. Genital burns are rare in isolation and are usually due to industrial flames or chemicals [315]. Both male and female genital piercings increase the risk for unexpected genital trauma [316].

Traumatic dislocation of the testicle rarely occurs and is most common in victims of road traffic accidents [317-320]. Bilateral dislocation of the testes has been reported in up to 25% of cases [318]. Testicular rupture is found in approximately 50% of cases of direct blunt scrotal trauma [321, 322]. It may occur under intense compression of the testis against the inferior pubic ramus or symphysis, resulting in a rupture of the tunica albuginea. A force of approximately 50 kg is necessary to cause testicular rupture [323]. Most penile avulsion injuries are self-inflicted, but some are a result of industrial accidents or assault.

Coital injury of the female genital tract can happen during consensual sexual intercourse. Up to 35% of all genital injuries in women are sustained during their first sexual contact. The most frequently found injuries are lacerations [324]. Blunt trauma to the vulva is rarely reported and usually presents as a large haematoma. The incidence of traumatic vulvar haematomas after vaginal deliveries has been reported as one in 310 deliveries [325]. The presence of a vulvar haematoma is closely related to an increased risk of associated vaginal, pelvic, or abdominal injuries [326, 327]. Blunt injuries of the vulva and vagina are associated with pelvic trauma in 30%, after consensual intercourse in 25%, following sexual assault in 20%, and other blunt trauma in 15% [328].

*4.5.2 **Diagnostic evaluation***

4.5.2.1 Patient history and physical examination

Penile fracture is associated with a sudden cracking or popping sound, pain and immediate detumescence. Local swelling of the penile shaft develops quickly, due to enlarging haematoma [240]. Bleeding may spread along the fascial layers of the penile shaft and extend to the lower abdominal wall if Buck's fascia is also ruptured. Sometimes, the rupture of the tunica may be palpable. Less severe penile injuries can be distinguished from penile fracture, as they are not usually associated with detumescence [302].

Testicular rupture is associated with immediate pain, nausea, vomiting, and sometimes fainting. The hemiscrotum is tender, swollen, and ecchymotic. The testis itself may be difficult to palpate. **Blunt vulvar** or perineal trauma in women may be associated with bleeding, pain and voiding problems, bladder catheterisation is usually required.

In genital trauma, a urinalysis should be performed. The presence of visible haematuria requires a retrograde urethrogram in males. In females, flexible or rigid cystoscopy is recommended to exclude urethral and bladder injury [326, 328]. In women with genital injuries and blood at the vaginal introitus, further gynaecological investigation is needed [326].

*4.5.3 **Imaging***

In cases of suspected penile fracture cavernosography, US or contrast-enhanced MRI [302, 329-331] can identify lacerations of the tunica albuginea in unclear cases [332], or provide reassurance that the tunica is intact. Magnetic resonance imaging is superior to US in diagnosing penile fracture [333, 334]. If a concomitant urethral injury is suspected, manage as outlined in section 4.4.

Ultrasound should be performed to determine intra- and/or extra-testicular haematoma, testicular contusion, or rupture [322, 335-343]. However, the literature is contradictory as to the usefulness of US compared to clinical examination alone. Some studies have reported convincing findings with a specificity of up to 98.6% [344]. Heterogeneous echo pattern of the testicular parenchyma with the loss of contour definition is a highly sensitive and specific radiographic finding for testicular rupture [333]. Others reported poor specificity (78%) and sensitivity (28%) for the differentiation between testicular rupture and haematocele, while accuracy is as low as 56% [336]. Colour Doppler-duplex US may provide useful information when used to evaluate testicular perfusion. If scrotal US is inconclusive, testicular CT or MRI may be helpful [345]; however, these techniques did not specifically increase the detection rates of testicular rupture [346].

*4.5.4 **Disease management***

4.5.4.1 Animal bites

Local wound management depends on the extent of tissue destruction. Antibiotics should be prescribed in accordance with local resistance patterns [347-349]. The possibility of rabies infection must be considered, taking into account the geographical location, animal involved, specific nature of the wound and the type of attack (provoked/unprovoked). Elderly and immunosuppressed patients should be vaccinated with human rabies immunoglobulin and human diploid cell vaccine [350, 351].

4.5.4.2 Human bites

In cases of human bites, apart from wound management, infection should be considered since transmission of viral diseases may occur, Hepatitis B vaccine/immunoglobulin and/or immunodeficiency virus (HIV) post-exposure prophylaxis should be offered. For further details, see Guidelines for the Management of Human Bite Injuries [352].

4.5.4.3 Blunt penile trauma

Blunt trauma to the flaccid penis does not usually cause tearing of the tunica. Subcutaneous haematoma after sexual intercourse, without associated rupture of the cavernosal tunica albuginea, does not require surgical intervention. In these cases, non-steroidal analgesics and ice-packs are recommended [353].

4.5.4.4 Penile fracture

The thickness of the tunica albuginea in the flaccid state (approximately 2 mm) decreases in erection to 0.25-0.5 mm and is therefore more vulnerable to traumatic injury [344, 354]. When a penile fracture is diagnosed, surgical intervention with closure of the tunica albuginea is recommended; it ensures the lowest rate of negative long-term sequelae and has no negative effect on the psychological wellbeing of the patient [355]. The approach is usually through a circumferential incision proximal to the coronal sulcus which enables complete degloving of the penis. Increasingly, local longitudinal incisions centred on the area of fracture or ventral longitudinal approaches are currently used [265]. A recent systematic review on the management of penile fractures concluded that immediate repair should be within 24 hours of presentation [356]; however, delayed presentation should not prevent exploration [305]. Further localisation may be gained with a flexible cystoscopy performed prior to incision, if urethral trauma is suspected and eventually proven [240]. Surgical closure of the tunica should be carried out using absorbable sutures.

4.5.4.5 Penetrating penile trauma

In penetrating penile trauma non-operative management is recommended for small superficial injuries with intact Buck's fascia [310]. In more significant penetrating penile injuries, surgical exploration and debridement of necrotic tissue is recommended. Even in extended injuries of the penis, primary alignment of the disrupted tissues may allow for acceptable healing because of the robust penile blood supply [314].

The principles of care are debridement of devitalised tissue, with the preservation of as much viable tissues as possible, haemostasis, diversion of urine in selected cases and the removal of foreign bodies. Tissues of questionable viability may be left for subsequent definitive surgery. If a delayed repair is needed, depending on the type of injury and the extent of tissue damage, it usually takes place four to six weeks after the trauma has occurred.

The surgical approach depends upon the site and extent of the injury, but a subcoronal incision with penile degloving usually gives good exposure. Initially, a defect in the tunica albuginea should be closed after copious irrigation. If there has been too much tissue loss, the defect can be repaired either immediately or after delay with a patch (either from an autologous saphenous vein or xenograft).

The elasticity of genital skin means it is usually possible to manage the loss of a moderate amount of penile skin; however, management is more difficult in extensive injuries with significant skin loss. The tissue chosen for reconstruction following trauma needs to provide good coverage and must be suitable for reconstruction. Split-thickness skin grafting provides good coverage and a dependable take that is reproducible and durable. However, split-thickness grafts contract more than full-thickness grafts and their use on the penile shaft should be kept to a minimum. Skin grafts with thickness of at least 0.4 mm should be used in order to reduce the risk of contraction [314]. Full-thickness skin grafting onto the penile shaft gives less contracture, a better cosmetic appearance and more resistance to trauma during intercourse, when re-established [353]. The donor site may be taken from the abdomen, buttock, thigh, or axilla and is chosen according to surgeon's preference and the pattern of injury. In cases of extensive destruction of deeper tissues, or if later prosthetic placement is being considered, skin flaps, with their secure vascular supply, can be used.

4.5.4.6 Penile avulsion injuries and amputation

Acute management involves resuscitation of the patient, and preparation for surgical re-implantation of the penis if it has been recovered and is not too badly damaged. Surgical re-implantation should be considered for all patients and should be performed within 24 hours of amputation [357].

The severed penis should be washed with sterile saline, wrapped in saline-soaked gauze, placed in a sterile bag, and immersed in iced water. The penis must not come into direct contact with the ice. A pressure dressing or a tourniquet should be placed around the penile stump to prevent excessive blood loss. Re-attachment can be achieved in a non-microsurgical way, but gives higher rates of post-operative urethral stricture and more problems with loss of sensation [358]. When operating microscopically, the corpora cavernosa and urethra are firstly aligned and repaired. Subsequently, the dorsal penile arteries, the dorsal vein and the dorsal nerves are anastomosed. The cavernosal arteries are generally too small to anastomose. The fascia and skin are closed in layers and both a urethral and a suprapubic catheter are placed [359].

If the severed penis cannot be found, or is unsuitable for re-attachment, then the end should be closed as it is done in partial penectomy. Later reconstruction may be employed to lengthen the penis (e.g., suspensory ligament division and V-Y plasty, pseudo-glans formation with split-thickness skin grafting, etc.). A delayed major reconstructive procedure, i.e. phalloplasty (either radial artery or pubic), is sometimes required for injuries which leave a very small or non-functioning penile stump [357].

4.5.4.7 Testicular dislocation

It can be either a subcutaneous dislocation with epifascial displacement of the testis or an internal dislocation. In the latter, the testis is positioned in the superficial external inguinal ring, inguinal canal or abdominal cavity. Traumatic dislocation of the testis is treated by manual replacement and secondary orchidopexy. If primary manual reposition cannot be performed, immediate orchidopexy is indicated.

4.5.4.8 Haematocoele

Conservative management is recommended in haematoceles smaller than three times the size of the contralateral testis [360]. In large haematoceles, non-operative management can fail, and delayed surgery (more than three days) is often required. Patients with large haematoceles have a higher rate of orchiectomy than patients who undergo early surgery, even in non-ruptured testes [293, 314, 321, 361, 362]. Early surgical intervention results in preservation of the testis in more than 90% of cases compared to delayed surgeries which result in orchiectomy in 45-55% of patients [321]. In addition, non-operative management is also associated with prolonged hospital stays. Therefore, large haematoceles should be treated surgically, irrespective of the presence of testicular contusion or rupture. At the very least, the blood clot should be evacuated from the tunica vaginalis sac to relieve disability and hasten recovery.

4.5.4.9 Testicular rupture

It is essential to surgically explore equivocal patients whenever imaging studies cannot definitively exclude testicular rupture. This involves exploration with evacuation of blood clots and haematoma, excision of any necrotic testicular tubules and closure of the tunica albuginea, usually with running 3.0-absorbable sutures.

4.5.4.10 Penetrating scrotal trauma

Penetrating injuries to the scrotum require surgical exploration with debridement of non-viable tissue. Depending on the extent of the injury, primary reconstruction of the testis and scrotum can usually be performed. In complete disruption of the spermatic cord, re-alignment without vaso-vasostomy may be considered if surgically feasible [363]. Staged secondary microsurgical vaso-vasostomy can be performed after

rehabilitation, although only a few cases have been reported [363]. If there is extensive destruction of the tunica albuginea, mobilisation of a free tunica vaginalis flap can be performed for testicular closure. If the patient is unstable or reconstruction cannot be achieved, orchiectomy is then indicated. Prophylactic antibiotics are recommended after scrotal penetrating trauma, although data to support this approach are lacking.

Extended laceration of scrotal skin requires surgical intervention for skin closure. Due to the elasticity of the scrotum, most defects can be primarily closed, even if the lacerated skin is only minimally attached to the scrotum [314]. Local wound management with extensive initial wound debridement and washout is important for scrotal convalescence. In the case of extensive loss of genital tissue, e.g., improvised explosive device blast injury, complex and staged reconstructive surgical procedures are often required [312]. Military testicular salvage rates increased over the last decades due to improvements of medical services (up to 67.6%) [364].

Table 4.5.1: Summary of key points for penile fracture and testicular trauma

Summary of key points:
Penile fracture
The most common causes of penile fracture are sexual intercourse, forced flexion, masturbation and rolling over.
Penile fracture is associated with a sudden cracking or popping sound, pain, immediate detumescence and local swelling.
MRI is superior to all other imaging techniques in diagnosing penile fracture.
Management of penile fracture is surgical intervention with closure of the tunica albuginea.
Testicular Trauma
Blunt testicular injury may occur under intense compression of the testis against the inferior pubic ramus or symphysis, resulting in a rupture of the tunica albuginea.
Testicular rupture is associated with immediate pain, nausea, vomiting, and sometimes fainting.
Scrotal US is the preferred imaging modality for the diagnosis of testicular trauma.
Surgical exploration in patients with testicular trauma ensures preservation of viable tissue when possible.

*4.5.5 **Complications***

The possibility of complications from genital trauma, including psychological effects, erectile dysfunction, urethral stricture, and infertility, is high. In patients with a history of penile fracture post-operative complications were reported in up to 20% of cases, development of plaques or nodules following surgery, post-operative curvature formation and erectile dysfunction occur in 13.9%, 2.8% and 1.9% of patients, respectively [302]. Post-surgical erectile dysfunction is more common in patients > 50 years and those with bilateral corporal involvement [365]. Skin necrosis is rare [305]. The tear size of the tunica albuginea is a parameter which may affect long-term follow-up results [366].

Conservative management of penile fracture increases complications, such as penile abscess, missed urethral disruption, penile curvature, and persistent haematoma requiring delayed surgical intervention [367]. Late complications after conservative management were fibrosis and angulations in 35% and impotence in up to 62% [304, 368].

Post-operative complications were reported in 8% of patients who underwent testicular repair after penetrating trauma [310]. Despite good management and regular follow-up of external genital gunshot wounds, such wounds are fraught with the possibility of complications such as erectile dysfunction, urethral stricture, and infertility. Delayed complications include chronic pain and testicular atrophy. Haematoceles initially treated non-operatively may eventually need delayed surgery if they develop infection or undue pain. Genital injuries are rarely life threatening, but fertility and testosterone production often become the male trauma patient's chief concern once acute issues are resolved [369].

*4.5.6 **Follow-up***

In patients with genital trauma follow-up should focus on diagnosis of and therapy for late complications. Erectile dysfunction, urethral stricture and assessment of fertility are the main concerns [308, 370].

4.5.7 ***Summary of evidence and recommendations for evaluation and management of genital trauma.***

Summary of evidence	LE
A concomitant urethral injury complicates penile fractures and requires specialised management.	3
Ultrasound can determine intra- and/or extra-testicular haematoma, testicular contusion, or rupture with heterogeneous echo pattern parenchyma and loss of contour definition a highly sensitive and specific finding.	3
Surgical treatment of penile fracture ensures the lowest rate of negative long-term sequelae on functional and psychological wellbeing of the patient.	3
In patients with testicular rupture or equivocal imaging, surgical exploration can secure preservation of viable tissue.	3

Recommendations	Strength rating
Exclude urethral injury in the case of penile fracture.	Strong
Perform ultrasound (US) for the diagnosis of testis trauma.	Strong
Treat penile fractures surgically, with closure of tunica albuginea.	Strong
Explore the injured testis in all cases of testicular rupture and in those with inconclusive US findings.	Strong

6. CONFLICT OF INTEREST

All members of the Urological Trauma Guidelines working group have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publicly accessible through the European Association of Urology website: http://uroweb.org/guideline. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

7. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Paris 2024. ISBN 978-94-92671-23-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, the Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aim and objectives

Lower urinary tract symptoms (LUTS) are a common complaint in adult men with a major impact on quality of life (QoL) and have a substantial economic burden. The present Guidelines focuses on offering practical evidence-based guidance on the assessment and treatment of men with various non-neurogenic benign forms of LUTS. The understanding of the lower urinary tract (LUT) as a functional unit, and the multifactorial aetiology of associated symptoms, means that LUTS now constitute the main focus, rather than the former emphasis on Benign Prostatic Hyperplasia (BPH). The term BPH is now regarded as inappropriate as it is Benign Prostatic Obstruction (BPO) that is treated if the obstruction is a significant cause of a man's LUTS. It must be emphasised that clinical guidelines present the best evidence available to the experts. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Non-neurogenic Male LUTS Guidelines Panel consists of an international group of experts with urological and clinical epidemiological backgrounds. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website Uroweb: http://uroweb.org/guideline/treatment-of-non-neurogenic-male-luts/.

1.3 Available publications

A quick reference document, the Pocket Guidelines, is available in print and on the Uroweb website. These are abridged versions, which may require consultation together with the full text version. All documents are accessible through the EAU website Uroweb: http://www.uroweb.org/guideline/treatment-of-non-neurogenic-male-luts/.

1.4 Publication history

*1.4.1 **Publication history***

The Non-neurogenic Male LUTS Guidelines was first published in 2000. Standard procedure for EAU Guidelines includes an annual assessment of newly published literature in the field to guide future updates.

*1.4.2 **Summary of changes***

All chapters of the 2024 Male LUTS Guidelines have been updated, based on the 2022 version of the Guidelines. References have been added throughout the document. Other key changes incorporated in this publication includes:

- A new section 4.2.4 on Symptoms of Lower Urinary Tract Dysfunction Research Network;
- An update in section 4.8 on bladder voiding efficiency;
- A new section 5.2.7.4 regarding α1-blockers + Phosphodiesterase 5 inhibitors including a summary of evidence and recommendations;
- New recommendation in section 5.3.1.1 on open prostatectomy;
- New section in 5.6.2.1 on urodynamic testing for the management of male urinary incontinence;
- A new algorithm for men presenting with urinary incontinence;
- Two new summary of evidence statements in section 5.6.5.3;
- New subchapter on the management of underactive bladder, section 5.7.

2. METHODS

2.1 Introduction

For the 2024 EAU Guidelines on Non-Neurogenic Male LUTS, incl. BPO, new and relevant evidence was identified, collated and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the Non-Neurogenic Male LUTS Guidelines was performed. The search was limited to studies representing high levels of evidence, i.e., systematic reviews (SR) with meta-analysis, randomised controlled trials (RCTs), and prospective non-randomised comparative studies, published in the English language. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time

frame between May 1st 2021 and May 1st 2023. A total of 3,608 unique records were identified, retrieved and screened for relevance.

Detailed search strategies for the 2024 guideline are available online:
http://www.uroweb.org/guideline/treatment-of-non-neurogenic-male-luts/supplementary-material.

Recommendation within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [1];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact and certainty of patient values and preferences on the intervention.

Strong recommendations typically indicate a high degree of evidence quality and/or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [2].

Additional methodology information and a list of associations endorsing the EAU Guidelines can be found in the online: https://uroweb.org/eau-guidelines/methodology-policies.

2.2 Review

The Non-Neurogenic Male LUTS Guidelines were peer reviewed prior to publication in 2016. The newly added section on underactive bladder in males was peer reviewed prior to the publication in 2024.

2.3 Patients to whom the guidelines apply

Recommendations apply to men who seek professional help for LUTS in various non-neurogenic and non-malignant conditions such as BPO, detrusor overactivity (DO)/overactive bladder (OAB), urinary incontinence, and/or nocturnal polyuria. Specific context usually requires a more extensive work-up e.g., concomitant neurological diseases, young age, prior LUT disease or surgery, which is not covered in these Guidelines, but may include several tests mentioned in the following sections. EAU Guidelines on Neuro-Urology, Urological Infections, Urolithiasis, or malignant diseases of the LUT have been developed by other EAU Guidelines Panels and are available online: www.uroweb.org/guidelines/.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOPHYSIOLOGY

Lower urinary tract symptoms can be divided into storage, voiding and post-micturition symptoms [3], and they are prevalent, cause bother and impair QoL [4-7]. An increasing awareness of LUTS and storage symptoms in particular, is warranted to discuss management options that could increase QoL [8]. Lower urinary tract symptoms are strongly associated with ageing [4, 5], associated costs and burden are therefore likely to increase with future demographic changes [5, 9]. Lower urinary tract symptoms are also associated with a number of modifiable risk factors, suggesting potential targets for prevention (e.g., metabolic syndrome) [10]. In addition, men with moderate-to-severe LUTS may have an increased risk of major adverse cardiac events [11].

Most elderly men have at least one LUTS [5]; however, symptoms are often mild or not very bothersome [7, 8, 12]. Lower urinary tract symptoms can progress dynamically: for some individuals LUTS persist and progress over long time periods, and for others they remit [5]. Lower urinary tract symptoms have traditionally been related to bladder outlet obstruction (BOO), most frequently when histological BPH progresses through benign prostatic enlargement (BPE) to BPO [3, 6]. However, increasing numbers of studies have shown that LUTS are often unrelated to the prostate [5, 13]. Bladder dysfunction may also cause LUTS, including

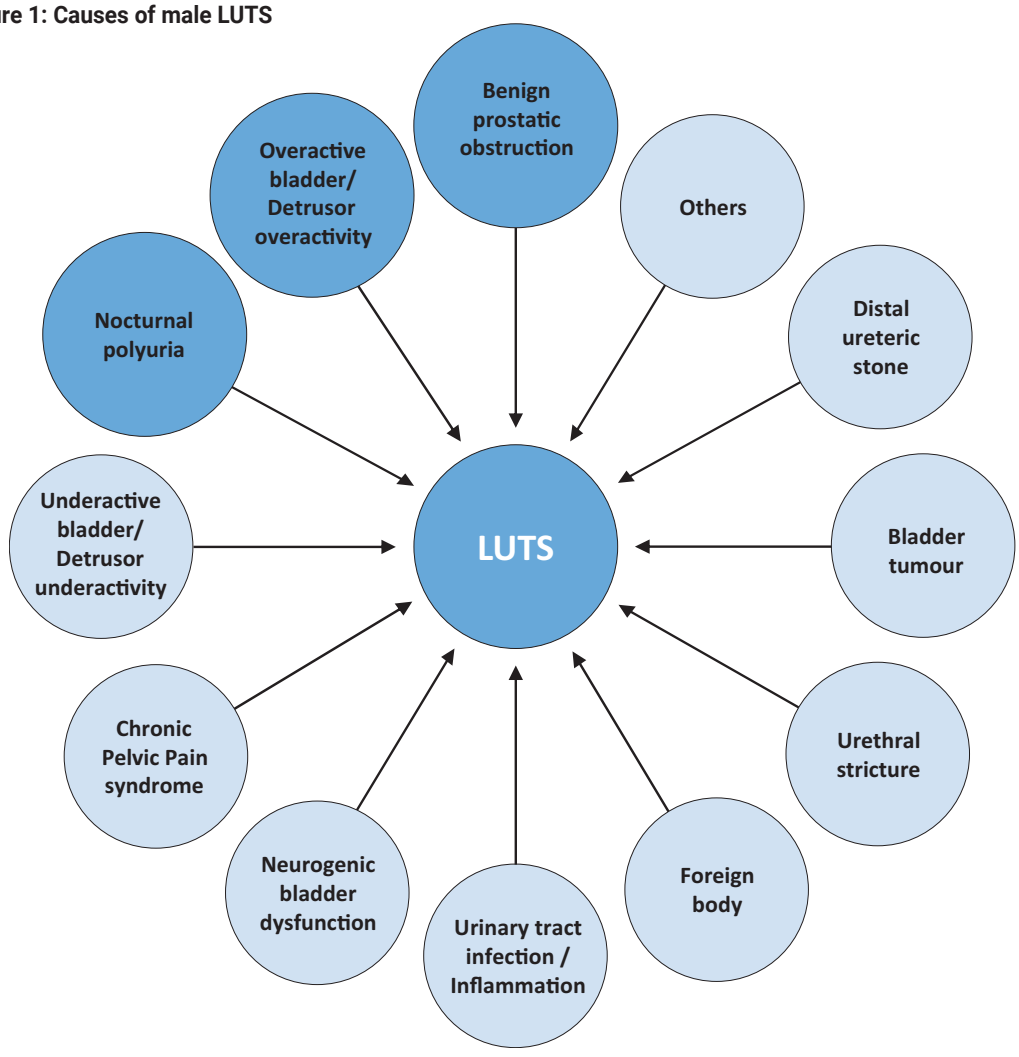
detrusor overactivity/OAB, detrusor underactivity (DU)/underactive bladder (UAB), as well as other structural or functional abnormalities of the urinary tract and its surrounding tissues [13]. Prostatic inflammation also appears to play a role in BPH pathogenesis and progression [14, 15]. In addition, many non-urological conditions also contribute to urinary symptoms, especially nocturia [5].

The definitions of the most common conditions related to male LUTS are presented below:

- Acute retention of urine is defined as a painful, palpable or percussible bladder, when the patient is unable to pass any urine [3].
- Chronic retention of urine is defined as a non-painful bladder, which remains palpable or percussible after the patient has passed urine. Such patients may be incontinent [3].
- Bladder outlet obstruction is the generic term for obstruction during voiding and is characterised by increasing detrusor pressure and reduced urine flow rate. It is usually diagnosed by invasive urodynamic or pressure/flow studie [3].
- Benign prostatic obstruction is a form of BOO and may be diagnosed when the cause of outlet obstruction is known to be BPE [3]. In the Guidelines the term BPO or BOO is used as reported by the original studies.
- Benign prostatic hyperplasia is a term used (and reserved) for the typical histological pattern, which defines the disease.
- Detrusor overactivity is a urodynamic observation characterised by involuntary detrusor contractions during the filling phase which may be spontaneous or provoked [3]. Detrusor overactivity is usually associated with OAB syndrome characterised by urinary urgency, with or without urgency urinary incontinence (UUI), usually with increased daytime frequency and nocturia, if there is no proven infection or other obvious pathology [16].
- Detrusor underactivity during voiding is characterised by decreased detrusor voiding pressure leading to a reduced urine flow rate. Detrusor underactivity causes underactive bladder syndrome which is characterised by voiding symptoms similar to those caused by BPO [17].

Figure 1 illustrates the potential causes of LUTS. In any man complaining of LUTS, it is common for more than one of these factors to be present.

Figure 1: Causes of male LUTS



4. DIAGNOSTIC EVALUATION

Tests are useful for diagnosis, monitoring, assessing the risk of disease progression, treatment planning, and predicting treatment outcomes. The clinical assessment of patients with LUTS has two main objectives:

- to identify the differential diagnoses, since the origin of male LUTS is multifactorial, the relevant EAU Guidelines on the management of applicable conditions should be followed;
- to define the clinical profile (including the risk of disease progression) of men with LUTS in order to provide appropriate care.

4.1 Medical history

The importance of assessing the patient's history is well recognised [18-20]. A medical history aims to identify the potential causes and relevant co-morbidities, including medical and neurological diseases. In addition, current medication, lifestyle habits, emotional and psychological factors must be reviewed. The Panel recognises the need to discuss LUTS and the therapeutic pathway from the patient's perspective. This includes reassuring the patient that there is no definite link between LUTS and prostate cancer (PCa) [21, 22].

As part of the urological/surgical history, a self-completed validated symptom questionnaire (see section 4.2) should be obtained to objectify and quantify LUTS [18, 20]. Bladder diaries or frequency volume charts (FVC) are particularly beneficial (see section 4.3) [23]. Sexual function should also be assessed, preferably with validated symptom questionnaires such as the International Index of Erectile Function (IIEF) [24].

Summary of evidence	LE
A medical and surgical history is an integral part of a patient's medical evaluation.	4
A medical and surgical history aims to identify the potential causes of LUTS as well as any relevant co-morbidities and to review the patient's current medication and lifestyle habits.	4

Recommendation	Strength rating
Take a complete medical history from men with LUTS.	Strong

4.2 Symptom score questionnaires

All published guidelines for male LUTS recommend using validated symptom score questionnaires [18, 20]. Several questionnaires have been developed which are sensitive to symptom changes and can be used to monitor treatment [25-31]. Symptom scores are helpful in quantifying LUTS and in identifying which type of symptoms are predominant; however, they are not disease-, gender-, or age-specific. A SR evaluating the diagnostic accuracy of individual symptoms and questionnaires, compared with urodynamic studies (the reference standard), for the diagnosis of BOO in males with LUTS found that individual symptoms and questionnaires for diagnosing BOO were not significantly associated with one another [32].

4.2.1 The International Prostate Symptom Score (IPSS)

The IPSS is an eight-item questionnaire, consisting of seven symptom questions and one QoL question [26]. The IPSS score is categorised as 'asymptomatic' (0 points), 'mildly symptomatic' (1-7 points), 'moderately symptomatic' (8-19 points), and 'severely symptomatic' (20-35 points). Limitations include lack of assessment of incontinence, post-micturition symptoms, and bother caused by each separate symptom.

4.2.2 The International Consultation on Incontinence Questionnaire for Male LUTS (ICIQ-MLUTS)

The ICIQ-MLUTS was created from the International Continence Society (ICS) Male questionnaire. It is a widely used and validated patient completed questionnaire including incontinence questions and bother for each symptom [27]. It contains thirteen items, with subscales for nocturia and OAB, and is available in 24 languages. [33]. The ICIQ-MLUTS explore more deeply the subtypes of males LUTS [34].

4.2.3 Danish Prostate Symptom Score (DAN-PSS)

The DAN-PSS [30] is a symptom score used mainly in Denmark and Finland. The DAN-PSS has twelve questions divided into parts A and B with questions on incontinence and measures the bother of each individual LUTS.

4.2.4 The Symptoms of Lower Urinary Tract Dysfunction Research Network (LURN-SI-10)

The LURN-SI-10 correlates strongly with the IPSS but identifies additional important symptomatology including incontinence and bladder pain in men with LUTS [35].

Summary of evidence	LE
Symptom questionnaires are sensitive to symptom changes.	3
Symptom scores can quantify LUTS and identify which types of symptoms are predominant; however, they are not disease-, or age-specific.	3

Recommendation	Strength rating
Use a validated symptom score questionnaire including bother and quality of life assessment during the initial assessment of male LUTS and for re-evaluation during and/or after treatment.	Strong

4.3 Frequency volume charts and/or bladder diaries

The recording of the volume and time of each void by the patient is referred to as an FVC. Inclusion of additional information such as fluid intake, use of pads, activities during recording, or which grades symptom severity and bladder sensation is termed a bladder diary [3]. Parameters that can be derived from the FVC and bladder diary include day-time and night-time voiding frequency, total voided volume, the fraction of urine production during the night (nocturnal polyuria index), and volume of individual voids.

The mean 24-hour urine production is subject to considerable variation. Likewise, circumstantial influence and intra-individual variation cause FVC parameters to fluctuate, though there is comparatively little data [36, 37]. The FVC/bladder diary is particularly relevant in nocturia, where it underpins the categorisation of underlying mechanism(s) [38-40]. The use of FVCs may cause a 'bladder training (BT) effect' and influence the frequency of nocturnal voids [41].

The duration of the FVC/bladder diary needs to be long enough to avoid sampling errors, but short enough to avoid non-compliance [23]. A SR of the available literature recommended FVCs should continue for at least three days [42]. There is no data as to whether the three days should be consecutive or scattered or whether it has to be on weekdays or weekends, as long as it is representative. The ICIQ-Bladder diary (ICIQ-BD) is the only diary that has undergone full validation [43].

Summary of evidence	LE
Frequency volume charts (FVC) and/or bladder diaries provide real-time documentation of urinary function and reduce recall bias.	3
Three- day FVCs provide reliable measurement of urinary symptoms in patients with LUTS similar to seven days and without losing the diagnostic accuracy.	2b

Recommendations	Strength rating
Use a bladder diary to assess male LUTS with a storage component, especially nocturia.	Strong
Tell the patient to complete a bladder diary for at least three days.	Strong

4.4 Physical examination and digital-rectal examination

Physical examination particularly focusing on the suprapubic area, the external genitalia, the perineum, and lower limbs should be performed. Urethral discharge, meatal stenosis, phimosis, and penile cancer must be excluded.

4.4.1 Digital-rectal examination and prostate size evaluation

Digital-rectal examination (DRE) is the simplest way to assess prostate volume, but the correlation to prostate volume is poor. Quality-control procedures for DRE have been described [44]. Transrectal ultrasound (TRUS) is more accurate in determining prostate volume than DRE. There is an underestimation of prostate volume by DRE. The underestimation increases with increasing TRUS volume, particularly where the volume is > 30 mL [45]. A model of visual aids has been developed to help urologists estimate prostate volume more accurately [46]. One study concluded that DRE was sufficient to discriminate between prostate volumes > or < 50 mL [47].

Summary of evidence	LE
Physical examination is an integral part of a patient's medical evaluation.	4
Digital-rectal examination can be used to assess prostate volume and texture; however, the correlation to actual prostate volume is poor.	3

Recommendation	Strength rating
Perform a physical examination including digital rectal examination in the assessment of male LUTS.	Strong

4.5 Urinalysis

Urinalysis (dipstick or microscopy) must be included in the primary evaluation of any patient presenting with LUTS to identify conditions, such as urinary tract infections (UTI), microhaematuria and diabetes mellitus. If abnormal findings are detected, further tests are recommended according to other EAU Guidelines, e.g., Guidelines on urinary tract cancers and urological infections [48-51].

Urinalysis is recommended in most Guidelines in the primary management of patients with LUTS [52, 53]. There is limited evidence, but general expert consensus suggests that the benefits outweigh the costs [54]. The value of urinary dipstick/microscopy for diagnosing UTI in men with LUTS without acute frequency and dysuria has been questioned [55].

Summary of evidence	LE
Urinalysis (dipstick or microscopy) may indicate a UTI, proteinuria, haematuria, or glycosuria requiring further assessment.	3
The benefits of urinalysis outweigh the costs.	4

Recommendation	Strength rating
Use urinalysis (by dipstick or microscopy) in the assessment of male LUTS.	Strong

4.6 Prostate-specific antigen

4.6.1 Prostate-specific antigen and the prediction of prostatic volume

Pooled analysis of RCTs, of men with LUTS and presumed BPO, showed that prostate-specific antigen (PSA) has a good predictive value for assessing prostate volume, with areas under the curve (AUC) of 0.76-0.78 for various prostate volume thresholds (30 mL, 40 mL, and 50 mL). To achieve a specificity of 70%, whilst maintaining a sensitivity between 65-70%, approximate age-specific criteria for detecting men with prostate glands exceeding 40 mL are PSA > 1.6 ng/mL, > 2.0 ng/mL, and > 2.3 ng/mL, for men with BPH in their 50s, 60s, and 70s, respectively [56].

A strong association between PSA and prostate volume was found in a large community-based study in the Netherlands [57]. A PSA threshold value of 1.5 ng/mL could best predict a prostate volume of > 30 mL, with a positive predictive value (PPV) of 78%. The prediction of prostate volume can also be based on total and free PSA. Both PSA forms predict the TRUS prostate volume (± 20%) in > 90% of the cases [58, 59].

4.6.2 Prostate-specific angtigen and the probability of PCa

The role of PSA in the diagnosis of PCa is presented by the EAU Guidelines on Prostate Cancer [60]. The potential benefits and harms of using serum PSA testing to diagnose PCa in men with LUTS should be discussed with the patient.

4.6.3 Prostate-specific antigen and the prediction of BPO-related outcomes

Serum PSA is a stronger predictor of prostate growth than prostate volume [61]. In addition, an RCT showed that PSA also predicted the changes in symptoms, QoL/bother, and maximum flowrate (Q_{max}) [62]. In a longitudinal study of men managed conservatively, PSA was a highly significant predictor of clinical progression to urinary retention [63, 64]. In the placebo arms of large double-blind studies, baseline serum PSA predicted the risk of acute urinary retention (AUR) and BPO-related surgery [65, 66]. An equivalent link was also confirmed by the Olmsted County Study. The risk for treatment was higher in men with a baseline PSA of > 1.4 ng/mL [67]. Patients with BPO seem to have a higher PSA level and larger prostate volumes. The PPV of PSA for the detection of BPO was recently shown to be 68% [68]. Furthermore, in an epidemiological study, elevated free PSA levels could predict clinical BPE, independent of total PSA levels [69].

Summary of evidence	LE
Prostate-specific antigen (PSA) has a good predictive value for assessing prostate volume and is a strong predictor of prostate growth.	1b
Baseline PSA can predict the risk of AUR and BPO-related surgery.	1b

Recommendations	Strength rating
Measure prostate-specific antigen (PSA) if a diagnosis of prostate cancer will change management.	Strong
Measure PSA if it assists in the treatment and/or decision-making process.	Strong
Counsel patients about PSA testing and the implications of a raised PSA test.	Strong

4.7 Renal function measurement

Renal function may be assessed by serum creatinine or estimated glomerular filtration rate (eGFR). Hydronephrosis, renal insufficiency or urinary retention are more prevalent in patients with signs or symptoms of BPO [70]. Even though BPO may be responsible for these complications, there is no conclusive evidence on the mechanism [71].

One study reported that 11% of men with LUTS had renal insufficiency [70]. Neither symptom score nor QoL was associated with the serum creatinine level. Diabetes mellitus or hypertension were the most likely causes of the elevated creatinine concentration. Comiter *et al.*, [72] reported that non-neurogenic voiding dysfunction is not a risk factor for elevated creatinine levels. Koch *et al.*, [73] concluded that only those with an elevated creatinine level or reduced eGFR require investigational ultrasound (US) of the kidney and bladder to assess post-void residual.

In the Olmsted County Study, there was a cross-sectional association between signs and symptoms of BPO (though not prostate volume) and chronic kidney disease (CKD) [74]. In 2,741 consecutive patients who presented with LUTS, decreased Q_{max}, a history of hypertension and/or diabetes were associated with CKD [75]. Another study demonstrated a correlation between Q_{max} and eGFR in middle-aged men with moderate-to-severe LUTS [76]. Patients with renal insufficiency are at an increased risk of developing post-operative complications [77].

Summary of evidence	LE
Decreased Q_{max} and a history of hypertension and/or diabetes are associated with CKD in patients who present with LUTS.	3
Patients with renal insufficiency are at an increased risk of developing post-operative complications.	3

Recommendation	Strength rating
Assess renal function if renal impairment is suspected based on history and clinical examination, or in the presence of hydronephrosis, or when considering surgical treatment for male LUTS.	Strong

4.8 Post-void residual urine

Post-void residual (PVR) urine can be assessed by transabdominal ultrasound (US), bladder scan or catheterisation. Post-void residual is not necessarily associated with BOO, since high PVR volumes can be a consequence of obstruction and/or poor detrusor function/DU [78, 79]. Using a PVR threshold of 50 mL, the diagnostic accuracy of PVR measurement has a PPV of 63% and a negative predictive value (NPV) of 52% for the prediction of BOO [80]. A large PVR is not a contraindication to watchful waiting (WW) or medical therapy, although it may indicate a poor response to treatment and especially to WW. In both the MTOPS and ALTESS studies, a high baseline PVR (PVR of ≥ 350 mL) was associated with an increased risk of symptom progression [65, 66].

Monitoring of changes in PVR over time may allow for identification of patients at risk of AUR [81]. This is of importance for the treatment of patients using antimuscarinic medication. In contrast, baseline PVR has little prognostic value for the risk of BPO-related invasive therapy in patients on α1-blockers or WW [82]. However, due to large test-retest variability and lack of outcome studies, no PVR threshold for treatment decision has yet been established; this is a research priority.

Since the role of PVR in males with LUTS has given inconclusive data, bladder voiding efficiency (BVE; [voided volume/total bladder capacity] × 100) has been introduced [83]. This parameter seems to be more reliable than PVR especially in patients with detrusor underactivity [84]. Together with BE, to overcome some limits of PVR, post-void residual urine ratio (PVR-R) was investigated. PVR-R represents the ratio of PVR to bladder volume (BV). This parameter indicates the non-functional bladder storage of urine after micturition and could be better related to the voiding emptying than the PVR per se. it is defined as PVR/total BV) × 100 [85].

Summary of evidence	LE
The diagnostic accuracy of PVR measurement, using a PVR threshold of 50 mL, has a PPV of 63% and a NPV of 52% for the prediction of BOO.	3
Monitoring of changes in PVR over time may allow for identification of patients at risk of AUR.	3

Recommendation	Strength rating
Measure post-void residual in the assessment of male LUTS.	Strong

4.9 Uroflowmetry

Urinary flow rate assessment is a widely used non-invasive urodynamic test. Key parameters are Q_{max}, voided volume, PVR, and flow pattern. Uroflowmetry parameters should preferably be evaluated with voided volume > 150 mL. As Q_{max} is prone to within-subject variation [86, 87], it is useful to repeat uroflowmetry measurements, especially if the voided volume is < 150 mL, or Q_{max} or flow pattern is abnormal.

The diagnostic accuracy of uroflowmetry for detecting BOO varies considerably and is substantially influenced by threshold values. A threshold Q_{max} of 10 mL/s has a specificity of 70%, a PPV of 70% and a sensitivity of 47% for BOO. The specificity using a threshold Q_{max} of 15 mL/s was 38%, the PPV 67% and the sensitivity 82% [88]. If Q_{max} is > 15 mL/s, physiological compensatory processes mean that BOO cannot be excluded. Low Q_{max} can arise as a consequence of BOO [89], DU or an under-filled bladder [90]. Therefore, it is limited as a diagnostic test as it is unable to discriminate between the underlying mechanisms.

Uroflowmetry can be used for monitoring treatment outcomes [91] and correlating symptoms with objective findings [88, 92]. Recently, a deep learning system for sound-based prediction of urinary flow has been proposed, as a simple home-based alternative to uroflowmetry, with acceptable correlation to conventional test [93].

Summary of evidence	LE
The diagnostic accuracy of uroflowmetry for detecting BOO varies considerably and is substantially influenced by threshold values. Specificity can be improved by repeated flow rate testing.	2b

Recommendations	Strength rating
Perform uroflowmetry in the initial assessment of male LUTS.	Weak
Perform uroflowmetry prior to medical or invasive treatment.	Strong

4.10 Imaging

*4.10.1 **Upper urinary tract***

Men with LUTS are not at increased risk for upper tract malignancy or other abnormalities when compared to the overall population [73, 94-96]. Several arguments support the use of renal US in preference to urological computed tomography (UROCT). Ultrasound allows for better characterisation of renal masses, the possibility of investigating the liver and retroperitoneum, and simultaneous evaluation of the bladder, PVR and prostate, together with a lower cost, no radiation dose and less side effects [94]. Ultrasound can be used for the evaluation of men with large PVR, haematuria, or a history of urolithiasis.

Summary of evidence	LE
Men with LUTS are not at increased risk for upper tract malignancy or other abnormalities when compared to the overall population.	3
Ultrasound can be used for the evaluation of men with large PVR, haematuria, or a history of urolithiasis.	4

Recommendation	Strength rating
Perform ultrasound of the upper urinary tract in men with LUTS.	Weak

*4.10.2 **Prostate***

Imaging of the prostate can be performed by transabdominal US, TRUS, computed tomography (CT), and magnetic resonance imaging (MRI). However, in daily practice, prostate imaging is performed by transabdominal (suprapubic) US or TRUS [94].

4.10.2.1 Prostate size and shape

Assessment of prostate size is important for the selection of interventional treatment, i.e., open prostatectomy (OP), enucleation techniques, transurethral resection, transurethral incision of the prostate (TUIP), or minimally invasive therapies. It is also important prior to treatment with 5α-reductase inhibitors (5-ARIs). Prostate volume predicts symptom progression and the risk of complications [96].

Transrectal US is superior to transabdominal volume measurement [97, 98]. The presence of a median lobe may guide treatment choice in patients scheduled for a minimally invasive approach since medial lobe presence can be a contraindication for some minimally invasive treatments (see section 5.3).

Summary of evidence	**LE**
Assessment of prostate size by TRUS or transabdominal US is important for the selection of interventional treatment and prior to treatment with 5-ARIs	3

Recommendations	**Strength rating**
Perform imaging of the prostate when considering medical treatment for male LUTS, if it assists in the choice of the appropriate drug.	Weak
Perform imaging of the prostate when considering surgical treatment.	Strong

*4.10.3 **Voiding cysto-urethrogram***

Voiding cysto-urethrogram (VCUG), on its own, is not recommended in the routine diagnostic work-up of men with LUTS, but it may be useful for the detection of vesico-ureteral reflux, bladder diverticula, or urethral diseases and can be combined with urodynamics in the form of video-urodynamics. Retrograde urethrography may additionally be useful for the evaluation of suspected urethral strictures.

4.11 Urethrocystoscopy

Patients with a history of microscopic or gross haematuria, urethral stricture, or bladder cancer, who present with LUTS, should undergo urethrocystoscopy during diagnostic evaluation. The evaluation of a prostatic middle lobe with urethrocystoscopy should be performed when considering interventional treatments for which the presence of middle lobe may affect the treatment offered e.g., Urolift.

A prospective study evaluated 122 patients with LUTS using uroflowmetry and urethrocystoscopy [99]. The pre-operative Q_{max} was normal in 25% of 60 patients who had no bladder trabeculation, 21% of 73 patients with mild trabeculation and 12% of 40 patients with marked trabeculation on cystoscopy. All 21 patients who presented with diverticula had a reduced Q_{max}.

Another study showed that there was no significant correlation between the degree of bladder trabeculation (graded from I to IV), and the pre-operative Q_{max} value in 39 symptomatic men aged 53-83 years [100]. The largest study published on this issue examined the relation of urethroscopic findings to urodynamic studies in 492 elderly men with LUTS [101]. The authors noted a correlation between cystoscopic appearance (grade of bladder trabeculation and urethral occlusion) and urodynamic indices, DO and low compliance. It should be noted, however, that BOO was present in 15% of patients with normal cystoscopic findings, while 8% of patients had no obstruction, even in the presence of severe trabeculation [101].

Summary of evidence	**LE**
Patients with a history of microscopic or gross haematuria, urethral stricture, or bladder cancer, who present with LUTS, should undergo urethrocystoscopy during diagnostic evaluation.	3
No study clearly identified a strong association between the urethrocystoscopic and urodynamic findings.	3

Recommendation	**Strength rating**
Perform urethrocystoscopy in men with LUTS prior to minimally invasive/surgical therapies if the findings may change treatment.	Weak

4.12 Urodynamics

In male LUTS, the most widespread invasive urodynamic techniques employed are filling cystometry and pressure flow studies (PFS). The major goal of urodynamics (UDS) is to explore the functional mechanisms of LUTS, to identify risk factors for adverse outcomes and to provide information for shared decision-making. Most terms and conditions (e.g., DO, low compliance, BOO/BPO, DU) are defined by urodynamic investigation.

4.12.1 ***Diagnosing bladder outlet obstruction***

Pressure flow studies are used to diagnose and define the severity of BOO, which is characterised by increased detrusor pressure and decreased urinary flow rate during voiding. Bladder outflow obstruction/ BPO has to be differentiated from DU, which exhibits decreased detrusor pressure during voiding in combination with decreased urinary flow rate [3]. Bladder outlet obstruction is calculated according to the equation $p_{det}Q_{max} – 2Q_{max}$ (BOO>40 = obstructed; BOO 20-40 = equivocal; and BOO<20 = unobstructed) [102], and to assess the contractility of the bladder, BCI is calculated according to the equation $P_{det}Q_{max}+5Q_{max}$ [103] (BCI>150 = strong contractility, 100-150 = normal contractility, and < 100 weak contractility) [83].

Urodynamic testing may also identify DO. Studies have described an association between BOO and DO [104, 105]. In men with LUTS attributed to BPO, DO was present in 61% and independently associated with BOO grade and ageing [104].

The prevalence of DU in men with LUTS is 11-40% [106, 107]. Detrusor contractility does not appear to decline in long-term BOO and surgical relief of BOO does not improve contractility [108, 109]. The UPSTREAM trial investigated whether urodynamics would reduce surgery without increasing urinary symptoms. UPSTREAM was a non-inferiority, RCT in men with bothersome LUTS, in whom surgery was an option, in 26 hospitals in England. In the UDS arm, 153/408 patients (38%) received surgery compared with 138/384 (36%) in the routine care (RC) arm. A total of 428 adverse events were recorded, with related events similar in both arms and eleven unrelated deaths. The UDS group was non-inferior to the RC group for IPSS, and UDS did not significantly reduce surgical rates. The authors concluded that routine use of UDS in the evaluation of uncomplicated LUTS has a limited role and should be used selectively [110]. However, in a prospective cohort study of urodynamically assessed patients prior to surgery, patients with DU alone with Bladder Contractility Index (BCI) [BCI] < 100 and BOO index [BOOI] < 40 had significantly worse outcome with regard to post-operative maximum flow rate at twelve month than those DU and BOO with BCI < 100 and BOOI ≥ 40) as well as patients with BOO alone with and BCI ≥ 100 and BOOI ≥ 40) [111]. Nevertheless, if urodynamic investigation is performed, a rigorous quality control is mandatory [112, 113].

Exploratory findings from the UPSTREAM Trial have characterised the basic diagnostic and urodynamic parameters to identify men who will benefit more from de-obstructive surgery [114]. The Investigators reported that surgery was more beneficial in those men with higher symptom scores (IPSS>16), age<74yr, poor urine flow (Q_{max} < 10ml/s), bladder outlet obstruction index > 47.6 and bladder contractility index > 123.

Due to the invasive nature of the test, a urodynamic investigation is generally only offered if conservative and medical treatment have failed. The Guidelines Panel attempted to identify specific indications for UDS based on age, findings from other diagnostic tests and previous treatments. The Panel allocated a different degree of obligation for UDS in men > 80 years and men < 50 years, which reflects the lack of evidence. In addition, there was no consensus whether UDS should or may be performed when considering surgery in men with bothersome predominantly voiding LUTS and Q_{max} > 10 mL/s, although the Panel recognised that with a Q_{max} < 10 mL/s, BOO is likely and UDS is not necessarily needed.

Patients with neurological disease, including those with previous radical pelvic surgery, should be assessed according to the EAU Guidelines on Neuro-Urology [115].

4.12.2 ***Videourodynamics***

Videourodynamics provides additional anatomical and functional information and may be recommended if the clinician considers this is needed to understand the pathophysiological mechanism of an individual patient's LUTS. There is only low-level evidence for the addition of imaging to UDS.

Summary of evidence	**LE**
Pressure-flow studies is not a test for routine use prior to prostate surgery for all patients.	3

Recommendations	Strength rating
Perform urodynamics (UDS) only in individual patients for specific indications prior to invasive treatment or when further evaluation of the underlying pathophysiology of LUTS is warranted.	Weak
Perform UDS in men who have had previous unsuccessful (invasive) treatment for LUTS prior to further invasive treatment.	Weak
Perform UDS in men considering invasive treatment who cannot void > 150 mL.	Weak
Perform UDS when considering surgery in men with bothersome predominantly voiding LUTS and Q_{max} > 10 mL/s.	Weak
Perform UDS when considering invasive therapy in men with bothersome, predominantly voiding LUTS with a post-void residual > 300 mL.	Weak
Perform UDS when considering invasive treatment in men with bothersome, predominantly voiding LUTS aged > 80 years.	Weak
Perform UDS when considering invasive treatment in men with bothersome, predominantly voiding LUTS aged < 50 years.	Weak

4.13 Non-invasive tests in diagnosing bladder outlet obstruction in men with LUTS

4.13.1 Prostatic configuration/intravesical prostatic protrusion

Prostatic configuration can be evaluated with TRUS, using the concept of the presumed circle area ratio (PCAR) [116]. The PCAR evaluates how closely the transverse US image of the prostate approaches a circular shape. The ratio tends toward one as the prostate becomes more circular. The sensitivity of PCAR was 77% for diagnosing BPO when PCAR was > 0.8, with 75% specificity [116].

Ultrasound measurement of intravesical prostatic protrusion (IPP) assesses the distance between the tip of the prostate median lobe and bladder neck in the midsagittal plane, using a suprapubically positioned US scanner, with a bladder volume of 150-250 mL; grade I protrusion is 0-4.9 mm, grade II is 5-10 mm and grade III is > 10 mm.

Intravesical prostatic protrusion correlates well with BOO, with a PPV of 94% and a NPV of 79% [117]. A SR examined the role of IPP in UDS determined BOO [118]. At cut-off > 10mm the sensitivity was found 0.71 and the specificity 0.77. Intravesical prostatic protrusion may also correlate with prostate volume, DO, bladder compliance, detrusor pressure at maximum urinary flow, BOO index and PVR, and negatively correlates with Q_{max} [119]. Furthermore, IPP also appears to successfully predict the outcome of a trial without catheter after AUR [120, 121]. Evidence from the above-mentioned SR, showed that at an IPP cut-off of > 10mm, the sensitivity and specificity to predict unsuccessful voiding trial without catheter (TWOC) was 0.51 and 0.79 respectively [118]. However, no information with regards to intra- or inter-observer variability and learning curve is yet available. Therefore, whilst IPP may be a feasible option to infer BPO in men with LUTS, the role of IPP as a non-invasive alternative to PFS in the assessment of male LUTS remains under evaluation.

4.13.2 Bladder/detrusor wall thickness and ultrasound-estimated bladder weight

For bladder wall thickness (BWT) assessment, the distance between the mucosa and the adventitia is measured. For detrusor wall thickness (DWT) assessment, the only measurement needed is the detrusor sandwiched between the mucosa and adventitia [122].

A correlation between BWT and UDS parameters has been reported. A threshold value of 5 mm at the anterior bladder wall with a bladder filling of 150 mL was best at differentiating between patients with or without BOO [123]. Detrusor wall thickness at the anterior bladder wall with a bladder filling > 250 mL (threshold value for BOO > 2 mm) has a PPV of 94% and a specificity of 95%, achieving 89% agreement with PFS [73]. Threshold values of 2.0, 2.5, or 2.9 mm for DWT in patients with LUTS are able to identify 81%, 89%, and 100% of patients with BOO, respectively [124]. A meta-analysis reported that DWT has high accuracy in diagnosing BOO with sensitivity 71% and specificity 88% [125].

All studies found that BWT or DWT measurements have a higher diagnostic accuracy for detecting BOO than Q_{max} or Q_{ave} of free uroflowmetry, measurements of PVR, prostate volume, or symptom severity. One study could not demonstrate any difference in BWT between patients with normal UDS, BOO or DO. However, the study did not use a specific bladder filling volume for measuring BWT [126]. Disadvantages of the method include the lack of standardisation, and lack of evidence to indicate which measurement (BWT/DWT) is preferable [127]. Measurement of BWT/DWT is therefore not recommended for the diagnostic work-up of men with LUTS.

Ultrasound-estimated bladder weight (UEBW) may identify BOO with a diagnostic accuracy of 86% at a cut-off value of 35 g [128, 129]. Severe LUTS and a high UEBW (> 35 g) are risk factors for prostate/BPO surgery in men on α-blockers [130].

4.13.3 Non-invasive pressure-flow testing

The penile cuff test (PCT), in which flow is interrupted to estimate isovolumetric bladder pressure, shows promising data, with good test repeatability [131] and interobserver agreement [132]. A nomogram has also been derived [133] whilst a method in which flow is not interrupted is also under investigation [134]. A SR and meta-analysis assessed the performance of PCT to recognise BOO, reported sensitivity 0.85, specificity 0.78, PPV 0.74 and NPV 0.87 [135]. However, there was marked heterogeneity among the included studies in the definition of obstruction.

The data generated with the external condom method [136] correlates with invasive PFS in a high proportion of patients [137]. Resistive index [138] and prostatic urethral angle [139] have also been proposed, but are still experimental.

4.13.4 The diagnostic performance of non-invasive tests in diagnosing bladder outlet obstruction in men with LUTS compared with pressure-flow studies

A SR including 42 studies investigated the diagnostic performance of non-invasive tests in diagnosing BOO in men with LUTS compared with UDS/PFS [140]. The majority of the included studies were prospective cohorts, focusing on BOO and not specifically on BPO, and the diagnostic accuracy of the following non-invasive tests were assessed: penile cuff test; uroflowmetry; DWT/BWT; bladder weight; external condom catheter method; IPP; Doppler US; prostate volume/height; and near-infrared spectroscopy. Overall, although the majority of studies have a low risk of bias, data regarding the diagnostic accuracy of these non-invasive tests is limited by the heterogeneity of the studies in terms of the threshold values used to define BOO, the different urodynamic definitions of BOO used across different studies and the small number of studies for each test. It was found that specificity, sensitivity, PPV and NPV of the non-invasive tests were highly variable. Therefore, even though several tests have shown promising results regarding non-invasive diagnosis of BOO, invasive urodynamics remains the modality of choice.

The diagnostic performance of non-invasive tests could be theoretically improved when two or more tests are combined along with clinical parameters, however the evidence is still limited. Investigators have proposed a model and a clinical nomogram that uses BWT, prostate volume and PVR ratio to predict BOO with reported accuracy 0.82 [141].

Summary of evidence	**LE**
Data regarding the diagnostic accuracy of non-invasive tests is limited by the heterogeneity of the studies as well as the small number of studies for each test.	1a
Specificity, sensitivity, PPV and NPV of the non-invasive tests were highly variable.	1a

Recommendation	**Strength rating**
Do not offer non-invasive tests as an alternative to urodynamics/pressure-flow studies for diagnosing bladder outflow obstruction in men.	Strong

4.14 Novel assessment

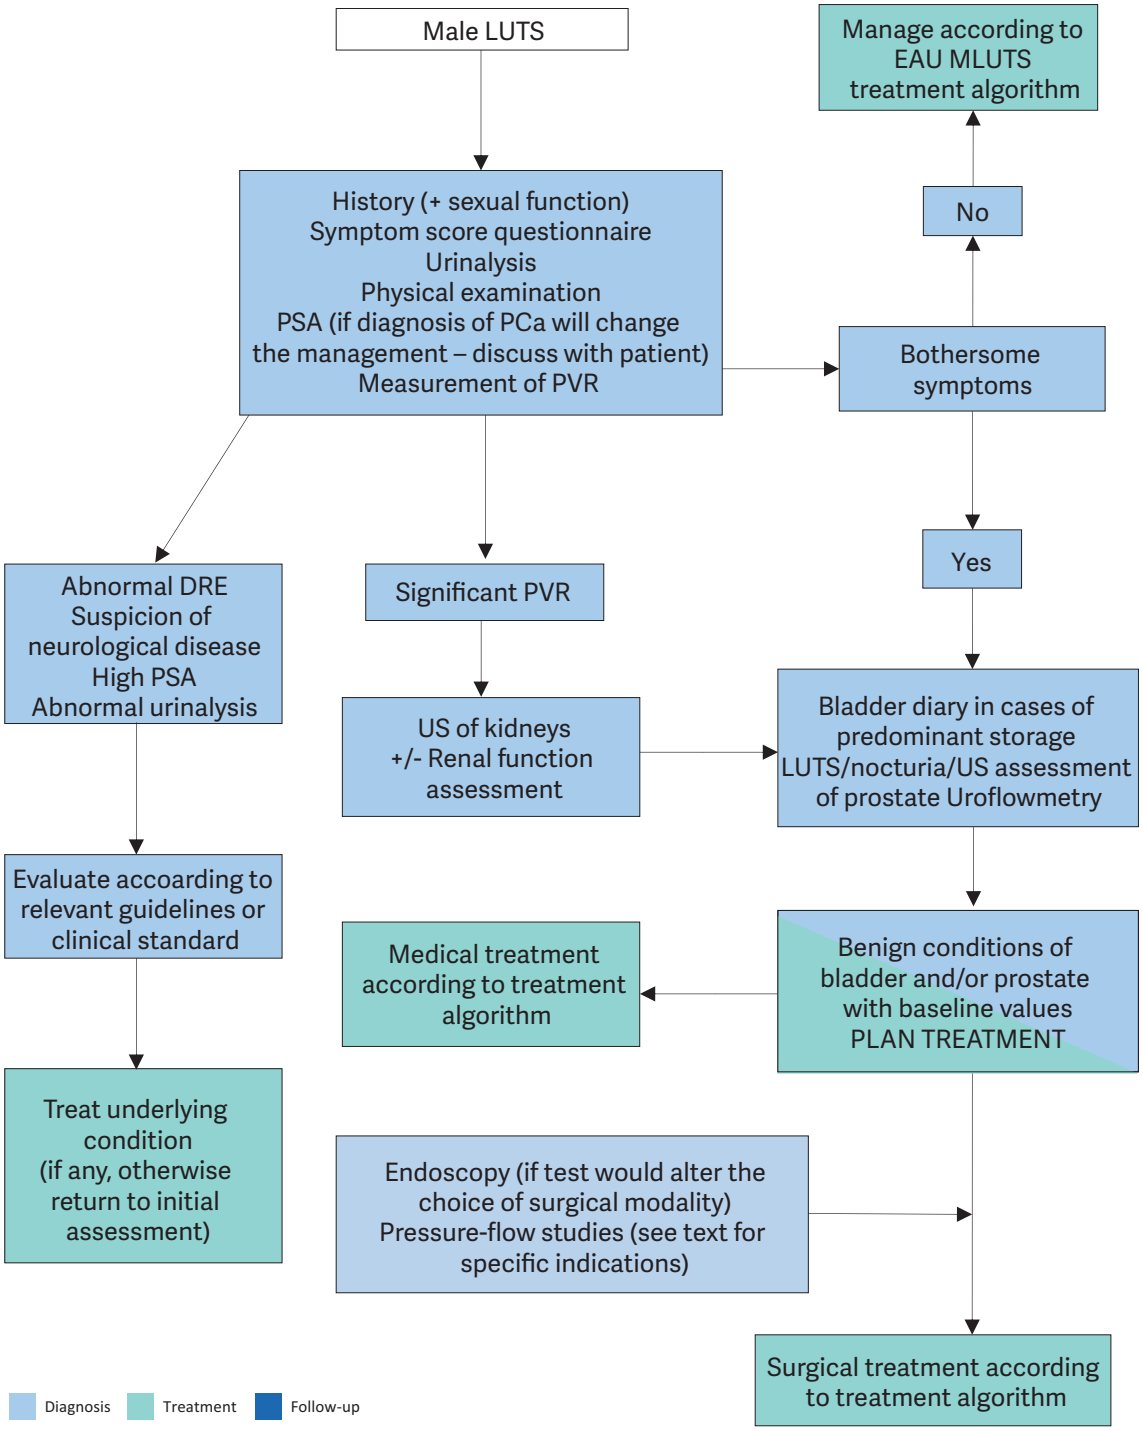
4.14.1 Visual prostate symptom score

A novel visual prostate symptom score (VPSS) has been prospectively tested vs. the IPPS and correlated positively with the IPSS score [142, 143]. This visual score can be used as an option in men with limited literacy.

4.14.2 Micro-RNA

The use of miR-221 has been shown to have the potential to be used as a biomarker and novel target in the early diagnosis and therapy of BPH [144].

Figure 2: Assessment algorithm of LUTS in men aged 40 years or older
Readers are strongly recommended to read the full text that highlights the current position of each test in detail.



DRE = digital-rectal examination; FVC = frequency volume chart; LUTS = lower urinary tract symptoms; PCa = prostate cancer; PSA = prostate specific antigen; PVR = post-void residual; US = ultrasound.
