Many men with LUTS are not troubled enough by their symptoms to need drug treatment or surgical intervention. All men with LUTS should be formally assessed prior to any allocation of treatment in order to establish symptom severity and to differentiate between men with uncomplicated (the majority) and complicated LUTS. Watchful waiting is a viable option for many men with non-bothersome LUTS as few will progress to AUR and complications (e.g. renal insufficiency or stones) [145, 146], whilst others can remain stable for years [147]. In one study, approximately 85% of men with mild LUTS were stable on WW at one year [148].

A study comparing WW and transurethral resection of the prostate (TURP) in men with moderate LUTS showed the surgical group had improved bladder function (flow rates and PVR volumes), especially in those with high levels of bother; 36% of WW patients crossed over to surgery within five years, leaving 64% doing well in the WW group [149, 150]. Increasing symptom bother and PVR volumes are the strongest predictors of WW failure. Men with mild-to-moderate uncomplicated LUTS who are not too troubled by their symptoms are suitable for WW.

5.1.2 Behavioural and dietary modifications

It is customary for this type of management to include the following components:

- education (about the patient's condition);
- reassurance (that cancer is not a cause of the urinary symptoms);
- periodic monitoring;
- lifestyle advice [147, 148, 151, 152] such as:
    - reduction of fluid intake at specific times aimed at reducing urinary frequency when most inconvenient (e.g., at night or when going out in public);
    - avoidance/moderation of intake of caffeine or alcohol, which may have a diuretic and irritant effect, thereby increasing fluid output and enhancing frequency, urgency and nocturia;
    - use of relaxed and double-voiding techniques;
    - urethral milking to prevent post-micturition dribble;
    - distraction techniques such as penile squeeze, breathing exercises, perineal pressure, and mental tricks to take the mind off the bladder and toilet, to help control OAB symptoms;
    - bladder retraining that encourages men to hold on when they have urgency to increase their bladder capacity and the time between voids;
    - reviewing the medication and optimising the time of administration or substituting drugs for others that have fewer urinary effects (these recommendations apply especially to diuretics);
    - providing necessary assistance when there is impairment of dexterity, mobility, or mental state;
    - treatment of constipation.

Evidence exists that self-management as part of WW reduces both symptoms and progression [151, 152]. Men randomised to three self-care management sessions in addition to standard care had better symptom improvement and QoL than men treated with standard care only, for up to a year [151]. A SR and meta-analysis found reasonable certainty in estimates that self-management intervention significantly reduced symptom severity in terms of IPSS at six months compared with usual care [153]. The reduction in IPSS score with self-management was similar to that achieved with drug therapy at six to twelve weeks. Self-management had a smaller, additional benefit at six weeks when added to drug therapy [153].

5.1.3 Practical considerations

The components of self-care management have not been individually studied. The above components of lifestyle advice have been derived from formal consensus methodology [154]. Further research in this area is required.

Summary of evidence	LE
Watchful waiting is usually a safe alternative for men who are less bothered by urinary difficulty or who wish to delay treatment. The treatment failure rate over a period of five years was 21%; 79% of patients were clinically stable.	1b
An additional study reported 81% of patients were clinically stable on WW after a mean follow-up of seventeen months.	2
Men randomised to three self-management sessions in addition to standard care had better symptom improvement and QoL than men treated with standard care alone at up to a year. Self-care management as part of WW reduces both symptoms and progression.	1b
Self-management achieved a clinically meaningful reduction in symptom severity at six months compared to usual care. There was also a small but significant additional benefit of adding self-management to drug therapy.	1b

Recommendations	Strength rating
Offer men with mild/moderate symptoms, minimally bothered by their symptoms, watchful waiting.	Strong
Offer men with LUTS lifestyle advice and self-care information prior to, or concurrent with, treatment.	Strong

5.2 Pharmacological treatment

5.2.1 α1-Adrenoceptor antagonists (α1-blockers)

Mechanism of action: α1-blockers aim to inhibit the effect of endogenously released noradrenaline on smooth muscle cells in the prostate and thereby reduce prostate tone and BOO [155]. However, α1-blockers have little effect on urodynamically determined bladder outlet resistance [156], and treatment-associated improvement of LUTS correlates poorly with obstruction [157]. Thus, other mechanisms of action may also be relevant.

Alpha 1-adrenoceptors located outside the prostate (e.g. urinary bladder and/or spinal cord) and α1-adrenoceptor subtypes (α1B- or α1D-adrenoceptors) may play a role as mediators of effects. Alpha 1-adrenoceptors in blood vessels, other non-prostatic smooth muscle cells, and the central nervous system may mediate adverse events.

Currently available α1-blockers are: alfuzosin hydrochloride (alfuzosin); doxazosin mesylate (doxazosin); silodosin; tamsulosin hydrochloride (tamsulosin); terazosin hydrochloride (terazosin); and naftopidil. Alpha 1-blockers exist in different formulations. Although different formulations result in different pharmacokinetic and tolerability profiles, the overall difference in clinical efficacy between the difference formulations seems negligible.

Efficacy: Indirect comparisons and limited direct comparisons between α1-blockers demonstrate that all α1-blockers have a similar efficacy in appropriate doses [158]. Clinical effects take a few weeks to develop fully, but significant efficacy over placebo can occur within hours to days [157].

Controlled studies show that α1-blockers typically reduce IPSS by approximately 30-40% and increase Q_{max} by approximately 20-25%. However, substantial improvements also occurred in the corresponding placebo arms [63, 159]. In open-label studies, an IPSS improvement of up to 50% and Q_{max} increase of up to 40% were documented [63, 159]. A SR and meta-analysis suggested that Q_{max} variation underestimates the real effect of α1-blockers on BPO, as small improvements in Q_{max} correspond to relevant improvements in BOO index in PFS [160].

Alpha 1-blockers can reduce both storage and voiding LUTS. Prostate size does not affect α1-blocker efficacy in studies with follow-up periods of less than one year, but α1-blockers do seem to be more efficacious in patients with smaller prostates (< 40 mL) in longer-term studies [65, 161-164]. The efficacy of α1-blockers is similar across age groups [159]. A pooled analysis of phase III and IV trials of silodosin 8 mg demonstrated that improvements in total, storage, voiding, and QoL IPSS scores were similar for the severe and not severe LUTS cohorts [165]. In addition, α1-blockers neither reduce prostate size nor prevent AUR in long-term studies [162-164]; however, evidence suggests that the use of α1-blockers (alfuzosin, tamsulosin and silodosin) improve resolution of AUR [166, 167]. Nonetheless, IPSS reduction and Q_{max} improvement during α1-blocker treatment appears to be maintained over at least four years.

Tolerability and safety: Tissue distribution, subtype selectivity, and pharmacokinetic profiles of certain formulations may contribute to the tolerability profile of specific drugs. The most frequent adverse events of α1-blockers are asthenia, dizziness and (orthostatic) hypotension. Vasodilating effects are most pronounced with doxazosin and terazosin and are less common with alfuzosin and tamsulosin [168]. Patients with cardiovascular co-morbidity and/or vaso-active co-medication may be susceptible to α1-blocker-induced vasodilatation [169]. In contrast, the frequency of hypotension with the α1A-selective blocker silodosin is comparable with placebo [170]. In a large retrospective cohort analysis of men aged > 66 years treated with α1-blockers the risks of falling (odds ratio [OR] 1.14) and of sustaining a fracture (OR 1.16) was increased, most likely as a result of induced hypotension [171]. In terms of cardiovascular risk, a large population-based study reported an increased risk of cardiac failure with long-term α-blocker use (HR 1.22), which was higher for non-selective α-blockers [172]. Whilst there has been concern about a possible risk of dementia with long-term use of α1-blockers, a large Finnish nationwide case-control study of 24,602 cases and 98,397 controls did not find evidence of a significant association [173].

An adverse ocular event termed intra-operative floppy iris syndrome (IFIS) was reported in 2005, affecting cataract surgery [174]. A meta-analysis on IFIS after alfuzosin, doxazosin, tamsulosin or terazosin exposure showed an increased risk for all α1-blockers [175]. However, the OR for IFIS was much higher for tamsulosin. It appears prudent not to initiate α1-blocker treatment prior to scheduled cataract surgery, and the ophthalmologist should be informed about α1-blocker use.

A SR concluded that α1-blockers do not adversely affect libido, or erectile function (ED), but can cause abnormal ejaculation (OR: 7.53) [176]. Originally, abnormal ejaculation was thought to be retrograde, but more recent data demonstrate that it is due to a decrease or absence of seminal fluid during ejaculation, with young age being an apparent risk factor. In a meta-analysis ejaculatory dysfunction (EjD) was significantly more common with α1-blockers than with placebo (OR: 5.88). In particular, EjD was significantly more commonly related with tamsulosin or silodosin (OR: 8.57 and 32.5) than placebo, while both doxazosin and terazosin (OR: 0.80 and 1.78) were associated with a low risk of EjD [177]. In the meta-regression, the occurrence of EjD was independently associated with the improvement of urinary symptoms and flow rate, suggesting that the more effective the α1-blocker is the greater the incidence of EjD.

Practical considerations: α1-blockers are usually considered the first-line drug treatment for male LUTS because of their rapid onset of action, good efficacy, and low rate and severity of adverse events. However, α1-blockers do not prevent occurrence of urinary retention or need for surgery. Ophthalmologists should be informed about α1-blocker use prior to cataract surgery. Elderly patients treated with non-selective α1-blockers should be informed about the risk of orthostatic hypotension. Sexually active patients treated with selective α1-blockers should be counselled about the risk of EjD.

Summary of evidence	**LE**
Alpha 1-blockers are effective in reducing urinary symptoms (IPSS) and increasing the peak urinary flow rate (Q_{max}) compared with placebo.	1a
Alfuzosin, terazosin and doxazosin showed a statistically significant increased risk of developing vascular-related events compared with placebo.	1a
Alfuzosin, doxazosin, tamsulosin and terazosin exposure has been associated with an increased risk of IFIS.	1a
Ejaculatory dysfunction is significantly more common with α1-blockers than with placebo, particularly with more selective α1-blockers such as tamsulosin and silodosin.	1a

Recommendation	**Strength rating**
Offer α1-blockers to men with moderate-to-severe LUTS.	Strong

*5.2.2 **5α-reductase inhibitors***

Mechanism of action: Androgen effects on the prostate are mediated by dihydrotestosterone (DHT), which is converted from testosterone by the enzyme 5α-reductase [178], which has two isoforms:

- 5α-reductase type 1: predominant expression and activity in the skin and liver.
- 5α-reductase type 2: predominant expression and activity in the prostate.

Two 5-ARIs are available for clinical use: dutasteride and finasteride. Finasteride inhibits only 5α-reductase type 2, whereas dutasteride inhibits both 5α-reductase types (dual 5-ARI). The 5-ARIs induce apoptosis of prostate epithelial cells [179] leading to prostate size reduction of about 18-28% and a decrease in circulating PSA levels of about 50% after six to twelve months of treatment [180]. Mean prostate volume and PSA reduction may be

even more pronounced after long-term treatment. Continuous treatment reduces the serum DHT concentration by approximately 70% with finasteride and 95% with dutasteride. However, prostate DHT concentration is reduced to a similar level (85-90%) by both 5-ARIs.

Efficacy: Clinical effects relative to placebo are seen after treatment of at least six months. After two to four years of treatment 5-ARIs improve IPSS by approximately 15-30%, decrease prostate volume by 18-28%, and increase Q_{max} by 1.5-2.0 mL/s in patients with LUTS due to prostate enlargement [65, 163, 164, 181-187]. An indirect comparison and one direct comparative trial (twelve months duration) indicated that dutasteride and finasteride are equally effective in the treatment of LUTS [180, 188]. Symptom reduction depends on initial prostate size.

Finasteride may not be more efficacious than placebo in patients with prostates < 40 mL [189]. However, dutasteride seems to reduce IPSS, prostate volume, and the risk of AUR, and to increase Q_{max} even in patients with prostate volumes of between 30 and 40 mL [190, 191]. A long-term trial with dutasteride in symptomatic men with prostate volumes > 30 mL and increased risk for disease progression showed that dutasteride reduced LUTS at least as much as the α1-blocker tamsulosin [163, 187, 192]. The greater the baseline prostate volume (or serum PSA level), the faster and more pronounced the symptomatic benefit of dutasteride as compared to tamsulosin.

5α-reductase inhibitors, but not α1-blockers, reduce the long-term (> 1 year) risk of AUR or need for surgery [65, 185, 193]. In the PLESS study, finasteride reduced the relative risk of AUR by 57% and need for surgery by 55% (absolute risk reduction 4% and 7%, respectively) at four years, compared with placebo [185]. In the MTOPS study, finasteride reduced the relative risk of AUR by 68% and need for surgery by 64% (absolute risk reduction 2% and 3%, respectively), also at four years [65]. A pooled analysis of three RCTs with two-year follow-up data, reported that treatment with finasteride decreased the relative risk of AUR by 57%, and surgical intervention by 34% (absolute risk reduction 2% for both) in patients with moderately symptomatic LUTS [194]. Dutasteride has also demonstrated efficacy in reducing the risks for AUR and BPO-related surgery. Open-label trials have demonstrated relevant changes in urodynamic parameters [195, 196]. Furthermore, finasteride might reduce blood loss during transurethral prostate surgery, probably due to its effects on prostatic vascularisation, although evidence for a clinically significant effect is mixed [197-199].

Tolerability and safety: The most common adverse events are reduced libido, erectile dysfunction (ED) and less frequently, ejaculation disorders such as retrograde ejaculation, ejaculation failure, or decreased semen volume [65, 164, 180, 200]. Gynaecomastia (with breast or nipple tenderness) develops in 1-2% of patients. Two studies have suggested that treatment with 5-ARIs is associated with a higher incidence of high-grade cancers although no causal relationship has been proven [201, 202]. There is a long-standing debate regarding potential cardiovascular side effects of 5-ARIs, in particular dutasteride [203]. Population-based studies in Taiwan and Ontario did not find an association between the use of 5-ARIs and increased cardiovascular side effects [203, 204]. In a British-Taiwanese population-based cohort study, the risk of type II diabetes was higher in men with 5-ARIs than in men receiving tamsulosin but did not differ between dutasteride and finasteride [205]. A large Swedish cohort study showed an increased risk of depression with both finasteride (HR 1.61) and dutasteride (HR 1.68), but no long-term association with dementia or suicide risk [206].

Practical considerations: Treatment with 5-ARIs should be considered in men with moderate-to-severe LUTS and an enlarged prostate (> 40 mL) and/or elevated PSA concentration (> 1.4-1.6 ng/mL). They can prevent the risk of AUR and need for surgery. Due to the slow onset of action, they are not suitable for short-term use. Their effect on PSA needs to be considered in relation to PCa screening.

Summary of evidence	**LE**
After two to four years of treatment, 5-ARIs improve IPSS by approximately 15-30%, decrease prostate volume by 18-28%, and increase Q_{max} by 1.5-2.0 mL/s in patients with LUTS due to prostate enlargement.	1b
5α-reductase inhibitors can prevent disease progression with regard to AUR and the need for surgery. Due to 5-ARIs slow onset of action, they are suitable only for long-term treatment (years).	1a
The most relevant adverse effects of 5-ARIs are related to sexual function, and include reduced libido, ED and less frequently, ejaculation disorders such as retrograde ejaculation, ejaculation failure, or decreased semen volume as well as breast enlargement and breast tenderness.	1b

Recommendations	Strength rating
Use 5α-reductase inhibitors (5-ARIs) in men who have moderate-to-severe LUTS and an increased risk of disease progression (e.g., prostate volume > 40 mL).	Strong
Counsel patients about the slow onset of action of 5-ARIs.	Strong

*5.2.3 **Muscarinic receptor antagonists***

Mechanism of action: The detrusor is innervated by parasympathetic nerves whose main neurotransmitter is acetylcholine, which stimulates muscarinic receptors (M-cholinoreceptors) on the smooth muscle cells. Muscarinic receptors are also present on other cell types, such as bladder urothelial cells and epithelial cells of the salivary glands. Five muscarinic receptor subtypes (M1-M5) have been described, of which M2 and M3 are predominant in the detrusor. The M2 subtype is more numerous, but the M3 subtype is functionally more important in bladder contractions [207, 208]. Antimuscarinic effects might also be induced or modulated through other cell types, such as the bladder urothelium or by the central nervous system [209, 210].

The following muscarinic receptor antagonists are licensed for treating OAB/storage symptoms: darifenacin hydrobromide (darifenacin); fesoterodine fumarate (fesoterodine); oxybutynin hydrochloride (oxybutynin); propiverine hydrochloride (propiverine); solifenacin succinate (solifenacin); tolterodine tartrate (tolterodine); and trospium chloride. Transdermal preparations of oxybutynin have been formulated and evaluated in clinical trials [211, 212].

Efficacy: Antimuscarinics were mainly tested in females in the past, as it was believed that LUTS in men were caused by the prostate, so should be treated with prostate-specific drugs. However, there is no scientific data for this assumption [213]. A sub-analysis of an open-label trial of OAB patients showed that age, but not gender had an impact on urgency, frequency, or urgency incontinence [214]. In a pooled analysis, which included a sub-analysis of male patients, fesoterodine 8 mg was superior to tolterodine extended release (ER) 4 mg for the improvement of severe urgency episodes/24 hours and the OAB-q Symptom Bother score at week twelve, the urinary retention rate was around 2% [215].

The efficacy of antimuscarinics as single agents in men with OAB in the absence of BOO have been tested [216-221]. Most trials lasted only twelve weeks. Four *post hoc* analyses of large RCTs on the treatment of OAB in women and men without presumed BOO were performed focusing only on the men [213, 217, 222]. Tolterodine can significantly reduce urgency incontinence, daytime or 24-hour frequency and urgency-related voiding whilst improving patient perception of treatment benefit [223]. Solifenacin significantly improved mean patient perception of bladder condition scores, mean OAB questionnaire scores, and overall perception of bladder problems. Fesoterodine improved micturition frequency, urgency episodes, and UUI episodes. In open-label trials with tolterodine, daytime frequency, nocturia, UUI, and IPSS were significantly reduced compared with baseline values after twelve to 25 weeks [218, 221]. The TIMES RCT reported that tolterodine ER monotherapy significantly improved UUI episodes per 24 hours compared to placebo, at week twelve. Tolterodine ER did not significantly improve urgency, IPSS total or QoL score compared with placebo [220].

A further analysis showed that men with PSA levels of < 1.3 ng/mL (smaller prostates) might benefit more from antimuscarinics [224]. Two other studies found a positive effect of antimuscarinics in patients with OAB and concomitant BPO [221, 225]. In a small RCT propiverine improved frequency and urgency episodes [225].

Tolerability and safety: Antimuscarinic drug trials generally show approximately 3-10% withdrawals, which is similar to placebo. Drug-related adverse events include dry mouth (up to 16%), constipation (up to 4%), micturition difficulties (up to 2%), nasopharyngitis (up to 3%), and dizziness (up to 5%).

Increased PVR in men without BOO is minimal and similar to placebo. Nevertheless, fesoterodine 8 mg showed higher PVRs (+20.2 mL) than placebo (-0.6 mL) or fesoterodine 4 mg (+9.6 mL) [218]. Incidence of urinary retention in men without BOO was similar to placebo for tolterodine (0-1.3% vs. 0-1.4%). With fesoterodine 8 mg, 5.3% had symptoms, which was higher than placebo or fesoterodine 4 mg (both 0.8%). These symptoms appeared during the first two weeks of treatment and mainly affected men aged 66 years or older.

Theoretically antimuscarinics might decrease bladder strength, and hence might be associated with PVR or urinary retention. A twelve week safety study on men with mild-to-moderate BOO showed that tolterodine increased the PVR (49 mL vs. 16 mL) but not AUR (3% in both arms) [226]. The urodynamic effects included larger bladder volumes at first detrusor contraction, higher maximum cystometric capacity, and decreased bladder contractility index, Q_{max} was unchanged. This trial indicated that short-term treatment with antimuscarinics in men with BOO is safe [213].

Practical considerations: Not all antimuscarinics have been tested in elderly men, and long-term studies on the efficacy of muscarinic receptor antagonists in men of any age with LUTS are not yet available. In addition, only patients with low PVR volumes at baseline were included in the studies. These drugs should therefore be prescribed with caution, and regular re-evaluation of symptom scores and PVR is advised. Men should be advised to discontinue medication if worsening voiding LUTS or urinary stream is noted after initiation of therapy.

Summary of evidence	LE
Antimuscarinic monotherapy can significantly improve urgency, UUI, and increased daytime frequency.	2
Antimuscarinic monotherapy can be associated with increased PVR after therapy, but acute retention is a rare event in men with a PVR volume of < 150 mL at baseline.	2

Recommendations	Strength rating
Use muscarinic receptor antagonists in men with moderate-to-severe LUTS who mainly have bladder storage symptoms.	Strong
Do not use antimuscarinic overactive bladder medications in men with a post-void residual volume > 150 mL.	Weak

*5.2.4 **Beta-3 agonist***

Mechanism of action: Beta-3 adrenoceptors are the predominant beta receptors expressed in the smooth muscle cells of the detrusor and their stimulation is thought to induce detrusor relaxation. The mode of action of beta-3 agonists is not fully elucidated [227].

Efficacy: Mirabegron 50 mg is the first clinically available beta-3 agonist with approval for use in adults with OAB. Mirabegron has undergone extensive evaluation in RCTs conducted in Europe, Australia, North America, and Japan [228-232]. Mirabegron demonstrated significant efficacy in treating the symptoms of OAB, including micturition frequency, urgency and UUI and also patient perception of treatment benefit. These studies had a predominantly female study population. A meta-analysis of eight RCTs including 10,248 patients (27% male) found that mirabegron treatment resulted in reduced frequency, urgency and UUI rates, as well as an improved voided volume with a statistically significant improvement of nocturia compared with both placebo and tolterodine [233].

Mirabegron has been evaluated in male patients with OAB in the context of LUTS either associated or not associated with BPO confirmed by urodynamics [234]. Mirabegron 25 mg daily led to increased satisfaction and improved QoL, but symptoms assessed by validated questionnaires (IPSS and OAB-SS), only improved in non-obstructed patients. Mirabegron as an add-on therapy has been studied in OAB patients with incontinence despite antimuscarinic therapy [235], again in a predominantly female study population. An Asian study with a higher proportion of male subjects (approximately one third) reported superiority over placebo in reducing frequency of micturition but did not report the results separately for the genders [236].

In a study of more than 1,000 patients of whom approximately 30% were male, combination therapy of mirabegron 25/50 mg and solifenacin 5/10 mg was associated with statistically significant improvements in patient outcomes and health related QoL vs. solifenacin 5 mg and placebo; however, they did not separate out the effects in men and women [237]. In another study, in which 28% patients were male, mirabegron significantly improved patient reported perception of their condition and QoL whether or not patients were incontinent [238]. A phase IV study, with a small proportion of male subjects, reported addition of mirabegron in people with persisting urgency despite solifenacin in a Japanese population [239].

An RCT has suggested Mirabegron might lead to improvement of urinary symptoms and sexual function in patients suffering from BPO and concurrent erectile dysfunction [240]. The study showed a significant improvement in the IIEF-15 total score and IPSS score in patients treated with Mirabegron + Doxazosin [240]. Nevertheless, further multicentre RCTs with large numbers of patients are required to consolidate these data.

Tolerability and safety: The most common treatment-related adverse events in the mirabegron groups were hypertension, UTI, headache and nasopharyngitis [228-231]. Mirabegron is contraindicated in patients with severe uncontrolled hypertension (systolic blood pressure ≥ 180 mmHg or diastolic blood pressure ≥ 110 mmHg, or both). Blood pressure should be measured before starting treatment and monitored regularly during treatment. A combination of thirteen clinical studies including 13,396 patients, 25% of whom were male, showed that OAB treatments (anticholinergics or mirabegron) were not associated with an increased risk of hypertension or cardiovascular events compared to placebo [241]. The proportion of patients with dry mouth and constipation in the mirabegron groups was notably lower than reported in RCTs of other OAB agents or of

the active control tolterodine [228]. Evaluation of urodynamic parameters in men with combined BOO and OAB concluded that mirabegron did not adversely affect voiding urodynamic parameters compared to placebo in terms of Q_{max}, detrusor pressure at maximum flow and BCI [242]. The overall change in PVR with mirabegron is small [242].

A small prospective study (mainly focused on males) has shown that mirabegron 25 mg is safe in patients aged 80 years or more with multiple co-morbidities [243]. A pooled analysis of three trials, each of twelve weeks and a one-year trial showed, in patients aged > 65 years, a more favourable tolerability profile for mirabegron than antimuscarinics [244]. The PILLAR phase IV study also showed that in a large population of 888 patients ≥ 65 years (approx. 30% of males), mirabegron 50 mg was safe and effective [245]. In an eighteen-week study of 3,527 patients (23% male), the incidence of adverse events was higher in the combination (solifenacin 5 mg plus mirabegron 25 mg) group (40%) than the mirabegron 25 mg alone group (32%). Events recorded as urinary retention were low (< 1%) but were reported slightly more frequently in the combined group when compared with the monotherapy and placebo groups. The PVR volume was slightly increased in the combined group compared with solifenacin 5 mg, and the mirabegron monotherapy and placebo groups. Combined therapy with solifenacin 5 mg plus mirabegron 25 mg and solifenacin 5 mg plus mirabegron 50 mg provided improvements in efficacy generally consistent with an additive effect [246].

In a retrospective analysis of persistence and adherence in 21,996 patients, of whom 30% were male, the median time to discontinuation was significantly longer for mirabegron (169 days) compared to tolterodine (56 days) and other antimuscarinics (30-78 days). There was no statistical difference between men and women [247].

The phase III EMPOWUR trial comparing vibegron to placebo and tolterodine showed once daily 75 mg vibegron provided statistically significant reductions in micturitions, urgency episodes and UUI [248]. Treatment was well tolerated with a favourable safety profile. However, the majority of the study population (85%) were female and vibegron is not yet licenced in Europe.

Practical considerations: Long-term studies on the efficacy and safety of mirabegron in men of any age with LUTS are not yet available. Available studies on mirabegron in combination with antimuscarinics in OAB patients had a predominantly female study population, while further trials are still pending.

Summary of evidence	**LE**
Mirabegron improves storage LUTS, including urinary frequency, urgency and UUI.	2
Patients prescribed mirabegron remained on treatment longer than those prescribed antimuscarinics.	3

Recommendation	**Strength rating**
Use beta-3 agonists in men with moderate-to-severe LUTS who mainly have bladder storage symptoms.	Weak

*5.2.5 **Phosphodiesterase 5 inhibitors***

Mechanism of action: Phosphodiesterase 5 inhibitors (PDE5Is) increase intracellular cyclic guanosine monophosphate, thus reducing smooth muscle tone of the detrusor, prostate, and urethra. Nitric oxide and PDE5Is might also alter reflex pathways in the spinal cord and neurotransmission in the urethra, prostate, or bladder [249]. Moreover, chronic treatment with PDE5Is seems to increase blood perfusion and oxygenation in the LUT [250]. Phosphodiesterase 5 inhibitors could also reduce chronic inflammation in the prostate and bladder [251]. The exact mechanism of PDE5Is on LUTS remains unclear.

Although clinical trials of several selective oral PDE5Is have been conducted in men with LUTS, only tadalafil (5 mg once daily) has been licensed for the treatment of male LUTS.

Efficacy: Randomised controlled trials have demonstrated that PDE5Is reduce IPSS, storage and voiding LUTS, and improve QoL. However, Q_{max} did not significantly differ from placebo in most trials [252]. A Cochrane review included a total of sixteen RCTs that examined the effects of PDE5Is compared to placebo and other standard of care drugs (α1-blockers and 5-ARIs) in men with LUTS [253]. In the updated meta-analysis, PDE5Is led to a small reduction (mean difference (MD) 1.89 lower; 95% CI: 2.27 lower to 1.50 lower; n = 4293) in IPSS compared to placebo [253]. There was no difference between PDE5Is and α1-blockers in IPSS [254]. Most evidence was limited to short-term treatment up to twelve weeks. In other meta-analyses, PDE5Is were also found to improve IPSS and IIEF score, but not always Q_{max} [255, 256]. A meta-regression suggested that younger men with low body mass index and more severe LUTS benefit the most from treatment with PDE5Is [255].

In a post hoc analysis of data pooled from four blinded trials of tadalafil 5 mg vs. placebo once daily, a minimum improvement of 25% in IPSS score was found in 60% in the tadalafil and in 44% in the placebo group [257]. The maximum trial duration was 52 weeks [258]. A subgroup analysis of pooled data from four RCTs demonstrated a significant reduction in LUTS, regardless of baseline severity, age, previous use of α-blockers or PDE5Is, total testosterone level or predicted prostate volume [259]. In a *post hoc* analysis of pooled data from four RCTs, tadalafil was shown to also be effective in men with cardiovascular risk factors/co-morbidities, except for patients receiving more than one antihypertensive medication. Among sexually active men > 45 years, tadalafil improved both LUTS/BPH and ED [259].

An integrated data analyses from four placebo controlled clinical studies showed that total IPSS improvement was largely attributed to direct (92.5%) vs. indirect (7.5%) treatment effects via IIEF-EF improvement [260]. Another analysis showed a small but significant increase in Q_{max} without any effect on PVR [261]. An integrated analysis of RCTs showed that tadalafil was not superior to placebo for IPSS improvement at twelve weeks in men ≥ 75 years (with varied effect size between studies) but was for men < 75 years [262]. An open label urodynamic study of 71 patients showed significant improvements in both voiding and storage symptoms, confirmed by improvements in BOO index (61.3 to 47.1), and resolution of DO in fifteen (38%) of 38 patients. Flow rate improved from 7.1 to 9.1 mL/s and mean IPSS from 18.2 to 13.4 [263].

A multicentre, double blind, placebo controlled RCT compared once daily tadalafil 20 mg vs. placebo during twelve weeks in men with LUTS with or without BOO. Urodynamic measures including detrusor pressure at maximum urinary flow rate, Q_{max}, maximum detrusor pressure, BOO or bladder capacity remained largely unchanged during the study with no statistically significant or clinically adverse event differences between tadalafil and placebo [264].

A study has shown that in patients with OAB and LUT obstruction unresponsive to previous treatment, the simultaneous administration of solifenacin, tadalafil, and dutasteride could be an effective and safe choice [265].

Tolerability and safety: Reported adverse effects in RCTs comparing the effect of all PDE5Is vs. placebo in men with LUTS include flushing, gastroesophageal reflux, headache, dyspepsia, back pain and nasal congestion [255].

Tadalafil is contraindicated in patients using nitrates or guanylate cyclase stimulators, such as riociguat, and in men with cardiac disease for whom sexual activity is inadvisable [266]. Tadalafil is also contraindicated in patients with myocardial infarction within the last 90 days, - patients with unstable angina or angina occurring during sexual intercourse, - patients with New York Heart Association Class 2 or greater heart failure in the last six months, - patients with uncontrolled arrhythmias, hypotension (< 90/50 mm Hg), or uncontrolled hypertension, - patients with a stroke within the last six months or if anterior ischaemic optic neuropathy with sudden loss of vision is known or was reported after previous use of PDE5Is [266]. Detailed information regarding tolerability/safety of all available PDE5Is for the treatment of erectile dysfunction in men treated with α-blockers for LUTS are provided by the EAU Guidelines on Sexual and Reproductive Health [267].

Practical considerations: To date, only tadalafil 5 mg once daily has been officially licensed for the treatment of male LUTS with or without ED. Long-term experience with tadalafil in men with LUTS is limited to one trial with a one-year follow-up [258]; limiting conclusions about efficacy or tolerability greater than one year. There is limited information on reduction of prostate size and no data on disease progression.

Summary of evidence	**LE**
Phosphodiesterase 5 inhibitors significantly improve IPSS and IIEF score, but not Qmax.	1a

Recommendation	**Strength rating**
Use phosphodiesterase type 5 inhibitors in men with moderate-to-severe LUTS with or without erectile dysfunction.	Strong

*5.2.6 **Plant extracts – phytotherapy***

Potential mechanism of action: Herbal drug preparations are made of roots, seeds, pollen, bark, or fruits. There are single plant preparations (mono-preparations) and preparations combining two or more plants in one pill (combination preparations) [268].

Possible relevant compounds include phytosterols, ß-sitosterol, fatty acids, and lectins [268]. In vitro, plant extracts can have anti-inflammatory, anti-androgenic and oestrogenic effects; decrease sexual hormone binding globulin; inhibit aromatase, lipoxygenase, growth factor-stimulated proliferation of prostatic cells, α-adrenoceptors, 5 α-reductase, muscarinic acetylcholine receptors, dihydropyridine receptors and vanilloid receptors; and neutralise free radicals [263, 268, 269]. The *in vivo* effects of these compounds are uncertain, and the precise mechanisms of plant extracts remain unclear.

Efficacy: The extracts of the same plant produced by different companies do not necessarily have the same biological or clinical effects; therefore, the effects of one brand cannot be extrapolated to others [270]. In addition, batches from the same producer may contain different concentrations of active ingredients [271]. A review of recent extraction techniques and their impact on the composition/biological activity of available *Serenoa repens* based products showed that results from different clinical trials must be compared strictly according to the same validated extraction technique and/or content of active compounds [272], as the pharmacokinetic properties of the different preparations can vary significantly.

Heterogeneity and a limited regulatory framework characterise the current status of phytotherapeutic agents. The European Medicines Agency (EMA) has developed the Committee on Herbal Medicinal Products (HMPC). European Union (EU) herbal monographs contain the HMPC's scientific opinion on safety and efficacy data about herbal substances and their preparations intended for medicinal use. The HMPC evaluates all available information, including non-clinical and clinical data, whilst also documenting long-standing use and experience in the EU. European Union monographs are divided into two sections: a) Well established use (marketing authorisation): when an active ingredient of a medicine has been used for more than ten years and its efficacy and safety have been well established (including a review of the relevant literature); and b) Traditional use (simplified registration): for herbal medicinal products which do not fulfil the requirements for a marketing authorisation, but there is sufficient safety data and plausible efficacy on the basis of long-standing use and experience.

The HPMC periodically invites all interested parties to submit any scientific data that the Committee should consider during their periodic review of the monographs. Table 1 lists the available EU monographs for herbal medicinal products and the current calls for update.

Table 1: European Union monographs for herbal medicinal products [273]

Herbal substance	HMPC evaluation	Therapeutic Indication by HMPC	Date of monograph
Serenoa repens, fructus (saw palmetto, fruit) Extraction solvent: hexane [274]	Well established use	Symptomatic treatment of BPH	14/01/2016 Addendum 1/9/21**
Serenoa repens, fructus (saw palmetto, fruit) Extraction solvent: ethanol [274]	Traditional use	LUTS related to BPH*	14/01/2016 Addendum 1/9/21**
Cucurbita pepo L, semen (pumpkin seed) Preparation as defined in the monograph [275]	Traditional use	LUTS related to BPH or related to an OAB*	25/03/2013 Call ended 30/4/21

Urtica dioica L., Urtica urens L., their hybrids or their mixtures, radix Preparation as defined in the monograph [277]	Traditional use	LUTS related to BPH*	05/11/2012 Call ended 30/6/21
Epilobium angustifolium L. and/or *Epilobium parviflorum Schreb., herba (Willow herb)* Preparation as defined in the monograph [278]	Traditional use	LUTS related to BPH*	13/01/2016 No call for update

** After serious conditions have been excluded by a medical doctor.*
*** Addendum concluded that no revision was needed.*

Panel interpretation: Only hexane extracted *Serenoa repens* (HESr) has been recommended for well-established use by the HMPC. Based on this a detailed scoping search covering the timeframe between the search cut-off date of the EU monograph and May 2021 was conducted for HESr.

A large meta-analysis of 30 RCTs with 5,222 men and follow-up ranging from four to 60 weeks, demonstrated no benefit of treatment with *S. repens* in comparison to placebo for the relief of LUTS [279]. It was concluded that *S. repens* was not superior to placebo, finasteride, or tamsulosin with regard to IPSS improvement, Q_{max}, or prostate size reduction; however, the similar improvement in IPSS or Q_{max} compared with finasteride or tamsulosin could be interpreted as treatment equivalence. Importantly, in the meta-analysis all different brands of *S. repens* were included regardless or not of the presence of HESr as the main ingredient in the extract.

Another SR focused on data from twelve RCTs on the efficacy and safety of HESr [280]. It was concluded that HESr was superior to placebo in terms of improvement of nocturia and Q_{max} in patients with enlarged prostates. Improvement in LUTS was similar to tamsulosin and short-term use of finasteride. An updated SR analysed fifteen RCTs and also included twelve observational studies. It confirmed the results of the previous SR on the efficacy of HESr [281]. Compared with placebo, HESr was associated with 0.64 (95% CI: 0.98 - 0.31) fewer voids/night and an additional mean increase in Q_{max} of 2.75 mL/s (95% CI: 0.57 - 4.93), both were significant. When compared with α-blockers, HESr showed similar improvements in IPSS (WMD 0.57; 95% CI: 0.27 - 1.42) and a comparable increase in Q_{max} when compared to tamsulosin (WMD 0.02; 95% CI: 0.71 - 0.66). Efficacy assessed using IPSS was similar after six months of treatment between HESr and 5-ARIs. Analysis of all available published data for HESr showed a mean significant improvement in IPSS from baseline of 5.73 points (95% CI: 6.91 - 4.54) [281].

A network meta-analysis tried to compare the clinical efficacy of *S. repens* (HESr and non-HESr) against placebo and α1-blockers in men with LUTS. Interestingly, only two RCTs on HESr were included in the analysis. It was found that *S. repens* achieved no clinically meaningful improvement against placebo or α1-blockers in short-term follow-up. However, *S. repens* showed a clinical benefit after a prolonged period of treatment, and HESr demonstrated a greater improvement than non-HESr in terms of IPSS [282].

With respect to safety and tolerability data from the SRs showed that HESr had a favourable safety profile with gastrointestinal disorders being the most frequent adverse effects (mean incidence 3.8%) while HESr had very limited impact on sexual function.

A cross-sectional study compared the combination of HESr with silodosin, to silodosin monotherapy in patients treated for at least twelve months (mean duration 13.5 months) [283]. It was reported that 69.9% of the combination therapy patients achieved the predefined clinically meaningful improvement (improvement more than three points in baseline IPSS) compared to 30.1% of patients treated only with silodosin. In addition, a greater than 25% improvement in IPSS was found in 68.8% and 31.2% of the patients in the combination and the monotherapy groups, respectively. These data suggest that combination of a α1-blocker with HESr may result in greater clinically meaningful improvements in LUTS compared to α1-blocker monotherapy [283].

Practical considerations: Available RCTs do not use the same endpoints (e.g., IPSS). More studies on the use of HESr in combination with other pharmacotherapeutic agents for male LUTS are pending. There is a need to define the subpopulation of patients who will benefit most from therapy with HESr.

Summary of evidence	**LE**
Hexane extracted *Serenoa repens* improves Q_{max} and results in fewer voids/night (0.64 [95% CI: 0.98 to 0.31]) compared to placebo.	2
Hexane extracted *Serenoa repens* has a very limited negative impact on sexual function.	2

Recommendations	**Strength rating**
Offer hexane extracted *Serenoa repens* to men with LUTS who want to avoid any potential adverse events especially related to sexual function.	Weak
Inform the patient that the magnitude of efficacy may be modest.	Strong

*5.2.7 **Combination therapies***

5.2.7.1 α1-blockers + 5α-reductase inhibitors

Mechanism of action: Combination therapy consists of an α1-blocker (Section 5.2.1) together with a 5-ARI (Section 5.2.2). The α1-blocker exhibits clinical effects within hours or days, whereas the 5-ARI needs several months to develop full clinical efficacy. Finasteride has been tested in clinical trials with alfuzosin, terazosin, doxazosin or terazosin, and dutasteride with tamsulosin.

Efficacy: Several studies have investigated the efficacy of combination therapy against an α1-blocker, 5-ARI, or placebo alone. Initial studies with follow-up periods of six to twelve months demonstrated that the α1-blocker was superior to finasteride in symptom reduction, whereas combination therapy of both agents was not superior to α1-blocker monotherapy [182, 183, 284]. In studies with a placebo arm, the α1-blocker was consistently more effective than placebo, but finasteride was not. Data at one year in the MTOPS study showed similar results [65].

Long-term data (four years) from the MTOPS and CombAT studies showed that combination treatment is superior to monotherapy for symptoms and Q_{max}, and superior to α1-blocker alone in reducing the risk of AUR or need for surgery [65, 163, 164].

The CombAT study demonstrated that combination treatment is superior to either monotherapy regarding symptoms and flow rate starting from month nine, and superior to α1-blocker for AUR and the need for surgery after eight months [164]. Thus, the differences in MTOPS may reflect different inclusion and exclusion criteria and baseline patient characteristics.

Discontinuation of the α1-blocker after six to nine months of combination therapy was investigated in an RCT and an open-label multicentre trial [285, 286]. The first trial evaluated the combination of tamsulosin with dutasteride and the impact of tamsulosin discontinuation after six months [285], with almost three quarters of patients reporting no worsening of symptoms. However, patients with severe symptoms (IPSS > 20) at baseline may benefit from longer combination therapy.

A more recent trial evaluated the symptomatic outcome of finasteride monotherapy at three and nine months after discontinuation of nine-month combination therapy [286]. Lower urinary tract symptom improvement after combination therapy was sustained at three months (IPSS difference 1.24) and nine months (IPSS difference 0.4). The limitations of the studies include short duration and short follow-up period after discontinuation.

In both the MTOPS and CombAT studies, combination therapy was superior to monotherapy in preventing clinical progression as defined by an IPSS increase of at least four points, AUR, UTI, incontinence, or an increase in creatinine > 50%. The MTOPS study found that the risk of long-term clinical progression (primarily due to increasing IPSS) was reduced by 66% with combined therapy vs. placebo and to a greater extent than with either finasteride or doxazosin monotherapy (34% and 39%, respectively) [65]. In addition, finasteride (alone or in combination), but not doxazosin alone, significantly reduced both the risks of AUR and the need for BPO-related surgery over the four-year study. In the CombAT study, combination therapy reduced the relative risks of AUR by 68%, BPO-related surgery by 71%, and symptom deterioration by 41% compared with tamsulosin, after four years [287]. To prevent one case of urinary retention and/or surgical treatment, thirteen patients need to be treated for four years with dutasteride and tamsulosin combination therapy compared to tamsulosin monotherapy while the absolute risk reduction (risk difference) was 7.7%.

The CONDUCT study compared efficacy and safety of a fixed-dose combination of dutasteride and tamsulosin to a WW approach with the potential initiation of tamsulosin (step-up approach) in a two-year RCT with a total of 742 patients. In both arms detailed lifestyle advice was given. This fixed-dose combination resulted in a rapid and sustained improvement in men with moderate LUTS at risk of disease progression, the difference in IPSS at 24 months was 5.4 in the active arm and 3.6 in the placebo arm [288]. Furthermore, tamsulosin plus dutasteride significantly reduced the relative risk of clinical progression (mainly characterised as a worsening in symptoms) by 43.1% when compared with WW, with an absolute risk reduction of 11.3% (number needed to treat [NNT] = 9).

The influence of baseline variables on changes in IPSS after combination therapy with dutasteride plus tamsulosin or either monotherapy was tested based on the four-year results of the CombAT study. Combination therapy provided consistent improvement of LUTS over tamsulosin across all analysed baseline variables at 48 months [289].

A combination of the 5-ARI finasteride and tadalafil 5 mg was tested in a large scale RCT against finasteride monotherapy. This study supports the concept of this novel combination therapy and is described in more detail in section 5.2.5 [290].

Tolerability and safety: Adverse events for both drug classes have been reported with combination treatment [65, 163, 164]. The adverse events observed during combination treatment were typical of α1-blockers and 5-ARIs. The frequency of adverse events was significantly higher for combination therapy. The MTOPS study demonstrated that the incidence of treatment related adverse events is higher during the first year of combined treatment between doxazosin and finasteride [291]. A meta-analysis measuring the impact of medical treatments for LUTS/BPH on ejaculatory function, reported that combination therapy with α1-blockers and 5-ARIs resulted in a three-fold increased risk of EjD compared with each monotherapy [177].

Practical considerations: Compared with α1-blockers or 5-ARI monotherapy, combination therapy results in a greater improvement in LUTS and increase in Q_{max} and is superior in prevention of disease progression. However, combination therapy is also associated with a higher rate of adverse events. Combination therapy should therefore be prescribed primarily in men who have moderate-to-severe LUTS who are at risk of disease progression (higher prostate volume, higher PSA concentration, advanced age, higher PVR, lower Q_{max}, etc.). Combination therapy should only be used when long-term treatment (more than twelve months) is intended, and patients should be informed of this. Discontinuation of the α1-blocker after six months might be considered in men with moderate LUTS.

Summary of evidence	**LE**
Long-term data (four years) from the MTOPS and CombAT studies showed that combination treatment is superior to monotherapy for symptoms and Qmax, and superior to α1-blocker alone in reducing the risk of AUR or need for surgery.	1b
The MTOPS study found that the risk of long-term clinical progression (primarily due to increasing IPSS) was reduced by 66% with combined therapy vs. placebo and to a greater extent than with either finasteride or doxazosin monotherapy.	1b
The CombAT study found that combination therapy reduced the relative risks of AUR by 68%, BPH-related surgery by 71%, and symptom deterioration by 41% compared with tamsulosin, after four years.	1b
Adverse events of both drug classes are seen with combined treatment using α1-blockers and 5-ARIs.	1b

Recommendation	**Strength rating**
Offer combination treatment with an α1-blocker and a 5α-reductase inhibitor to men with moderate-to-severe LUTS and an increased risk of disease progression (e.g. prostate volume > 40 mL).	Strong

5.2.7.2 α1-blockers + muscarinic receptor antagonists

Mechanism of action: Combination treatment consists of an α1-blocker together with an antimuscarinic aiming to antagonise both α1-adrenoceptors and muscarinic receptors. The possible combinations have not all been tested in clinical trials to date.

Efficacy: Several RCTs and prospective studies investigated combination therapy, lasting four to twelve weeks, either as an initial treatment in men with OAB and presumed BPO or as a sequential treatment for storage symptoms persisting while on an α1-blocker [212, 223, 287, 292-296]. Combination treatment has marginal efficacy in reducing urgency, UUI, voiding frequency, nocturia, or IPSS compared with α1-blockers or placebo alone, and improves QoL [223, 296]. A SR and meta-analysis of RCTs (six studies of treatment-naïve patients, and five studies of men with persistent storage LUTS despite prior treatment with α-blockers) concluded that the addition of antimuscarinics to α-blockers marginally reduced number of micturition episodes per day (standard mean difference -0.19) but did not have a significant impact on number of urgency episodes, and had a higher side effect profile [297]. Similar findings were also reported in a Cochrane review of RCTs of men with LUTS secondary to BPO, with a small improvement in IPSS (mean difference 2.04) and QoL (mean difference 0.71) with combination therapy compared to α-blocker monotherapy, although overall certainty of evidence was deemed moderate to very low [298].

Symptom improvement is higher regardless of PSA concentration with combination therapy, whereas tolterodine alone improved symptoms mainly in men with a serum PSA of < 1.3 ng/mL [224].

In a meta-analysis of sixteen studies with 3,548 patients with BPH/OAB, initial combination treatment of an α1-blocker with anticholinergic medication showed no difference in total IPSS and Q_{max} between the two groups [299].

Effectiveness of therapy is evident primarily in those men with moderate-to-severe storage LUTS [300]. Long term use of combination therapy has been reported in patients receiving treatment for up to one year, showing symptomatic response is maintained, with a low incidence of AUR [301]. In men with moderate-to-severe storage symptoms, voiding symptoms and PVR < 150 mL, the reduction in symptoms using combination therapy is associated with patient-relevant improvements in health related QoL compared with placebo and α1-blocker monotherapy [302].

Combined behavioural and drug therapy yielded greater improvements in OAB symptoms than drug therapy alone, but not behavioural therapy alone in a RCT evaluating the effectiveness of combined behavioural strategies and drug therapy for OAB symptoms in men [303].

Tolerability and safety: Adverse events of both drug classes are seen with combined treatment using α1-blockers and antimuscarinics. The most common side-effect is dry mouth. Some side-effects (e.g. dry mouth or ejaculation failure) may show increased incidence which cannot simply be explained by summing the incidence with the drugs used separately. Increased PVR may be seen, but is usually not clinically significant, and risk of AUR is low up to one year of treatment [220, 304, 305]. Antimuscarinics do not cause evident deterioration in Q_{max} used in conjunction with an α1-blocker in men with OAB symptoms [296, 306].

An RCT investigated safety in terms of maximum detrusor pressure and Qmax for solifenacin (6 mg or 9 mg) with tamsulosin in men with LUTS and BOO compared with placebo [307]. The combination therapy was non-inferior to placebo for the primary urodynamic variables; Q_{max} was increased vs. placebo [307].

Practical considerations: Class effects are likely to underlie efficacy and QoL using an α1-blocker and antimuscarinic. Trials used mainly storage symptom endpoints, were of short duration, and included only men with low PVR volumes at baseline. Therefore, measuring PVR is recommended during combination treatment.

Summary of evidence	LE
Combination treatment with α1-blockers and antimuscarinics is effective for improving LUTS-related QoL impairment.	2
Combination treatment with α1-blockers and antimuscarinics is more effective for reducing urgency, UUI, voiding frequency, nocturia, or IPSS compared with α1-blockers or placebo alone.	2
Adverse events of both drug classes are seen with combined treatment using α1-blockers and antimuscarinics.	1
There is a low risk of AUR using α1-blockers and antimuscarinics in men known to have a PVR volume of < 150 mL.	2

Recommendations	Strength rating
Use combination treatment of a α1-blocker with a muscarinic receptor antagonist in patients with moderate-to-severe LUTS if relief of storage symptoms has been insufficient with monotherapy with either drug.	Weak
Do not prescribe combination treatment in men with a post-void residual volume > 150 mL.	Weak

5.2.7.3 α1-blockers + Beta-3 agonist

Mechanism of action: Combination therapy consists of an α1-blocker (Section 5.2.1) together with a beta-3-agonist (Section 5.2.4) as an add-on therapy in males receiving α1-blockers with persisting OAB symptoms.

Efficacy: The MATCH study explored the effect of the addition of mirabegron 50 mg to tamsulosin 0.2 mg compared to tamsulosin plus placebo in 544 patients [308]. A statistically significant difference of 0.52 voids per day was seen in favour of mirabegron. Total IPSS score also improved but was not significant between the groups. Another RCT evaluated add-on therapy with mirabegron for OAB symptoms persisting after treatment with tamsulosin 0.2 mg daily in men with BPO [309]. Combination therapy was associated with greater improvements in OAB symptom score, in urinary urgency and daytime frequency as well as the storage sub-score of IPSS and QoL index compared to monotherapy with tamsulosin [310].

The PLUS phase IV trial [309] compared mirabegron and placebo in a population of males treated with a standard dose of tamsulosin 0.4 mg. After a four-week run-in period of treatment with tamsulosin 0.4 mg alone, 715 patients were randomised between placebo and mirabegron 25 mg, upgraded to 50 mg after one month. While mean number of micturition's were significantly reduced in the experimental arm, the effect size was deemed as low (mean adjusted difference of 0.39 voids per day). Similar results were seen for mean voided volume and urgency episodes, but total IPSS, IPSS sub-scores and OAB-q symptom score were not significantly different between the groups.

An RCT comparing the efficacy of mirabegron 50 mg or fesoterodine 4 mg add-on therapy to silodosin in LUTS patients with persisting OAB symptoms reported that at three months, fesoterodine add-on therapy showed a significantly greater improvement than mirabegron add-on therapy in OAB symptom score and urgency score and IPSS-QoL score [237]. Fesoterodine was also superior in alleviating DO.

Tolerability and safety: In the MATCH study main adverse events were in line with previous trials, and cardiovascular events were uncommon in the studied populations [308]. The PLUS phase IV trial also reported adverse events similar to those seen in previous trials (hypertension, headache and nasopharyngitis being the

most frequent) [309]. There were six episodes of retention recorded (1.7%) and overall, no clinically significant specific change was seen in Q_{max} and PVR. An open-label, randomised, 2-arm, 2-sequence study reported that the addition of mirabegron or tamsulosin to patients under tamsulosin or mirabegron mono therapy did not cause clinically relevant changes in cardiovascular safety or safety profiles [311].
Solifenacin and mirabegron were also compared in another RCT that has shown comparable efficacy but a better safety profile for mirabegron [312].

Practical consideration: Add-on therapy with mirabegron in patients with remaining symptoms under α1-blocker therapy has been evaluated only in short-term clinical trials. The short-term benefit remains uncertain with a low effect size in urinary frequency compared to placebo, and more studies with longer follow-up are required

Summary of evidence	LE
Combination treatment with α1-blockers and mirabegron results in a slight decrease of number of voids and urgency episodes per day compared with α1-blockers alone.	1b
Adverse events of both drug classes are seen with combined treatment using α1-blockers and mirabegron.	1b

Recommendations	Strength rating
Use combination treatment of a α1-blocker with mirabegron in patients with persistent storage LUTS after treatment with α1-blocker monotherapy.	Weak

5.2.7.4 α1-blockers + Phosphodiesterase 5 inhibitors

Mechanism of action: Combination treatment consists of an α1-blocker together with a phosphodiesterase 5 inhibitor (Section 5.2.5) with the intent to achieve better improvements in LUTS.

Efficacy: A meta-analysis of five RCTs (two studies with tadalafil 20 mg daily, two with sildenafil 25 mg, and one with vardenafil 20 mg), showed that combination therapy significantly improved IPSS score (-1.8), IIEF score (+3.6) and Q_{max} (+1.5 mL/s) compared with α-blockers alone [255]. Both a SR and Cochrane review found similar findings, and a network meta-analysis of 55 RCTs (excluding 5-ARIs) found that the combination of PDE5Is and α-blockers had greater IPSS improvement than monotherapy and any other combination therapy [253, 313, 314]. These results have been confirmed by prospective studies which have shown an improvement in the IPSS QoL, IIEF-5 score and Q_{max} in patients taking PDE5Is and α-blockers [252, 315].

Tolerability and safety: No serious AEs have been reported in the association of PDE5-Is and α-blockers. In RCT comparing α-blockers alone with combined therapy, AEs occur with similar incidence across the two treatments arms suggesting that the addition of PDE5Is to α-blockers is well tolerated [316].

Practical consideration: The combination of α-blockers and PDE5Is versus α-blockers monotherapy leads to greater improvements in LUTS, QoL, erectile function and Q_{max} without increase in AEs.
Data from meta-analyses suggest how younger men with low body mass index and more severe LUTS may be the population that benefits most from this association [255]. However, further studies with large populations and longer follow-up are needed to confirm these findings.

Summary of evidence	LE
Combination of PDE5Is and alpha blockers improves IPSS, but magnitude of effect of clinical significance is low.	1a

Recommendations	Strength rating
Use combination treatment of a α1-blockers + Phosphodiesterase 5 inhibitors in patients with bothersome LUTS, particularly in patients willing to improve their erectile function.	Weak
Inform the patients that the magnitude of the effect is modest.	Weak

Note: All patients should be counselled about pharmacological treatment related adverse events in order to select the most appropriate treatment for each individual patient

5.3 Surgical treatment of benign prostatic obstruction

Surgical treatment is one of the cornerstones of LUTS/BPO management. Based on its ubiquitous availability, as well as its efficacy, monopolar TURP (M-TURP) has long been considered as the reference technique for the surgical management of LUTS/BPO. However, in recent years various techniques have been developed with the aim of providing a safe and effective alternative to M-TURP. Previously, the surgical section of the Guidelines was based on technology rather than surgical approach. As the clinical reality is primarily reflected by surgical approach and not necessarily by a specific technology, the chapter on surgical management has been restructured. It is now divided into the following five sections:

1. Resection;
2. Enucleation;
3. Vaporisation;
4. Alternative ablative techniques; and
5. Non-ablative techniques.

In addition, most of the studies are restricted by prostate size, which is also reflected in the present Guidelines. Notably, only a small fraction of RCTs are performed in patients with a prostate > 80 mL; therefore, high-level evidence for larger prostates are limited.

Based on Panel consensus, timeframes defining short-, mid- and long-term follow-up of patients submitted to surgical treatments are twelve, 36, and over 36 months, respectively. The durability of a technique is reflected by the re-operation rate during follow-up, the failure to wean patients off medication as well as the initiation of novel LUTS medication after surgery. However, for the majority of techniques only the re-operation rate is reported, and clinicians should inform patients that long-term surgical RCTs are often lacking. Some patients value sexual function and perceived higher safety over maximum efficacy and it is not therefore surprising that some patients consciously choose an alternative ablative or non-ablative technique despite the knowledge that it might not be their definitive treatment. In contrast, many urologists are critical about these procedures due to their inferior relief of BOO.

Recommendations on new devices or interventions will only be included in the Guidelines once supported by a minimum level of evidence. To clarify this the Panel have published their position on certainty of evidence (CoE) [317]. In summary, a device or technology is only included once supported by RCTs looking at both efficacy and safety, with adequate follow-up, and secondary studies to confirm the reproducibility and generalisability of the first pivotal studies [317]. Otherwise, there is a danger that a single pivotal study can be overexploited by device manufacturers. Studies that are needed include proof of concept, RCTs on efficacy and safety, as well as cohort studies with a broad range of inclusion and exclusion criteria to confirm both reproducibility and generalisability of the benefits and harms [317]. The panel assesses the quality of all RCTs and if they do not meet the standard required the intervention will continue to have no recommendation i.e., an RCT does not guarantee inclusion in the Guidelines.

In addition, the Guidelines continues to include techniques under investigation. These are devices or technologies that have shown promising results in initial studies; however, they do not meet the aforementioned criteria yet to provide a CoE which allows the Panel to regard these devices or technologies as recommended alternatives. To account for evolving evidence, recommendations for some techniques under investigation have been made; however, these techniques remain under investigation until further studies provide the recommended CoE.

*5.3.1 **Resection of the prostate***

5.3.1.1 Monopolar and bipolar transurethral resection of the prostate

Mechanism of action: Transurethral resection of the prostate is either performed in a M-TURP or bipolar TURP (B-TURP) fashion. Transurethral resection of the prostate removes tissue from the transition zone of the gland in various degrees resulting in a volume and PSA reduction of 25 -58%. Contrary to M-TURP, in B-TURP systems, the energy does not travel through the body to reach a skin pad. Bipolar circuitry is completed locally; energy is confined between an active (resection loop) and a passive pole situated on the resectoscope tip (“true” bipolar systems) or the sheath (“quasi” bipolar systems) using normal saline for irrigation thereby eliminating TUR-syndrome [318, 319].

Efficacy: In a meta-analysis of twenty RCTs with a maximum follow-up of five years, M-TURP resulted in a substantial mean Q_{max} improvement (+162%), a significant reduction in IPSS (-70%), QoL score (-69%), and PVR (-77%) [320]. Monopolar-TURP delivers durable outcomes as shown by studies with a follow-up of eight to 22 years [321]. One study with a mean follow-up of thirteen years reported a significant and sustained decrease in most symptoms and improvement in urodynamic parameters. Failures were associated with DUA rather than re-growth of BPH [109]. A second prostatic operation, usually re-TURP, has been reported at a constant annual

rate of approximately 1-2%. A SR analysing 29 RCTs found a retreatment rate of 2.6% after a mean follow-up of sixteen months [322]. Data from an Austrian nationwide study of two cohorts totalling 41,059 men submitted to M-TURP showed that the overall retreatment rates (re-TURP, urethrotomy and bladder neck incision) remained unchanged during the last decade (0.9%, 3.7%, 9.5% and 12.7% at three months, one year, five years, and eight years, respectively), and that the respective incidence of re-TURP was 0.8%, 2.4%, 6.1% and 8.3%, respectively [323, 324].

Bipolar TURP is the most widely investigated alternative to M-TURP. Pooled results from 59 RCTs have been reported to date [325]. Early pooled results as well as at twelve months, concluded that no clinically relevant differences exist in short-term efficacy (IPSS, QoL score and Q_{max}) [325, 326]. Subsequent meta-analyses supported these conclusions though trial quality was generally poor [320, 327-330]. The largest meta-analysis published to date, confirmed that B-TURP compared to M-TURP results in little to no difference in urological symptoms and bother (IPSS and QoL score) at twelve months [325]. Data from RCTs with mid- to long-term follow-up (up to 60 months) showed no differences in efficacy parameters [331-339]. A meta-analysis of RCTs comparing B-TURP vs. M-TURP, reported similar efficacy at 36 months in terms of IPSS, and Q_{max} [340].

A meta-analysis was conducted to evaluate the quasi-bipolar transurethral resection in saline (TURis), Olympus Medical system vs. M-TURP. Ten unique RCTs (1,870 patients) were included, and it was concluded that TURis was of equivalent efficacy to M-TURP [341].

Tolerability and safety: Peri-operative mortality and morbidity of M-TURP have decreased over time, but morbidity remains considerable (0.1% and 11.1%, respectively) [342]. Data from an Austrian nationwide study of two cohorts totalling 41,059 men submitted to M-TURP showed a 20% reduction in mortality rate over time, to 0.1% at 30 days and 0.5% at 90 days [323, 324].

The risk of TUR-syndrome decreased to < 1.1% [322, 343]. Data from 10,654 M-TURPs reported bleeding requiring transfusion in 2.9% [342]. Short- to mid-term complications reported in an analysis of RCTs using M-TURP as a comparator were: bleeding requiring transfusion 2% (0-9%), TUR-syndrome 0.8% (0-5%), AUR 4.5% (0-13.3%), clot retention 4.9% (0-39%), and UTI 4.1% (0-22%) [320]. Long-term complications of M-TURP comprise urinary incontinence (UI), urinary retention and UTIs, bladder neck contracture (BNC), urethral stricture, retrograde ejaculation and ED [322].

Early pooled results concluded that no differences exist in short-term urethral stricture/BNC rates, but B-TURP is preferable to M-TURP due to a more favourable peri-operative safety profile (elimination of TUR-syndrome; lower clot retention/blood transfusion rates; shorter irrigation, catheterisation, and possibly hospitalisation times) [326]. Subsequent meta-analyses supported these conclusions [320, 327-330, 340]; however, trial quality was relatively poor and limited follow-up might cause under-reporting of late complications, such as urethral stricture/BNC [326]. The largest meta-analysis published to date, concluded that B-TURP compared to M-TURP reduced TUR-syndrome and blood transfusion events by twenty and 28 fewer events per 1,000 participants, respectively [325]. The study also concluded that B-TURP may carry a similar risk of UI and may result in similar rates of re-TURP in the short-term (four fewer events and one more re-TURP per 1000 participants, respectively), compared to M-TURP [325]. An RCT based meta-analysis has shown that TURis reduces the risk of TUR-syndrome and the need for blood transfusion compared to M-TURP [330]. It was concluded that TURis is associated with improved peri-operative safety, eliminating the risk of TUR-syndrome, reducing the risk of blood transfusion/clot retention and hospital stay. No significant difference was detected in urethral stricture rates.

Data from the vast majority of individual RCTs with mid- to long-term follow-up (up to 60 months), showed no differences between M-TURP and B-TURP in urethral stricture/BNC rates [331-339], in accordance with all published meta-analyses. However, two individual RCTs have shown opposing results [338, 344]. A significantly higher stricture (urethral stricture + BNC) rate was detected in the B-TURP arm performed with a "quasi" bipolar system (TURis, Olympus Medical) in patients with a prostate volume > 70 mL at 36-months follow-up [338]. In addition, a significantly higher BNC, but not urethral stricture, rate was detected in the B-TURP arm performed with a "true" bipolar system (Gyrus PK SuperPulse, Olympus Medical) in 137 patients at twelve months follow-up [344].

Randomised controlled trials using the erectile function domain of the IIEF (IIEF-ED) and the ejaculatory domain of the male sexual-health questionnaire (Ej-MSHQ) showed that M-TURP and B-TURP have a similar effect on erectile and ejaculatory function [345, 346]. Comparative evaluations of the effects on overall sexual function, quantified with IIEF-15, showed no differences between B-TURP and M-TURP at twelve months follow-up (erection, orgasmic function, sexual desire, intercourse satisfaction, overall satisfaction) [346, 347]. Furthermore, the largest meta-analysis published to date, showed that erectile function measured by IIEF-5 appears to be similar at twelve months follow-up after B-TURP and M-TURP [325].

A comparative study [348] evaluated the safety of B-TURP in patients taking therapeutic oral anticoagulation (phenprocoumon) or anti-platelet drug therapy (acetylsalicylic acid or clopidogrel), without stopping or bridging the medication. Outcomes under acetylsalicylic acid were comparable to the unmedicated control group. Under oral anticoagulation therapy catheterisation (median 41-hours vs. 24-hours) and hospitalisation time was longer (median four days vs. three days), AUR rate was higher (18% vs. 6%), but blood transfusion rates did not differ to the control group. Under anti-platelet therapy blood transfusion (19% vs. 1%) and re-hospitalisation rates (19% vs. 3%) were higher.

Practical considerations: Monopolar-TURP is an effective treatment for moderate-to-severe LUTS secondary to BPO. The choice should be based primarily on prostate volume (30-80 mL suitable for M-TURP). No studies on the optimal cut-off value exist, but the complication rates increase with prostate size [342]. The upper limit for M-TURP is suggested as 80 mL (based on Panel consensus, under the assumption that this limit depends on the surgeon's experience, choice of resectoscope size and resection speed), as surgical duration increases, there is a significant increase in the rate of complications and the procedure is safest when performed in under 90 minutes [349].

Bipolar TURP in patients with moderate-to-severe LUTS secondary to BPO has similar efficacy with M-TURP but lower peri-operative morbidity. The duration of improvements with B-TURP were documented in a number of RCTs with mid-term follow-up. Long-term results (up to five years) for B-TURP showed that safety and efficacy are comparable to M-TURP [331-339]. The choice of B-TURP should be based on equipment availability, surgeon's experience, and patient's preference.

Summary of evidence	**LE**
Bipolar- or M-TURP is the current standard surgical procedure for men with prostate sizes of 30-80 mL and bothersome moderate-to-severe LUTS secondary of BPO.	1a
Bipolar-TURP achieves short-, mid- and long-term results comparable with M-TURP, but B-TURP has a more favourable peri-operative safety profile.	1a

Recommendation	**Strength rating**
Offer bipolar- or monopolar-transurethral resection of the prostate to surgically treat moderate-to-severe LUTS in men with prostate size of 30-80 mL.	Strong

5.3.1.2 Holmium laser resection of the prostate

With the advent of holmium laser enucleation of the prostate (section 5.3.2.3) and the fact that no relevant publications on holmium laser resection of the prostate (HoLRP) have been published since 2004, HoLRP of the prostate does not play a role in contemporary treatment algorithms.

5.3.1.3 Thulium:yttrium-aluminium-garnet laser vaporesection of the prostate

Mechanism of action: In the *Thulium:yttrium-aluminium-garnet laser* (Tm:YAG), a wavelength between 1,940 and 2,013 nm is emitted in continuous wave mode. The laser is primarily used in front-fire applications [350]. Different applications such as vaporesection (ThuVARP) have been published [351].

Efficacy: Several meta-analyses with pooled data from both RCTs, and non-RCTs have evaluated ThuVARP vs. M-TURP [352-354], and B-TURP [355-357]. The largest meta-analyses included nine RCTs and seven non-RCTs and reported no clinically relevant differences in efficacy (IPSS, QoL score and Q_{max}) between ThuVARP and M-TURP or B-TURP at twelve months [356]. A multicentre, RCT with 410 men reported that ThuVARP and TURP are equivalent in terms of IPSS but not Q_{max}, with TURP deemed superior at twelve months follow-up [358]. The beneficial effect of TURP in terms of Q_{max} was strengthened in men aged < 70 years and in those diagnosed with LUTS rather than urinary retention. No differences in individual patient-reported urinary symptoms were seen between arms, with the exception of some evidence to indicate potential reduction in nocturia in the TURP arm. Data from one RCT with long-term follow-up showed no difference in efficacy and re-operation rates between ThuVARP and M-TURP (2.1% vs. 4.1%, respectively) [359]. A prospective multicentre study on ThuVARP, including 2,216 patients, showed durable post-operative improvement in IPSS, QoL, Q_{max}, and PVR for the entire eight years of follow-up [360].

Tolerability and safety: In a number of meta-analyses longer operation times, shorter catheterisation/ hospitalisation times and less blood loss without significant differences in transfusion rates or in any other short-term complication rates have been reported for ThuVARP compared to TURP [352-357]. A significantly higher transfusion rate was reported after M-TURP in two meta-analyses [354, 356]. However, overall RCT quality

was relatively low with limited follow-up potentially accounting for under-reporting of late complications, such as urethral stricture/BNC [356]. A multicentre RCT with 410 men, followed up for twelve months reported that ThuVARP and TURP show similar operation, catheterisation, and hospitalisation times between arms with no difference in the frequency or severity of surgical complications or in blood transfusions rate or haemoglobin change [358, 361]. Patients with urinary retention had similarly positive outcomes to those with LUTS [358, 361]. Data from three RCTs with mid- to long-term follow-up (18 to 48 months) showed no differences in late complication rates between ThuVARP and TURP [359, 362, 363].

Haemoglobin drop was significantly higher in the bridging group in a retrospectively analysed case series of 103 patients who underwent ThuVARP and received either low molecular weight heparin bridging or continued antiplatelet/anticoagulant therapy [364].

Practical considerations: As a limited number of RCTs with mid- to long-term follow-up support the efficacy of ThuVARP, there is a need for ongoing investigation of the technique.

Summary of evidence	**LE**
Laser vaporesection of the prostate using Tm:YAG laser (ThuVARP) has similar operation, catheterisation and hospitalisation times compared to TURP. ThuVARP and TURP are equivalent in terms of IPSS but not Q_{max}, with TURP deemed superior at twelve months follow-up. ThuVARP and TURP show similar short-term safety. Mid- to long-term results on efficacy and safety compared to TURP are very limited.	1b

Recommendation	**Strength rating**
Offer laser resection of the prostate using Tm:YAG laser (ThuVARP) as an alternative to TURP.	Weak

5.3.1.4 Transurethral incision of the prostate

Mechanism of action: Transurethral incision of the prostate (TUIP) involves incising the bladder outlet without relevant tissue removal. Transurethral incision of the prostate is conventionally performed with Collins knife using electrocautery; however, alternative energy sources such as holmium laser may be used [365]. The mainstay of this technique is in prostate sizes < 30 mL without a middle lobe.

Efficacy: An RCT comparing conventional TUIP vs. TUIP using holmium laser in prostates ≤ 30 mL with a follow-up of twelve months, found both procedures to be equally effective in relieving BOO with similarly low re-operation rates [365]. A meta-analysis of ten RCTs found similar LUTS improvements and lower but significant improvements in Q_{max} for TUIP [366]. In this meta-analysis, an upper limit of prostate size was reported as an entry criterion for eight studies with five < 30 mL and three < 60 mL. A meta-analysis of six trials showed that re-operation was more common after TUIP (18.4%) than after M-TURP (7.2%) [366].

Tolerability and safety: An RCT comparing conventional TUIP vs. TUIP using holmium laser reported both procedures to be safe with low complication rates; however, the operation time and retrograde ejaculation rate was significantly lower in the conventional TUIP arm [365]. No cases of TUR-syndrome have been recorded after TUIP. The risk of bleeding after TUIP is small [366].

Practical considerations: Transurethral incision of the prostate is an effective treatment for moderate-to-severe LUTS secondary to BPO. The choice between M-TURP and TUIP should be based primarily on prostate volume (< 30 mL TUIP) [366].

Summary of evidence	**LE**
Transurethral incision of the prostate shows similar efficacy and safety to M-TURP for treating moderate-to-severe LUTS secondary to BPO in men with prostates < 30 mL.	1a
No case of TUR-syndrome has been recorded, the risk of bleeding requiring transfusion is negligible and retrograde ejaculation rate is significantly lower after TUIP, but the re-operation rate is higher compared to M-TURP.	1a
The choice between TUIP and TURP should be based primarily on prostate volume (< 30 mL and 30-80 mL suitable for TUIP and TURP, respectively).	4

Recommendation	Strength rating
Offer transurethral incision of the prostate to surgically treat moderate-to-severe LUTS in men with prostate size < 30 mL, without a middle lobe.	Strong

*5.3.2 **Enucleation of the prostate***

5.3.2.1 Open prostatectomy

Mechanism of action: Open prostatectomy (OP) is the oldest surgical treatment for moderate-to-severe LUTS secondary to BPO. Obstructive adenomas are enucleated using the index finger, approaching from within the bladder (Freyer procedure) or through the anterior prostatic capsule (Millin procedure). It is used for substantially enlarged glands (> 80-100 mL).

Efficacy: Open prostatectomy reduces LUTS by 63-86% (12.5-23.3 IPSS points), improves QoL score by 60-87%, increases mean Q_{max} by 375% (+16.5-20.2 mL/s), and reduces PVR by 86-98%. Efficacy is maintained for up to six years [367-372]. Data from an Austrian nationwide study of 2,452 men submitted to OP showed that the endourological re-intervention rates after primary OP were 0.9%, 3.0%, 6.0%, and 8.8%, at three months, one year, five years, and eight years, respectively [323].

Two meta-analyses [373, 374] evaluated the overall efficacy of OP performed via a transvesical approach vs. two transurethral enucleation techniques for treating patients with large glands, namely bipolar transurethral enucleation of the prostate (B-TUEP) and holmium laser enucleation of the prostate (HoLEP). Five RCTs compared OP with B-TUEP [372, 375-378] and four RCTs compared OP with HoLEP [367, 368, 379, 380]. At three, six, twelve and 24-months follow-up there were no significant differences in Q_{max} [374]. Post-void residual, PSA, IPSS and QoL score showed no significant differences during twelve-months follow-up [374]. Open prostatectomy and HoLEP had similar improvements regarding Q_{max}, IPSS score and re-operation rates after five years in one RCT [367].

Tolerability and safety: Two meta-analyses evaluated the overall safety of OP performed via a transvesical approach vs. B-TUEP and HoLEP [373, 374]. Operation time did not differ significantly between OP and B-TUEP but was significantly shorter for OP compared to HoLEP. Catheterisation and hospitalisation time were significantly longer for OP, which was also associated with more blood transfusions. There were no significant differences regarding other complications. There was no significant difference in IIEF-5 at three, six, twelve and 24-months follow-up.

Open prostatectomy mortality has decreased significantly during the past two decades (< 0.25%) [371, 381]. Data from a study of 1,286 men submitted to OP showed mortality rates of 0.2% at 30 days and 0.4% at 90 days [324].

The estimated transfusion rate was about 7-14% [367, 370, 371, 373] Long-term complications include transient UI (up to 10%), BNC and urethral stricture (about 6%) [367-369, 373, 382].

Practical considerations: Open prostatectomy is the most invasive surgical method, but it is an effective and durable procedure for the treatment of LUTS/BPO. In the absence of an endourological armamentarium including a holmium laser or a bipolar system and with appropriate patient consent, OP is a reasonable surgical treatment of choice for men with prostates > 80 mL.

Summary of evidence	LE
Open prostatectomy is an effective and durable procedure for the treatment of LUTS/BPO, but it is the most invasive surgical method.	1b
Open prostatectomy shows similar short- and mid-term efficacy to B-TUEP and HoLEP for treating moderate-to-severe LUTS secondary to BPO in patients with large prostates.	1a
Open prostatectomy has a less favourable peri-operative safety profile compared to B-TUEP and HoLEP.	1a
The long-term functional results of OP are comparable to HoLEP.	1b

Recommendation	Strength rating
Offer open prostatectomy in the absence of anatomical endoscopic enucleation of the prostate to treat moderate-to-severe LUTS in men with prostate size > 80 mL.	Strong

5.3.2.2 Bipolar transurethral enucleation of the prostate

Mechanism of action: Following the principles of bipolar technology (section 5.3.1.1), the obstructive adenoma is enucleated endoscopically by the transurethral approach. Currently, two technologies exist, namely plasmakinetic (PK) enucleation of the prostate (PKEP) and bipolar plasma enucleation of the prostate (BPEP) [378, 383, 384]. Bipolar transurethral enucleation of the prostate is followed by either morcellation [378, 385] or resection [383, 386-390] of the enucleated adenoma.

Efficacy: Two meta-analyses, reported similar efficacy at twelve months in terms of IPSS, QoL score and Q_{max} for B-TUEP (PKEP or BPEP) vs. B-TURP [391, 392]. Another meta-analysis evaluating B-TUEP vs. B-TURP, reported similar efficacy at 36 months in terms of IPSS, and Q_{max} [340]. One RCT evaluating PKEP vs. M-TURP reported a significant improvement in IPSS, QoL score, and Q_{max}, with urodynamically proven de-obstruction favouring PKEP at 36-months follow-up [387]. One RCT evaluating PKEP vs. B-TURP in patients with prostate volume > 80 mL reported no clinically relevant differences in IPSS, QoL score, and Q_{max}, at six months follow up [393]. Another RCT evaluating BPEP vs. B-TURP in patients with prostate volume > 80 mL reported not clinically relevant differences in IPSS, QoL score, Q_{max} and PVR at 24-months follow-up [394] Two RCTs evaluated the mid-term efficacy of PKEP vs. B-TURP at 36 months [388, 389] and one RCT evaluated long-term efficacy at 60 months [390]. Efficacy was significantly better for PKEP in patients with large prostates at 36, 48 and 60 months [388, 390]. Comparative data on efficacy for B-TUEP vs. OP and the various forms of laser enucleation are presented in section 5.3.2.1 – 5.3.2.5, respectively.

Tolerability and safety: Two meta-analyses evaluating B-TUEP vs. B-TURP reported similar operation, catheterisation and hospitalisation times; lower acute urine retention rates; significantly reduced haemoglobin drop and blood transfusion rates; no difference in ED; and no difference in all other reported complication rates including urethral stricture/BNC rates for B-TUEP at 24-months follow-up [391, 392]. [394]. A meta-analyses evaluating PKEP vs. TURP reported that mid-term IIEF-5 scores were comparable [395]. Another meta-analyses reported less bleeding with B-TUEP compared to M-TURP but similar UI rates and AUR after catheter removal [340]. An RCT evaluating PKEP vs. M-TURP in patients with prostate volume < 80 mL and 36-month follow-up reported that PKEP is superior to M-TURP in terms of catheterisation, and hospitalisation time [387]. No significant differences between the arms were reported in operation time, blood transfusion rates, sexual function, or any other reported complications (TUR-syndrome, clot retention, incontinence, retrograde ejaculation, urethral structures/BNC) [387]. One RCT evaluating PKEP vs. B-TURP in patients' prostate volume > 80 mL and six months follow-up reported that PKEP is superior to B-TURP in terms of operation, catheterisation and hospitalisation time [393]. Significant differences were reported in blood transfusion, BNC and retrograde ejaculation rates favouring PKEP, but no differences in urethral stricture and ED rates were reported [393]Another RCT evaluating BPEP vs. B-TURP in patients with prostate volume > 80 mL reported that BPEP had longer operative time but shorter catheterisation, hospitalisation time with no differences in blood transfusion, urethral stricture and UI rates at 24-months follow-up [394]. No difference in urethral stricture/BNC rates was reported at 60 months follow-up [390]. Comparative data on efficacy for B-TUEP vs. OP and the various forms of laser enucleation are presented in section 5.3.2.1 – 5.3.2.5, respectively.

Summary of evidence	**LE**
Bipolar transurethral PKEP shows favourable mid- to long-term efficacy compared to TURP.	1b
Bipolar transurethral PKEP has a favourable peri-operative safety profile and demonstrates similar mid- to long-term safety compared to TURP.	1b

Recommendation	**Strength rating**
Offer bipolar transurethral (plasmakinetic) enucleation of the prostate to men with moderate-to-severe LUTS as an alternative to transurethral resection of the prostate.	Weak

5.3.2.3 Holmium laser enucleation of the prostate

Mechanism of action: The holmium:yttrium-aluminium garnet (Ho:YAG) laser (wavelength 2,140 nm) is a pulsed solid-state laser that is absorbed by water and water-containing tissues. Tissue coagulation and necrosis are limited to 3-4 mm, which is enough to obtain adequate haemostasis [396].

Efficacy: An initial meta-analyses reported no significant differences in short-term efficacy (Q_{max}) and re-intervention rates (4.3% vs. 8.8%) between HoLEP and M-TURP [397]; however, subsequent meta-analyses reported favourable short-term efficacy (Q_{max} and IPSS) for HoLEP [320, 353, 391, 398]. Meta-analyses reported similar efficacy at 24-months in terms of IPSS, and Q_{max} [340]. Three meta-analyses evaluating HoLEP vs.

B-TURP showed no significant differences in short-term efficacy (IPSS, QoL score and Q_{max}) [340, 391, 399]. One RCT comparing HoLEP with B-TURP in patients with prostate volume < 80 mL reported no significant difference in IPSS, QoL score and Q_{max} at 24-months [400]. One RCT comparing HoLEP with M-TURP in a small number of patients with mean prostate volume < 80 mL and a seven year follow-up found that the functional long-term results were comparable [396]. Another RCT comparing HoLEP with B-TURP in patients with prostate volume > 80 mL reported no significant difference in IPSS, QoL score and Q_{max} at 36 months, however, the overall re-treatment rate was significantly lower following HoLEP with less patients restarting α-blockers and less re-operations [401]. Comparative efficacy data for HoLEP vs. OP is presented in section 5.3.2.1. One RCT evaluating HoLEP vs. PKEP in patients with mean prostate volume < 80 mL reported similar improvements in IPSS and Q_{max} at twelve months follow-up [385]. In another RCT comparing HoLEP with PkEP improvements of IPSS, QoL, PVR, and Q_{max} were stable at 3-year follow-up without differences between the groups [402, 403].

An RCT comparing HoLEP vs. bipolar transurethral enucleation reported no significant difference in IPSS, QoL score, PVR, and Q_{max} at one, three-, and twelve-months follow-up [404].

A SR and meta-analysis based on retrospective series, revealed a superior enucleation efficiency associated with *en-bloc* and the two-lobe techniques compared to the three-lobe technique, but no superiority on functional outcomes were reported [405].

Tolerability and safety: Several meta-analyses found that HoLEP has longer operation times, shorter catheterisation and hospitalisation times, reduced blood loss, fewer blood transfusions but no significant differences in urethral strictures (2.6% vs. 4.4%) and stress urinary incontinence (SUI) (1.5% vs. 1.5%) rates compared to M-TURP [353, 391, 397, 398, 406]. Another meta-analysis reported that HoLEP has shorter catheterisation times, fewer blood transfusions, urethral strictures and UTIs but no significant differences in clot retention rates and AUR after catheter removal compared to M-TURP [340]. Three meta-analyses evaluated HoLEP vs. B-TURP [391, 399, 407]. One, reported longer operation times for HoLEP, but no significant differences in hospitalisation time or complication rates [391] whilst another reported no significant differences in operation and catheterisation times or short-term complication rates [399]. Data from a large national database on peri-operative outcomes of 2,869 laser enucleation of the prostate and 37,577 TURP procedures supports that laser enucleation of the prostate is associated with longer operation times, shorter hospitalisation times, similar complication rates (including transfusions, and re-operations), but lower rates of infectious complications [408]. A SR reported that HoLEP has lower AUR rates after catheter removal but similar haemoglobin drop, UTI, urethral stricture, and UI rates [340]. An RCT comparing HoLEP with B-TURP in patients with prostate volume < 80 mL reported longer operation time, shorter catheterisation and hospitalisation times and a lower risk for haemorrhage for HoLEP with no significant differences in blood transfusion rates or other complication rates at 24 months [400]. Another RCT comparing HoLEP with B-TURP in patients with prostate volume > 80 mL reported shorter operation, catheterisation and hospitalisation times and lower blood transfusion rates for HoLEP but no differences in complication rates including UI and IIEF-5 score at 36 months [401]Comparative data on safety of HoLEP vs. OP are presented in section 5.3.2.1. One RCT evaluating HoLEP vs. PKEP in patients with mean prostate volume < 80 mL reported significantly shorter operation times for HoLEP, but similar catheterisation and hospitalisation times and complication rates at twelve months follow-up [385]. Another RCT comparing HoLEP with PkEP found a higher haemoglobin drop and a prolonged haematuria in the PkEP group but no clinical significant blood loss in either arm occurred [402, 403]. An RCT comparing HoLEP vs. bipolar B-TUEP demonstrated shorter operation and hospitalisation times and earlier catheter removal for HoLEP [404].

Another RCT comparing high (2J, 50 Hz) with medium power (2J, 30 Hz) HoLEP demonstrated comparable peri-operative safety and long-term durability [409].

A double-blind RCT of pulse modulation use in HoLEP (Virtual basket) demonstrated statistically significantly outcomes related to haemostasis (18 vs. 29 min, $p < 0.01$) and operation time (101 vs. 126 min, $p < 0.01$), when compared to conventional HoLEP [410]. This was confirmed in a SR and meta-analysis of seven studies comparing pulse modulation use with standard HoLEP. Shorter enucleation, better haemostasis and shorter total surgical time was found with pulse modulating HoLEP [411].

One RCT evaluating tranexamic acid use in HoLEP surgery did not find any difference with regard to bleeding complications and peri-operative safety [412].

Holmium laser enucleation of the prostate has been safely performed in patients using anticoagulant and/or antiplatelet medications. However, current limitations include: a lack of RCTs; limited data on short- and mid-term complications and bridging therapy; data presentation does not allow for separate interpretation of either antiplatelet and anticoagulant therapy [413].

A meta-analysis of seven RCTs evaluating HoLEP vs. TURP reported that short- and mid-term IIEF-5 scores were comparable, whilst long-term scores were significantly better for HoLEP [414]. Two other meta-analyses detected no difference in mid-term retrograde ejaculation rates [415].

The impact on erectile function is comparable [416, 417] however the conclusion that retrograde ejaculation is also comparable between HoLEP and TURP is highly dependent on the use template [416, 417]. Erectile function did not decrease from baseline in either group; three quarters of sexually active patients had retrograde ejaculation after HoLEP. Data have shown that ejaculation and orgasm perception are the two most impacted domains after HoLEP [418]. Attempts to maintain ejaculatory function with HoLEP have been reported to be successful in up to 46.2% of patients [419].

An RCT comparing HoLEP vs. B-TUEP, reported shorter operation and hospitalisation times and earlier catheter removal for HoLEP [404].

Practical considerations: The experience of the surgeon is the most important factor affecting the overall occurrence of complications in HoLEP [420, 421]. Mentorship programmes are advised to improve surgical performance from both an institutional and personal learning curve perspective [422-424]. Pulse modulation use in HoLEP (Virtual basket) demonstrated statistically significantly outcomes related to haemostasis and operation times, clinical and health economic benefits remains to be determined.

Summary of evidence	**LE**
Laser enucleation of the prostate using Ho:YAG laser (HoLEP) demonstrates similar mid- to long-term efficacy when compared to TURP.	1b
Laser enucleation of the prostate using Ho:YAG laser (HoLEP) demonstrates similar short-term safety when compared to TURP.	1a
Laser enucleation of the prostate using Ho:YAG laser (HoLEP) demonstrates longer operation times, but a more favourable peri-operative profile when compared to TURP.	1a

Recommendation	**Strength rating**
Offer laser enucleation of the prostate using Ho:YAG laser (HoLEP) to men with moderate-to-severe LUTS as an alternative to transurethral resection of the prostate or open prostatectomy.	Strong

5.3.2.4 Thulium:yttrium-aluminium-garnet laser enucleation of the prostate

Mechanism of action: The Tm:YAG laser has been described in section 5.3.1.3. Enucleation using the Tm:YAG laser includes thulium vapoenucleation of the prostate (ThuVEP) and thulium Laser enucleation of the prostate (ThuLEP) (blunt enucleation). (Super) pulsed or continuous wave (CW) thulium:yttrium-aluminium garnet (wavelength 2,013 nm) or thulium fibre lasers (wavelength 1,940 nm) are be used for laser enucleation of the prostate and are well absorbed by water and water-containing tissues.

Efficacy: Two meta-analyses evaluating ThuLEP vs. M-TURP and B-TURP reported no clinically relevant differences in short-term efficacy (Q_{max}, IPSS and QoL score) [340, 391]. An RCT with five years follow-up comparing ThuLEP with B-TURP found no difference between the two procedures for Q_{max}, IPSS, PVR, and QoL [425]. A meta-analysis [426] evaluating ThuLEP vs. HoLEP showed no clinically relevant differences in IPSS, QoL score and Q_{max} at twelve months in accordance with one RCT showing similar results at eighteen months [427]. Furthermore, ThuLEP and PKEP were compared in one RCT with twelve months follow-up with no difference with regard to efficacy [428]. There are mainly prospective case studies on ThuVEP showing a significant improvement in IPSS, Q_{max}, and PVR after treatment [429-432]. In a retrospective comparative series, there were no differences between (super)pulsed and CW ThuLEP with regard to intra-operative, peri-operative data and clinical efficacy (Q_{max}, IPSS, QoL) [433].

Tolerability and safety: Two meta-analyses evaluating ThuLEP vs. M-TURP and B-TURP reported a longer operation time and shorter catheterisation time for ThuLEP compared to M-TURP and a shorter hospitalisation time for ThuLEP compared to B-TURP [340, 391]. Lower blood transfusion rates compared to M-TURP, lower clot retention rates compared to B-TURP, and no difference in the other complication rates were also reported for ThuLEP [340, 391]. One meta-analysis [426] evaluating ThuLEP vs. HoLEP showed a significant difference in enucleation time favouring ThuLEP, but no significant differences in operation, catheterisation and hospitalisation times, and short-term complication rates. One RCT showed no urethral and bladder neck strictures at eighteen months after ThuLEP and HoLEP, respectively [427]. ThuLEP and PKEP were compared in one RCT with twelve months follow-up [428]. No significant difference in complication rates was detected, but haemoglobin level decrease and catheterisation time was significantly lower for ThuLEP. An RCT comparing ThuLEP with B-TURP reported a significant difference in IIEF-5 score favouring ThuLEP at twelve months [434].

In comparative studies ThuVEP shows high intra-operative safety [435], also in case series of patients with large prostates [429] and anticoagulation or bleeding disorders [430, 431]. A study focusing on post-operative complications after ThuVEP reported adverse events in 31% of cases, with 6.6% complications greater then Clavien grade 2 [436]. One case control study on ThuVEP with 48 month follow-up reported long-term durability of voiding improvements and overall re-operation rates of 2.4% [431].

Practical considerations: ThuLEP seems to offer similar efficacy and safety when compared to TURP, bipolar enucleation and HoLEP; whereas, ThuVEP is not supported by RCTs. Based on the limited number of RCTs there is a need for ongoing investigation of these techniques [437, 438].

Summary of evidence	LE
Enucleation of the prostate using the Tm:YAG laser demonstrates similar efficacy when compared to M-TURP/bipolar transurethral (plasmakinetic) enucleation, HoLEP and B-TURP in the short-, mid-, and long-term, respectively.	1b
Enucleation of the prostate using the Tm:YAG laser (ThuLEP) demonstrates similar safety compared to TURP/bipolar transurethral (plasmakinetic) enucleation, and HoLEP in the short- and mid-term, respectively.	1b
Vapoenucleation of the prostate using a Tm:YAG laser (ThuVEP) seems to be safe in patients with large prostates and those receiving anticoagulant or antiplatelet therapy.	2b

Recommendations	Strength rating
Offer enucleation of the prostate using the Tm:YAG laser (ThuLEP, ThuVEP) to men with moderate-to-severe LUTS as an alternative to transurethral resection of the prostate, holmium laser enucleation or bipolar transurethral (plasmakinetic) enucleation.	Weak
Offer Tm:YAG laser enucleation of the prostate to patients receiving anticoagulant or antiplatelet therapy.	Weak

5.3.2.5 Diode laser enucleation of the prostate

Mechanism of action: For prostate surgery, diode lasers with a wavelength of 940, 980, 1,318, and 1,470 nm (depending on the semiconductor used) are marketed for vaporisation and enucleation. Only a few have been evaluated in clinical trials [439].

Efficacy: One RCT comparing 1,318 nm diode laser enucleation of the prostate (DiLEP) with B-TURP in patients with mean prostate volume < 80 mL reported no significant differences in IPSS, QoL score, Q_{max} and PVR at six months follow-up [440]. Another RCT comparing 1,470 nm DiLEP with B-TURP in patients with mean prostate volume < 80 mL also reported no significant differences in IPSS, QoL score, Q_{max} and PVR at twelve months follow-up [441]. In addition, three RCTs comparing 980 nm DiLEP with PKEP in patients with mean prostate volume < 80 mL [442, 443] and > 80 mL [444] reported no significant differences in IPSS, QoL score, Q_{max} and PVR at twelve months follow-up. An RCT of DilEP (980 nm) vs. HoLEP detected no significant difference in Q_{max}, PVR, IPSS, and QoL within twelve months follow-up [445].

Tolerability and safety: One small RCT comparing 1,318 nm DiLEP with B-TURP in patients with mean prostate volume < 80 mL and six months follow-up reported a significantly longer operation time for DiLEP, but shorter catheterisation and hospitalisation times, as well as less blood loss (without differences in blood transfusion rates) [440]. No differences in complication rates were reported between the two arms [440]. Another RCT comparing 1,470 nm DiLEP with B-TURP in patients with prostate volume < 80 mL and twelve months follow-up reported significantly shorter operation, catheterisation, and hospitalisation times with less blood loss (without differences in blood transfusion rates) for DiLEP, with no differences in complication rates between the two arms [441]. Three RCTs comparing 980 nm DiLEP with PKEP in patients with prostate volume < 80 mL [442, 443] and > 80 mL [444] and twelve months follow-up reported conflicting peri-operative outcomes. All trials reported no differences in blood transfusion rates and complication rates [442-444].

An RCT of DiLEP (980 nm) vs. HoLEP with twelve months follow-up demonstrated no significant difference in peri-operative outcomes including operation and hospitalisation times [445].

Practical considerations: Diode laser enucleation seems to offer similar efficacy and safety when compared to either B-TURP or bipolar transurethral (plasmakinetic) enucleation. Based on the limited number of mainly low-quality RCTs, and controversial data on the retreatment rate, results for DiLEP should be evaluated in further higher quality RCTs.

Summary of evidence	LE
Laser enucleation of the prostate using the 1,318 nm or 1,470 laser showed comparable short-term efficacy and safety to B-TURP. Peri-operative parameters like blood loss, catheterisation time and hospital stay are in favour of diode enucleation.	1b
Laser enucleation of the prostate using the 980 nm laser showed comparable short-term efficacy and safety to bipolar transurethral (plasmakinetic) enucleation.	1b

Recommendation	Strength rating
Offer 120-W 980 nm, 1,318 nm or 1,470 nm diode laser enucleation of the prostate to men with moderate-to-severe LUTS as a comparable alternative to bipolar transurethral (plasmakinetic) enucleation or bipolar transurethral resection of the prostate.	Weak

5.3.2.6 Enucleation techniques under investigation

5.3.2.6.1 Minimal invasive simple prostatectomy

Mechanism of action: The term minimal invasive simple prostatectomy (MISP) includes laparoscopic simple prostatectomy (LSP) [446] and robot-assisted simple prostatectomy (RASP) [447]. Both LSP and RASP are performed using different personalised techniques, based on the transcapsular (Millin) or transvesical (Freyer) approach.

Efficacy: A SR and meta-analyses showed that in 27 observational studies including 764 patients mean increase in Q_{max} was 14.3 mL/s, and the mean improvement in IPSS was 17.2 [448]. There were no differences in improvements in Q_{max} and IPSS [448]. A meta-analysis comparing MISP vs. OP reported no significant differences with regard to functional and symptom parameters between the two techniques [449]. A multicentre RCT with median follow-up of 26 months did not demonstrate any significantly different functional or peri-operative results between LSP, RASP and HoLEP [450]. A SR and meta-analysis of five non-randomised comparative trials comparing RASP with LSP demonstrated a shorter length of hospital stay after RASP as well as a higher post-operative Q_{max} [451, 452]. An RCT comparing HoLEP versus MISP for large volume (≥ 120 mL) prostate glands resulted in longer catheterisation time, in the LSP group than RASP and HoLEP groups (p=0.002). Furthermore, MISP resulted in longer hospitalisation, and lower rate of patients with new-onset of storage LUTS [452].

Tolerability and safety: A meta-analysis comparing MISP vs. OP demonstrated shorter hospital stay, as well as blood loss and transfusion rates for MISP [449, 453]. In In comparative studies to OP, length of hospital stay, length of catheter use, and estimated blood loss were significantly lower in the MISP group, while the duration of surgery was longer. There were no differences in peri-operative complications between both procedures [448]. In a multicentre RCT comparing LSP, RASP and HoLEP LSP demonstrated significantly longer catheterisation times than RASP and HoLEP, whilst RASP and LSP showed longer hospitalisation times and lower rates of *de novo* bladder storage symptoms [450]. In a comparative analysis of robotic vs. OP for large-volume prostates, a propensity score-matched analysis was performed with five covariates. Robotic compared with OP demonstrated a significant shorter average length of hospital stay, but longer mean operative time. The robotic approach was associated with a lower estimated blood loss. Improvements in maximal flow rate, IPSS, QoL, PVR and post-operative PSA levels were similar for both groups. There was no difference in complications between the groups [454].

Practical considerations: Currently, most studies on MISP are of a retrospective nature. Adequately powered RCT against reference options are needed to compare efficacy, safety, and hospitalisation times, learning curve and costs of MISP and both OP and endoscopic methods.

Summary of evidence	LE
Minimal invasive simple prostatectomy is feasible in men with prostate sizes > 80 mL needing surgical treatment; however, RCTs are needed.	2a

5.3.2.6.2 532 nm ('Greenlight') laser enucleation of the prostate

Two approaches for Potassium-Titanyl-Phosphate (KTP) and the lithium triborate (LBO) laser-based enucleation technique exist [455]. GreenLEP is an anatomical enucleation technique following the principle of blunt dissection of the adenoma with the sheath and laser energy for incision as described for ThuLEP [456]. A variation is the *in-situ* vaporisation of apically enucleated tissue, also referred to as anatomic vaporisation-

incision technique [456, 457]. To date, no high quality adequate RCTs evaluating enucleation using the KTP/LBO laser have been carried out [458, 459].

*5.3.3 **Vaporisation of the prostate***

5.3.3.1 Bipolar transurethral vaporisation of the prostate

Mechanism of action: Mechanism of action: Bipolar transurethral vaporisation of the prostate (B-TUVP) utilises a bipolar electrode and a high-frequency generator to create plasma field (thin layer of highly ionised particles) to vaporise prostatic tissue [460]. Bipolar transurethral vaporisation of the prostate displays thinner (< 2 mm) coagulation zones [461], compared to monopolar TUVP (up to 10 mm) [462], potentially resulting in fewer irritative side-effects and SUI [461, 463, 464].

Efficacy: Bipolar-TUVP has been compared to TURP in thirteen RCTs, including a total of 1,244 men with a prostate size of < 80 mL [334, 465-476]. Early RCTs evaluated the PK B-TUVP system [465-469]; however, during the last decade, only the "plasma" B-TUVP system with the "mushroom- or button-like" electrode (Olympus, Medical) has been evaluated [334, 470-476]. Results have been pooled in three meta-analyses [320, 477, 478], and a narrative synthesis has been produced in two SRs [320, 479].

Follow-up in most RCTs is twelve months [465-468, 470-472, 474, 476] with the longest being 36 months in a small RCT (n = 40) and eighteen months in a subsequent RCT (n = 340); evaluating PK [469] and plasma B-TUVP [334], respectively. Pooled results from meta-analyses concluded that no significant differences exist in short-term efficacy (IPSS, QoL score, Q_{max} and PVR) between PK B-TUVP and TURP [320, 340, 478] and this was confirmed in a separate SR of seven RCTs [479]. However, the promising initial efficacy profile of the former may be compromised by inferior clinical outcomes (IPSS and Q_{max}) at mid-term. Higher quality RCTs with longer follow-up are necessary to draw definite conclusions on mid and long-term outcomes [320, 469].

Tolerability and safety: Early pooled results concluded that no statistically significant differences exist for intra-operative and short-term complications between PK B-TUVP and TURP, but peri-operative complications are significantly fewer after B-TUVP [320]. However, the results of a statistical analysis comparing pooled specific complication rates were not directly reported in this meta-analysis [320]. Mid-term complications (urethral stricture, ED, and retrograde ejaculation) are similar [469], but larger RCTs with longer follow-up are necessary to draw definite conclusions [320, 469]. A SR of seven RCTs comparing PK and plasma B-TUVP with TURP concluded that most RCTs shorter catheterisation (42.5 vs. 77.5 hours) and hospitalisation times (3.1 vs. 4.4 days) with B-TUVP [479], but another SR concluded that heterogeneity of RCTs, and methodological limitations do not permit firm conclusions [320]. A meta-analysis reported that B-TUVP has shorter and similar catheterisation time compared to M-TURP and B-TURP, respectively; significantly fewer clot retentions/blood transfusions compared to M-TURP but not B-TURP; and no difference in other complication rates compared to either TURP technique [340]. A meta-analysis of six RCTs specifically evaluating plasma B-TUVP vs. TURP, concluded that no significant differences exist between the techniques in overall complication and transfusion rates [478]. However, a statistically significant difference was detected in major complication rates (Clavien 3, 4), including urethral stricture, severe bleeding necessitating re-operation and UI, and in the duration of catheterisation, favouring plasma B-TUVP.

Practical considerations: Bipolar-TUVP and PK TUVP have similar short-term efficacy to TURP, but with a favourable short-term safety profile. However, heterogeneity of RCTs, non-standardised techniques and methodological limitations do not permit firm conclusions, and multicentre, long-term RCTs s are needed.

Summary of evidence	**LE**
Bipolar-TUVP and TURP have similar short-term efficacy.	1a
Plasmakinetic B-TUVP has a favourable peri-operative profile, similar mid-term safety but inferior mid-term efficacy compared to TURP.	1a
Plasma B-TUVP has a lower short-term major morbidity rate compared to TURP.	1a

Recommendation	**Strength rating**
Offer bipolar transurethral vaporisation of the prostate as an alternative to transurethral resection of the prostate to surgically treat moderate-to-severe LUTS in men with a prostate volume of 30-80 mL.	Weak

5.3.3.2 532 nm ('Greenlight') laser vaporisation of the prostate

Mechanism of action: The KTP and LBO lasers have been described in section 5.3.2.6.2.

Efficacy: Meta-analyses of RCTs comparing photoselective vaporisation of the prostate (PVP) using the 80-W and 120-W lasers with TURP have reported no difference in Q_{max} and IPSS between 80-W or 120-W PVP and TURP [480, 481]. Another meta-analysis of four RCTs including 559 patients, on the 120-W laser, demonstrated no significant difference in functional and symptomatic parameters at 24-month follow-up when compared to TURP [482]. A meta-analysis of two RCTs reported similar efficacy of 120-W PVP, compared to M-TURP at 36-months follow-up [340].

The only available RCT for the 180-W laser reported non-inferiority to TURP in terms of IPSS, Q_{max}, PVR, prostate volume reduction, PSA decrease and QoL questionnaires. Efficacy outcomes were similar to TURP with stable results at 24-months follow-up [483].

One RCT comparing HoLEP to PVP, in patients with prostates > 60 mL, showed comparable symptom improvement, but significantly higher flow rates and lower PVR volume after HoLEP at short-term follow-up; in addition, PVP showed a 22% conversion rate to TURP [484].

One RCT compared B-TUVP with PVP with the 180-W XPS Laser. Comparable improvement in IPSS and Q_{max} were reported at 24-months follow-up [485].

Tolerability and safety: A meta-analysis of RCTs comparing the 80-W and 120-W lasers with TURP showed shorter catheterisation time (mean difference 32 hours) and length of hospital stay (mean difference 1.85 days) after PVP [320]. Blood transfusions and clot retention were less with PVP. No difference was noted in post-operative urinary retention, UTI, meatal stenosis, urethral stricture, or bladder neck stenosis [320]. A meta-analysis including trials with the 120-W laser likewise reported lower transfusion rates, catheterisation time and duration of hospital stay compared to TURP. Re-operation rates and operation time were in favour of TURP. No significant differences were demonstrated for treatment for urethral stricture, BNC, incidence of incontinence and UTI [482]. A meta-analysis confirmed that PVP was superior to both M-TURP/B-TURP with regard to catheterisation and to M-TURP but not to B-TURP with regard to transfusion rate and clot retention [340]. In an RCT comparing the 120-W HPS laser with TURP, with a follow-up of 36-months, the re-operation rate was significantly higher after PVP (11% vs. 1.8%) [486].

180-W Greenlight laser prostatectomy is non-inferior to TURP in terms of peri-operative complications. Re-operation free survival during a 24-month follow-up was comparable between the TURP-arm and the 180-W XPS laser-arm [483].

A retrospective feasibility study on 537 patients with a median follow-up of 31 months, of which 517 were treated in an outpatient basis, showed that outpatient PVP with the 180-W XPS laser can be performed safely with a low re-admission and complication rate [487].

One retrospective long-term follow up study on 21,869 patients treated in twenty centres in Finland compared short-term and long-term morbidity in patients undergoing monopolar or bipolar TURP or any of the three generations of PVP [488]. Re-operations for bleeding were less frequent after PVP. Cumulative incidence for re-operation was higher after PVP (23.5%) than after TURP in long-term follow-up (17.8%) [488].

Based mostly on case series, the 80-,120- and 180-W Greenlight laser appears to be safe in high-risk patients undergoing anticoagulation treatment [489-492]; however, patients under anticoagulation therapy were either excluded from or represented a very small sample in currently available RCTs. In one study, anticoagulated patients had significantly higher rates of bladder irrigation (17.2%) compared with those not taking anticoagulants (5.4%) [492]. In contrast, another retrospective study focusing on the 180-W LBO laser did not find any significant differences between patients receiving or not receiving anticoagulants [493]. A retrospective study of a mixed cohort of patients, treated with 80-W KTP PVP and 120-W LBO HPS, revealed that delayed gross haematuria was common in patients (33.8%) during an average follow-up of 33 months [494]. A retrospective review of a database of patients undergoing 180-W PVP, without interruption of anticoagulation therapy, had a 30.5% rate of peri-operative adverse events with a significant occurrence of high grade Clavien Dindo events [495].

Safety in patients with urinary retention, impaired detrusor contractility, elderly patients or prostates > 80 mL was shown in various prospective short-term non-randomised trials.

A retrospective study on 1,077 patients [496] with a median eighteen months follow-up, compared the functional results and the safety profile of PVP in patients younger and older than 75 years of age. The authors did not find any differences in terms of complications in older patients, with only 0.6% of Clavien III and an overall complications rate of 29.6%. Data on functional outcomes in the older group of patients, showed amelioration of all parameters from the baseline, with 111.7% of improvement of peak flow and 69.5% of IPSS reduction without statistical differences with the counterparts at twelve months. However this similarity of results disappears by extending the study period up to a median of eighteen months, underlying the fact that younger patients maintain their improvement more than older patients, who nevertheless maintain a relevant improvement compared to their baseline [496].

No RCT including prostates > 100 mL has been reported; therefore, comparison of retreatment rates between prostate volumes of different sizes is not possible [497-499].

A meta-analysis of five RCTs comparing collectively all three "Greenlight" lasers with TURP detected no difference in retrograde ejaculation rates [415]. Additional studies have also reported no difference between OP/TURP and Greenlight PVP for erectile function [500, 501]. However, IIEF-5 scores were significantly decreased at six-, twelve-, and 24- months in patients with pre-operative IIEF-5 greater than nineteen [502].

No significant difference with respect to peri- and post-operative complications was reported in an RCT comparing B-TUVP and PVP with the 180-W XPS Laser. Redo TURP for recurrent adenoma was required in 9.8% (B-TUVP) and 1.7% (PVP) of the patients during 24-months follow-up, respectively [485].

Practical considerations: The 180-W XPS represents the current standard of generators for PVP; however, the number and quality of supporting publications are low, especially for large glands (> 100 mL), with no long-term follow-up.

Summary of evidence	**LE**
Laser vaporisation of the prostate using the 80-W KTP and the 120-W LBO laser (PVP) demonstrated higher intra-operative safety with regard to haemostatic properties when compared to TURP. Peri-operative parameters such as catheterisation time and hospital stay are in favour of PVP, whereas operation time and risk of re-operation are in favour of TURP. Short-term results for the 80-W KTP laser and mid-term results for the 120-W LBO laser were comparable to TURP.	1a
Laser vaporisation of the prostate using the 180-W LBO laser (PVP) demonstrated higher intra-operative safety with regard to haemostatic properties when compared to TURP. Peri-operative parameters such as catheterisation time and hospital stay were in favour of PVP, whereas operation time was in favour of TURP. Short- to mid-term results are comparable to TURP.	1b
Laser vaporisation of the prostate using the 80-W KTP and 120-W LBO lasers seems to be safe for the treatment of patients receiving antiplatelet or anticoagulant therapy.	2
Laser vaporisation of the prostate using the 180-W LBO laser seems to be safe for the treatment of patients receiving antiplatelet or anticoagulant therapy; however, the level of evidence available is low.	3

Recommendations	**Strength rating**
Offer 80-W 532-nm Potassium-Titanyl-Phosphate (KTP) laser vaporisation of the prostate to men with moderate-to-severe LUTS with a prostate volume of 30-80 mL as an alternative to transurethral resection of the prostate (TURP).	Strong
Offer 120-W 532-nm Lithium Borat (LBO) laser vaporisation of the prostate to men with moderate-to-severe LUTS with a prostate volume of 30-80 mL as an alternative to TURP.	Strong
Offer 180-W 532-nm LBO laser vaporisation of the prostate to men with moderate-to-severe LUTS with a prostate volume of 30-80 mL as an alternative to TURP.	Strong
Offer laser vaporisation of the prostate using 80-W KTP, 120- or 180-W LBO lasers for the treatment of patients receiving antiplatelet or anticoagulant therapy with a prostate volume < 80 mL.	Weak

5.3.3.3 Vaporisation techniques under investigation

5.3.3.3.1 Diode laser vaporisation of the prostate

Mechanism of action: Diode lasers with a wavelength of 980 nm are marketed for prostate vaporisation; however, only a few have been evaluated in clinical trials [350].

Efficacy: Two RCTs for 120-W 980 nm diode laser vaporisation vs. M-TURP are available [503, 504]. The first RCT with 24-month follow-up reported similar efficacy (IPSS, Q_{max} and PVR) at one and six months. However, at twelve- and 24-months improvements in IPSS and Q_{max} were significantly in favour of TURP, and repeat TURP was more frequent in the diode laser group [503]. The second RCT reported equivalent results for both interventions at three-month follow-up [504].

Tolerability and safety: A meta-analysis comparing diode laser vaporisation vs. M-TURP reported shorter catheterisation time and lower transfusion rates for diode laser vaporisation [340]. In an RCT reflecting on peri-operative and post-operative complications no significant differences were demonstrated for clot retention, AUR after catheter removal, UUI and UTI [503]. Moreover, for late complications no significant differences could be demonstrated for re-operation rate, urethral stricture, bladder neck sclerosis, *de novo* sexual dysfunction and

mean time of dysuria [503]. Published studies on 980 nm diode laser vaporisation indicate high haemostatic potential, although anticoagulants or platelet aggregation inhibitors were taken in 24% and 52% of patients, respectively [505, 506]. In a number of studies, a high rate of post-operative dysuria was reported [503, 505-507].

Early publications on diode vaporisation reported high re-operation rates (8-33%) and persisting SUI (9.1%) [503, 505-507].

Practical considerations: Diode laser vaporisation leads to similar improvements in clinical and symptomatic parameters during short-term follow-up and provides good haemostatic properties. Based on the limited number of mainly low quality RCTs, and controversial data on the retreatment rate, results for diode laser vaporisation should be evaluated in further higher quality RCTs.

Summary of evidence	**LE**
Laser vaporisation of the prostate using the 120-W 980 nm diode laser demonstrated high intra-operative safety with regard to haemostatic properties when compared to TURP. Peri-operative parameters like catheterisation time and hospital stay were in favour of diode lasers. Evidence is limited by the number and quality of the available studies.	1b
In a number of studies, post-operative complications such as severe storage symptoms and persisting incontinence, occurred with laser vaporisation of the prostate using the 120-W 980 nm diode laser.	3
Laser vaporisation using the 120-W 980 nm diode laser seems to be safe with regard to haemostasis in patients receiving anticoagulant therapy.	3

*5.3.4 **Alternative ablative techniques***

5.3.4.1 Aquablation – image guided robotic waterjet ablation: AquaBeam

Mechanism of action: AquaBeam uses the principle of hydro-dissection to ablate prostatic parenchyma while sparing collagenous structures like blood vessels and the surgical capsule. A targeted high velocity saline stream ablates prostatic tissue without the generation of thermal energy under real-time transrectal ultrasound guidance. After completion of ablation haemostasis is performed with a Foley balloon catheter on light traction or diathermy or low-powered laser if necessary [508].

Efficacy: In a double-blind, multicentre, pivotal RCT, 181 patients with a prostate size of 30-80mL were randomised to TURP or Aquablation [509, 510]. Mean total operative time was similar for Aquablation and TURP (33 vs. 36 minutes), but resection time was significantly lower for Aquablation (4 vs. 27 minutes). At six months patients treated with Aquablation and TURP experienced large IPSS improvements (-16.9 and -15.1, respectively), satisfying the non-inferiority hypothesis. At one year follow-up, mean IPSS reduction was 15.1 with a mean reduction in IPSS score of 67% for both groups. No significant difference in improvement of IPSS, QoL, Q_{max} and reduction of PVR was reported between the groups [511].

Improvements in IPSS and Q_{max} were maintained after five years in both groups [512]. Mean IPSS decrease were 16.9 and 15.1 points in the Aquablation and TURP groups, respectively. Similarly, 5-year improvements in Q_{max} were 125% and 89% compared to baseline for Aquablation and TURP, respectively. Over five years, surgical retreatments were 5.1% and 1.5% respectively [512].

Results of AquaBeam in patients with large prostates (80-150mL) were evaluated in a cohort study of 101 men (WATER II) [509]. After twelve months, significant improvements were seen in IPSS (mean decrease of 17 points), Q_{max} (increase of 12.5 cc/sec) and PVR (a drop of 171 cc in those with PVR > 100 at baseline). At 5-years follow-up, 3% of patients required surgical retreatment [513].
Urodynamic studies of 66 patients enrolled in the WATER trial at six months follow-up showed significant changes in $p_{det}Q_{max}$ (reductions of 35 and 34 cm H20, respectively) and large improvements in BOO index in both groups [514].

Tolerability and safety: Results for the WATER trial have shown comparable hospital stay and catheterisation duration (1.4 and 1 day, respectively) [509]. One case of blood transfusion was reported after Aquabeam and none after TURP. In a SR of seven patient groups involving 446 patients treated by aquablation, although there was a significant haemoglobin drop (2.06 g/dL), it did not translate into increased transfusion rates. In WATER, fewer men in the Aquablation group had a persistent Clavien-Dindo grade 1 or 2 or higher adverse event compared to TURP (26% vs. 42%) at three months. Among sexually active men the rate of anejaculation was lower in those treated with Aquablation compared to TURP (10% vs. 36%, respectively). There were no procedure-related adverse events after six months [511].

In patients with a prostate volume between 80-150 mL (WATERII trial), bleeding related events were observed in fourteen patients (13.9%) of which eight (7.9%) occurred prior to discharge and six (5.9%) occurred within one month of discharge. Blood transfusions were required in eight patients, return to the theatre for fulguration in three patients, and both transfusion and fulguration in two patients [515]. Maintenance of antegrade ejaculation was slightly lower in WATER II at 81% compared to 90% in the smaller prostates of WATER I [516]. In WATER II there was a 2% *de novo* incontinence rate at twelve months [517].

In an analysis of procedural differences including data from WATER I and II, compared to a single pass of ablation, the use of two or more passes during Aquablation resulted in lower IPSS scores by four points, and lower IPSS QoL scores by 0.7 points at 24 and 36 months. Similarly, 36-month Q_{max} values were higher by 5 ml/sec in those with two or more passes than in those with one pass [518].

Practical considerations: During long-term follow-up, aquablation provides non-inferior functional outcomes compared to TURP in patients with LUTS and a prostate volume between 30-80 mL. Additional longer term, higher quality follow-up is necessary to assess better the clinical value of aquablation. There are still concerns about management of bleeding and bladder neck cautery is often performed at the end of the procedure.

Summary of evidence	**LE**
Aquablation appears to be as effective as TURP both subjectively and objectively.	1b

Recommendations	**Strength rating**
Offer Aquablation* to patients with moderate-to-severe LUTS and a prostate volume of 30-80 mL as an alternative to transurethral resection of the prostate.	Weak
Inform patients about the risk of bleeding and the lack of long-term follow-up data.	Strong

** Aquablation remains under investigation as evidence levels as described by Speakman et al. [317] has not been reached.*

5.3.4.2 Prostatic artery embolisation

Mechanism of action: Prostatic artery embolisation (PAE) can be performed as a day procedure under local anaesthesia with access through the femoral or radial arteries. Digital subtraction angiography displays arterial anatomy, and the appropriate prostatic arterial supply is selectively embolised to effect stasis in treated prostatic vessels. Different technical variations (including bead size) have been described for PAE, which needs specific training [519, 520].

Efficacy: Superior efficacy of PAE compared with a sham procedure was found in a six-month randomised, single-blind, sham-controlled trial in 80 patients with LUTS, refractory to medical treatment. The decrease in IPSS at six months was 5.03 +/- 8.13 in the sham group and 17.1 +/- 7.25 in the PAE group [521].

A SR and meta-analysis including RCTs and two non-RCTs comparative studies (n = 708 patients) showed that TURP achieved a significantly higher mean post-operative difference for IPSS and IPSS-QoL, 3.80 and 0.73 points, respectively compared to PAE [522]. All of the functional outcomes assessed were significantly superior after TURP: 3.62 mL/s for Q_{max}, 11.51 mL for prostate volume, 11.86 mL for PVR, and 1.02 ng/mL for PSA [522].

According to a Cochrane network meta-analysis, PAE may result in little to no difference in urologic symptoms scores as well as QoL compared to TURP at short-term follow-up of three to twelve months [523]. A network meta-analysis included outcome data at three to six months follow-up and concluded that improvement of IPSS was similarly high after TURP and PUL.

A meta-analysis of eleven RCTs comparing TURP and PAE found no significant difference between TURP and PAE for patient-reported outcomes including IPSS and QoL at twelve months. PAE was less effective regarding improvements in most functional outcomes such as maximum flow rate, prostate volume, and prostate-specific antigen [524].

A Cochrane review reported that compared to TURP, the impact on urological symptoms and QoL improvement as perceived by patients appears to be similar following PAE [525]. This review did reveal major uncertainty as to how major adverse events compare.

According to a non-inferiority trial, 21% of patients who initially had PAE underwent TURP within two years [526]

In a single-centre retrospective analysis of 75 PAE patients over a three-year period, PAE was shown to be a safe, effective, and durable treatment option for non-index patients with urinary retention (87% catheter free) or gross haematuria (resolved 87.5%) [527].

Tolerability and safety: Available RCTs, as well as SR and meta-analysis show conflicting results about the comparative rate of adverse events after PAE or TURP, depending on studies included, definition of adverse events, and follow-up. In a SR of comparative studies PAE resulted in significantly more adverse events than TURP/OP (41.6% vs. 30.4%). The frequency of AUR after the procedures was significantly higher in the PAE group (9.4% vs. 2.0%) [528]. In another compilation of studies, PAE was associated with significantly fewer overall adverse events but similar rates of severe side effects, as well as and shorter hospitalisation times (mean difference = -1.94 days), but longer procedural times (mean difference = 51.43 min) [529].

Another SR and meta-analysis of four studies (506 patients) comparing PAE and TURP found no significant difference in the post-operative complication rate between TURP and PAE [530].

According to a Cochrane network meta-analysis, PAE may also result in a large reduction in major adverse events than TURP, but the confidence interval includes substantial benefits and harms [523]. In addition, uncertainty exists about the effect of PAE on retreatment compared to TURP at follow-up from 12 to 60 months.

A meta-analysis did reveal major uncertainty as to how major adverse events compare between TURP and PAE [525].

Concerning sexual adverse events, the mean differences in IIEF-5 score were not significantly different between TURP and PAE in a meta-analysis [529]. Another meta-analysis of two RCTs detected no difference in retrograde ejaculation rates [415]. Post-operative erectile function measured by IIEF-5 was in favour of PAE with mean difference in change of 2.56 points. In another updated meta-analysis PAE was consistently associated with lower sexual dysfunction than TURP (OR 0.24) [531]. According to a Cochrane network meta-analysis, uncertainty exists on the effect of PAE on erectile function and ejaculatory function as compared to TURP [523].

Concerns still exist about non-target embolisation, reported in earlier studies [532]; however, more recent studies report less incidents [522, 533]. A SR of 22 studies reporting radiation exposure during PAE, with a twenty-fold range of exposures, estimated that the median risk for a 66-year-old patient of a cancer related death was 0.117%, equivalent to a reduced life expectancy of 5.4 days. Radiation exposure therefore should be part of the counselling for patients considered for PAE. These data suggest there is potential for significant radiation reduction in some centres using appropriate protocols [534].

Practical considerations: A multidisciplinary team approach of urologists and radiologists is mandatory and patient selection should be done by urologists and interventional radiologists. The investigation of patients with LUTS to indicate suitability for invasive techniques should be performed by urologists only. This technically demanding procedure should only be done by an interventional radiologist with specific mentored training and expertise in PAE [535]. There are data suggesting that larger prostates have a higher chance of a superior outcome with PAE in post hoc analysis of RCTs, but larger trials are required to clarify the most suitable patients for PAE [515, 536].

Further data with medium- and long-term follow-up are still required and comparison with other minimally invasive techniques would be valuable. However, current evidence of safety and efficacy of PAE appears adequate to support the use of this procedure for men with moderate-to-severe LUTS provided proper arrangements for consent and audit are in place; therefore, a recommendation has been given, but PAE remains under investigation.

Summary of evidence	**LE**
Prostatic artery embolisation is less effective than TURP at improving symptoms and urodynamic parameters such as flow rate.	1a
Procedural time is longer for PAE compared to TURP, but blood loss, catheterisation and hospitalisation time are in favour of PAE.	1b

Recommendations	Strength rating
Offer prostatic artery embolisation (PAE)* to men with moderate-to-severe LUTS who wish to consider minimally invasive treatment options and accept less optimal outcomes compared with transurethral resection of the prostate.	Weak
Perform PAE only in units where the work up and follow-up is performed by urologists working collaboratively with trained interventional radiologists for the identification of PAE suitable patients.	Strong

** PAE remains under investigation*

5.3.4.3 Alternative ablative techniques under investigation

5.3.4.3.1 Convective water vapour energy (WAVE) ablation: The Rezum system

Mechanism of action: The Rezum system uses radiofrequency power to create thermal energy in the form of water vapour, which in turn deposits the stored thermal energy when the steam phase shifts to the liquid phase upon cell contact. The steam disperses through the tissue interstices and releases stored thermal energy onto prostatic tissue effecting cell necrosis. The procedure can be performed in an office-based setting. Usually, one to three injections are needed for each lateral lobe and one to two injections may be delivered into the median lobe (depending on the prostate size).

Efficacy: In a multicentre RCT, 197 men were enrolled and randomised in a 2:1 ratio to treatment with water vapour energy ablation or sham treatment [537]. At three months relief of symptoms, (measured by a change in IPSS and Q_{max}) were significantly improved and maintained after WAVE therapy compared to the sham arm, although only the active treatment arm was followed up to twelve months. No relevant impact was observed on PVR. Quality of life outcome was significantly improved with a meaningful treatment response of 52% at twelve months. Further validated objective outcome measures such as BPH impact index (BPHII), Overactive Bladder Questionnaire Short Form for OAB bother, and impact on QoL and ICS Male Item Short Form Survey for male incontinence demonstrated improvements of symptoms at three months follow-up with sustained efficacy throughout the study period of twelve months. The reported two-year results in the Rezum cohort arm of the same study and the recently reported five-year results confirmed durability of the clinical outcome after convective water vapour energy ablation [538]. Surgical retreatment rate was 4.4% over five year. A Cochrane review found no studies comparing convective radiofrequency water vapour thermal therapy to any other active treatment form, such as TURP [539]. Another network meta-analysis included outcome data at three to six months follow-up and concluded that improvement of IPSS was similarly high after TURP and WAVE [540]. Objective outcomes (PVR and Q_{max}) were improved to the greatest extent after TURP, with moderate improvement after WAVE.

Tolerability and safety: Safety profile was favourable with adverse events documented to be mild-to-moderate and resolving rapidly. Preservation of erectile and ejaculatory function after convective water vapour thermal therapy was demonstrated utilising validated outcome instruments such as IIEF and Male Sexual Health Questionnaire-Ejaculation Disorder Questionnaire [537].

Practical considerations: There are two SRs of the Rezum cohort studies. One concludes that Rezum provides improvement in BPH symptoms that exceeds established minimal clinically important difference thresholds, preserves sexual function, and is associated with low surgical retreatment rates over four years. Therefore, suggesting that it may be a valuable addition to the urological armamentarium to treat LUTS in men with BPH [541]. The other, a Cochrane review reported that the certainty of evidence ranged from moderate to very low, with study limitations and imprecision being the most common reasons for down-grading of the evidence [539]. A Cochrane network meta-analysis reported uncertainty about the effects of Rezum on retreatment compared to sham treatment at three months follow-up and the certainty of evidence is very low [523]. Randomised controlled trials against a reference technique are needed to confirm the first promising clinical results and to evaluate mid- and long-term efficacy and safety of water vapour energy treatment.

5.3.5 ***Non-ablative techniques***

5.3.5.1 Prostatic urethral lift

Mechanism of action: Prostatic urethral lift (PUL) is a minimally invasive approach under local or general anaesthesia. Encroaching lateral lobes are compressed by small permanent suture-based implants delivered under cystoscopic guidance resulting in an opening of the prostatic urethra leaving a continuous anterior channel through the prostatic fossa.

Efficacy: Several reports have shown that PUL achieves a significant improvement in IPSS (-39% to -52%), Q_{max} (+32% to +59%) and QoL (-48% to -53%) [542-547]. In a meta-analysis of retrospective and prospective trials, pooled estimates showed an overall improvement following PUL, including IPSS, Q_{max}, and QoL [547]. A Cochrane review of the sham RCT and the RCT against TURP concluded that PUL appears less effective than TURP in improving urological symptoms (IPSS, Q_{max}) in both short- and long term, while QoL outcomes may be similar [548]. Prostatic urethral lift was evaluated vs. sham in a multicentre study with one [544] three [549] and five [550] years follow-up of the treated cohort. Improvements in IPSS, QoL, and Q_{max} were durable with improvement rates of 36%, 50%, and 44% at 60-month follow-up, respectively [550]. A network meta-analysis included outcome data at three to six months follow-up and concluded that improvement of IPSS was similarly high after TURP and PUL. Objective outcomes (PVR and Q_{max}) were improved to the greatest extent after TURP, with less improvement after PUL [540].

A retrospective observational study of 1,413 consecutive patients from North America and Australia split patients into those still voiding (Group A) and those in retention (Group B). The results from Group A were comparable to the results from the clinical trials and of the 165 patients in Group B 69% were catheter free after five days, 83% after one month and 89% by study end [551].

Tolerability and safety: The most common complications reported post-operatively included haematuria (16-63%), dysuria (25-58%), pelvic pain (5-17.9%), urgency (7.1-10%), transient incontinence (3.6-16%), and UTI (2.9-11%) [544, 547, 549, 550]. Most symptoms were mild-to-moderate in severity and resolved within two to four weeks after the procedure. In an RCT comparing PUL to TURP, surgical recovery was measured using a validated instrument. They found that recovery from PUL is more rapid and more extensive in the first three to six months [552]. A SR and meta-analysis found that sexual function with regard to erectile and ejaculatory function remained stable or improved slightly during the 24-month follow-up [547, 548, 553].
In an RCT comparing PUL to TURP, PUL resulted in superior quality of recovery and ejaculatory function preservation. Ejaculatory function and bother scores did not change significantly in either treatment arm [552].

A SR of surgical re-interventions of eleven studies (2,016 patients), among which TURP/laser (51%), repeat PUL (32.7%) and device explant (19.6%) were most common, revealed an annual rate of surgical re-intervention of 6% per year (95% CI: 3.0-8.9) [554]. The re-treatment rate was 13.6% over five years in a multicentre study comparing PUL vs. sham [550].

Practical considerations: There are only limited data on treating patients with an obstructed/protruding middle lobe [555]. The effectiveness in large prostate glands has not been shown yet. Long-term studies are needed to evaluate the duration of the effect in comparison to other techniques.

Summary of evidence	**LE**
Prostatic urethral lift improves IPSS, Q_{max} and QoL; these improvements are inferior to TURP at 24 months.	1b
Prostatic urethral lift has a low incidence of sexual side effects.	1b
Patients should be informed that long-term effects, including the risk of retreatment, have not been evaluated.	4

Recommendation	**Strength rating**
Offer Prostatic urethral lift (Urolift®) to men with LUTS interested in preserving ejaculatory function, with prostates < 70 mL and no middle lobe.	Strong

5.3.5.2 Intra-prostatic injections
Mechanism of action: Various substances have been injected directly into the prostate in order to improve LUTS including Botulinum toxin-A (BoNT-A), fexapotide triflutate (NX-1207) and PRX302. The primary mechanism of action of BoNT-A is through the inhibition of neurotransmitter release from cholinergic neurons [556]. The mechanisms of action for the injectables NX-1207 and PRX302 are not completely understood, but experimental data suggest apoptosis-induced atrophy of the prostate with both drugs [556].

Efficacy: A SR and meta-analysis showed no differences in efficacy of BoNT-A compared with placebo and concluded that there is no evidence of clinical benefit in medical practice [557]. The positive results from Phase II-studies have not been confirmed in Phase III-trials for PRX302 [558, 559]. Fexapotide triflutate (NX-1207) was evaluated in two multicentre placebo controlled double-blind randomised parallel group trials including a total

of 995 patients with a mean follow-up of 3.6 years, IPSS change from baseline was significantly higher and AUR rate was significantly reduced in the treatment arm. The authors concluded that NX-1207 is an effective transrectal injectable for long-term treatment for LUTS and that treated patients have reduced need for further intervention [560].

Tolerability and Safety: A SR and meta-analysis showed low incidence rates of procedure-related adverse events [557]. Two multicentre placebo controlled double-blind randomised parallel group trials with long-term follow-up evaluating NX-1207 detected no significant safety differences between the study arms [560].

Practical considerations: Positive results for PRX 302 from Phase II-studies have not been confirmed in Phase III-trials yet. Nevertheless, an RCT evaluating transperineal intraprostatic BoNT-A injection vs. TURP concluded that IPSS significantly decreased in all patients, with a non-significant difference between the arms and that the BoNT-A injection significantly maintained erectile function compared to TURP at twelve months [561]. More high-quality evidence against reference techniques is needed.

Summary of evidence	**LE**
Results from clinical trials have shown no clinical benefits for BoNT-A compared to placebo for the management of LUTS due to BPO.	1a
Results from clinical trials have shown clinical benefits for NX-1207 compared to placebo for the management of LUTS due to BPO.	1b

Recommendation	**Strength rating**
Do not offer intraprostatic Botulinum toxin-A injection treatment to patients with male LUTS.	Strong

5.3.5.3 Non-ablative techniques under investigation

5.3.5.3.1 (i)TIND

Mechanism of action: The iTIND is a nitinol device composed of three elongated struts and an anchoring leaflet. Under direct visualisation iTIND is deployed inside the prostate in expanded configuration. The intended mode of action is to compress obstructive tissue by the expanded device, thereby exerting radial force leading to ischaemic necrosis resulting in a Turner Warwick like incision. The iTIND device is left in position for five days and removed in an outpatient setting by standard urethroscopy.

Efficacy: A single-arm, prospective study of 32 patients with a three-year follow-up was conducted to evaluate feasibility and safety of the procedure [562]. The change from baseline in IPSS, QoL and Q_{max} was significant at every follow-up [563]. In a multicenter RCT, 175 men were randomised 2:1 between iTIND and sham procedures. Patients were assessed at baseline, 45 days, three, and twelve months postoperatively. A total of 78.6% of patients in the iTIND arm showed a reduction of ≥ 3 points in IPSS, vs. 60% of patients in the control arm at three months. At twelve months follow-up, the iTIND group reported a mean decrease of 9.25 in IPSS, of 1.9-point in QoL and a 3.52mL/s increase in Q_{max} compared to baseline [564]. In a prospective multicentre study, 81 patients were enrolled and treated with a second generation iTIND device. At twelve-month follow-up, mean IPSS decreased from 22.5 to 8.8 and Q_{max} at one month increased from 7.3 to 14.7 ml/s at twelve months [565].

Another network meta-analysis included outcome data at three to six months follow-up and concluded that IPSS improvement was lower after iTIND compared to TURP. Improvements in objective outcomes (PVR and Q_{max}) were also lower after iTIND [540].

Tolerability and safety: The device were reported as well tolerated by all patients. Four early complications (12.5%) were recorded, including one case of urinary retention (3.1%), one case of transient incontinence due to device displacement (3.1%), and two cases of infection (6.2%). No further complications were recorded during the 36-month follow-up period [563]. In the RCT against sham study adverse events were typically mild and transient, most were Clavien-Dindo grade 1 or 2 with 38.1% in the iTIND arm and 17.5% in the control arm [564]. No new ejaculatory or erectile dysfunction has been reported [564, 565].

In a prospective multicentre study, 81 patients were enrolled and treated with a second generation iTIND device. During the twelve-month period, two patients required medical therapy, two patients required TURP, and ten patients were lost to follow-up [565].

Practical considerations: Randomised controlled trials comparing iTIND to a reference technique are ongoing.

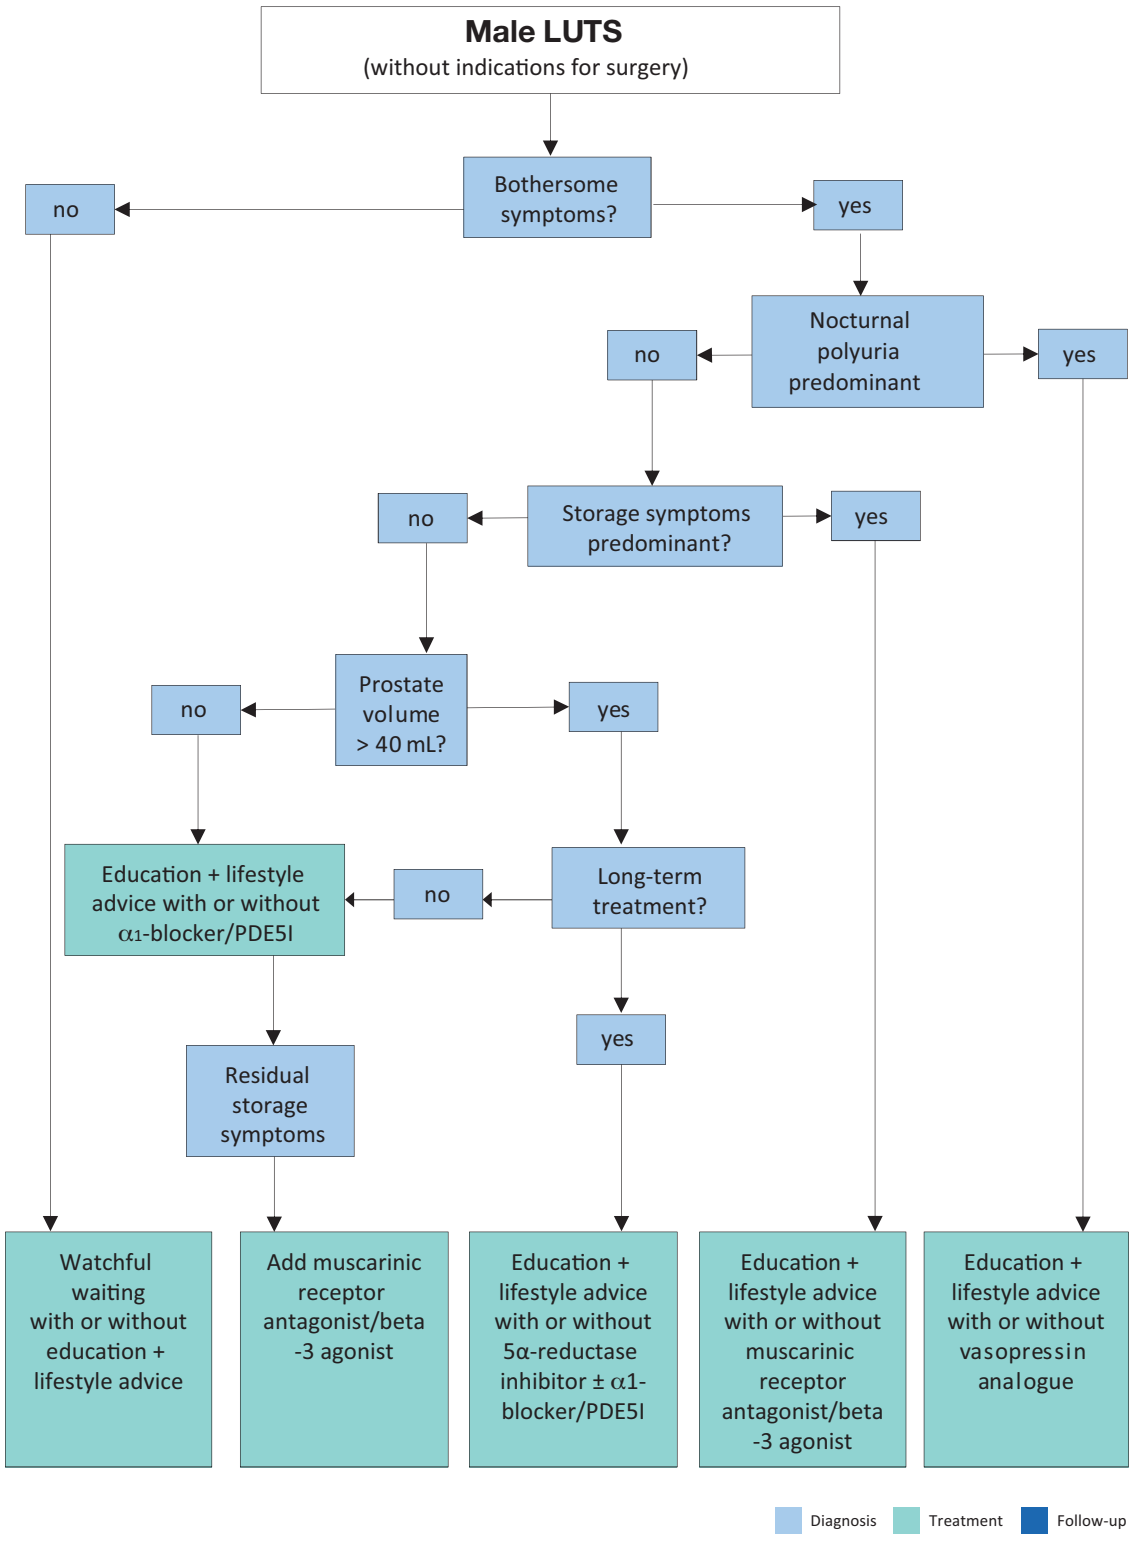
5.4 Patient selection for LUTS/BPO treatment

The choice of treatment depends on the assessed findings of patient evaluation, ability of the treatment to change the findings, treatment preferences of the individual patient, and the expectations to be met in terms of speed of onset, efficacy, side effects, QoL, and disease progression.

Behavioural modifications, with or without medical treatments, are usually the first choice of therapy. Figure 3 provides a flow chart illustrating treatment choice according to evidence-based medicine and patient profiles. Surgical treatment is usually required when patients have experienced recurrent or refractory urinary retention, overflow incontinence, recurrent UTIs, bladder stones or diverticula, treatment-resistant macroscopic haematuria due to BPH/BPE, or dilatation of the upper urinary tract due to BPO, with or without renal insufficiency (absolute operation indications, need for surgery).

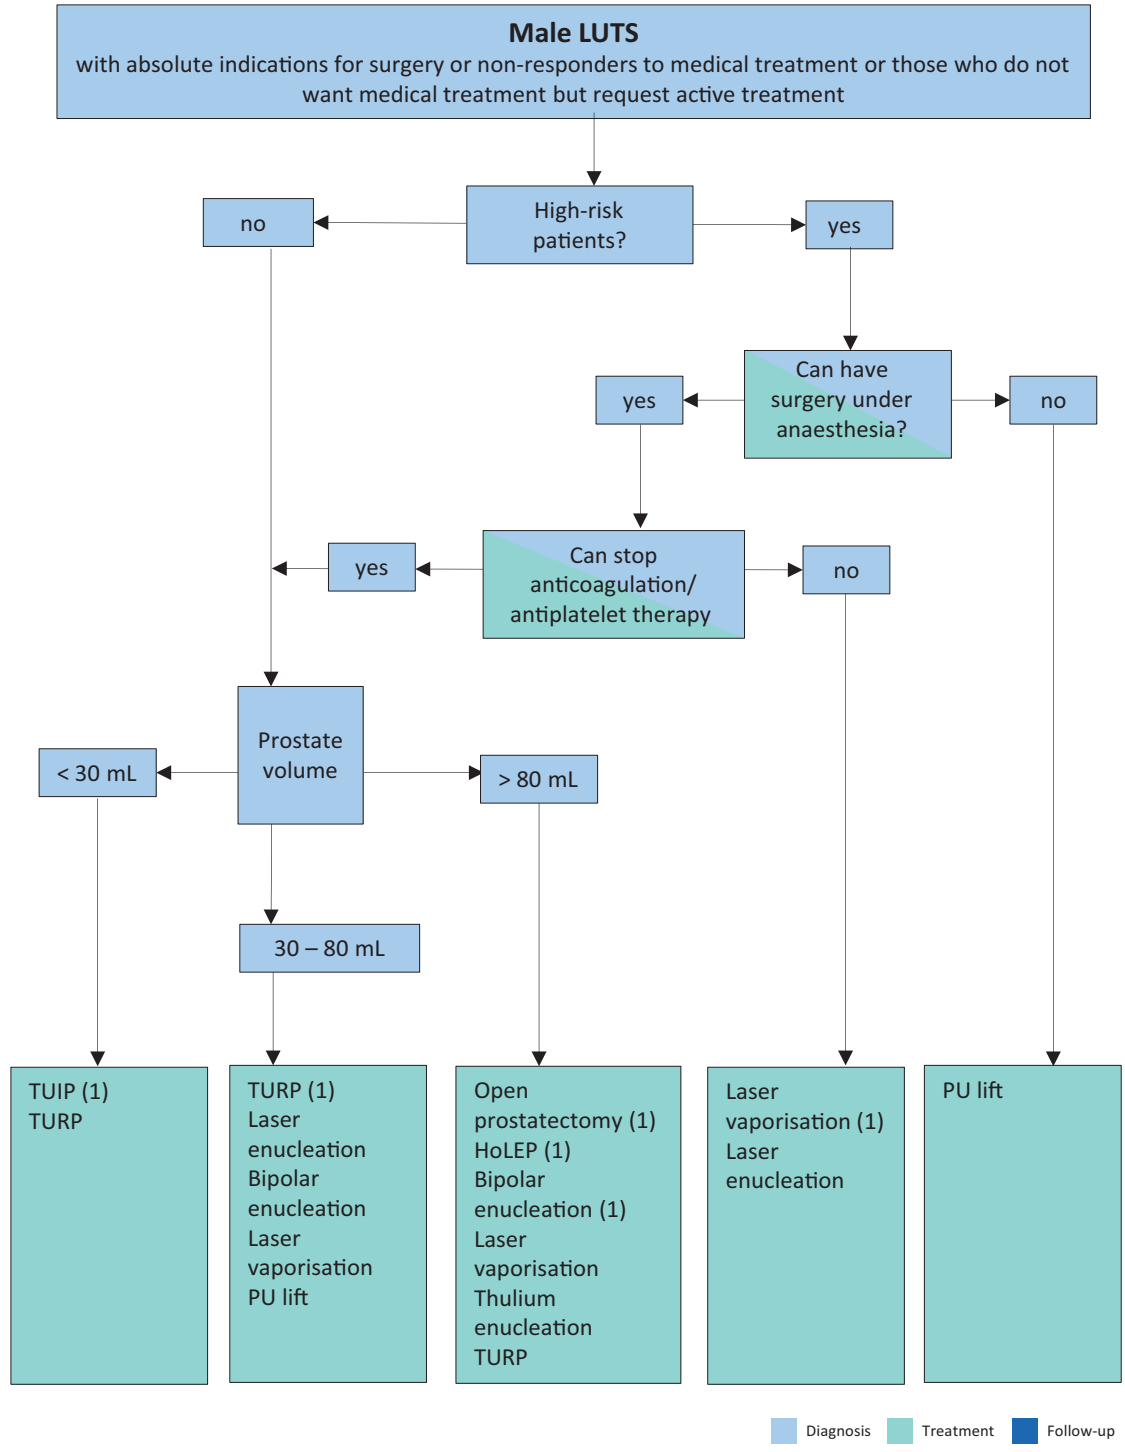
Additionally, surgery is usually needed when patients have not obtained adequate relief from LUTS or PVR using conservative or medical treatments (relative operation indications). The choice of surgical technique depends on prostate size, co-morbidities of the patient, ability to have anaesthesia, patients' preferences, willingness to accept surgery-associated specific side-effects, availability of the surgical armamentarium, and experience of the surgeon with these surgical techniques. An algorithm for surgical approaches according to evidence-based medicine and the patient's profile is provided in Figure 4.

Figure 3: Treatment algorithm of male LUTS using medical and/or conservative treatment options. Treatment decisions depend on results assessed during initial evaluation. Note that patients' preferences may result in different treatment decisions.



PDE5I = phosphodiesterase type 5 inhibitors.

Figure 4: Treatment algorithm of bothersome LUTS refractory to conservative/medical treatment or in cases of absolute operation indications. The flowchart is stratified by the patient's ability to have



(1) Current standard/first choice. The alternative treatments are presented in alphabetical order.
Laser vaporisation includes GreenLight, thulium, and diode laser vaporisation.
Laser enucleation includes holmium and thulium laser enucleation.
HoLEP = holmium laser enucleation; TUIP = transurethral incision of the prostate; TURP = transurethral resection of the prostate; PU = prostatic urethral.

5.5 Management of Nocturia in men with lower urinary tract symptoms

The following section reports a SR of therapy for the management of nocturia in men with LUTS. It also emphasises the need to consider the wide range of possible causes of nocturia [566].

Nocturia has been defined as the complaint of waking at night to void [3]. The ICS Standardisation Steering Committee has introduced the concept of *main sleep period,* defined as "the period from the time of falling asleep to the time of intending to rise for the next "day" [567].

Nocturia reflects the relationship between the amount of urine produced while asleep, and the ability of the bladder to store the urine received. Nocturia can occur as part of lower urinary tract dysfunction (LUTD), such as OAB and chronic pelvic pain syndrome. Nocturia can also occur in association with other forms of LUTD, such as BOO, but here it is debated whether the link is one of causation or simply the co-existence of two common conditions. Crucially, nocturia may have behavioural, sleep disturbance (primary or secondary) or systemic causes unrelated to LUTD (Table 2). Differing causes often co-exist and each has to be considered in all cases. Only where LUTD is contributory should nocturia be termed a LUTS.

Table 2: Categories of nocturia

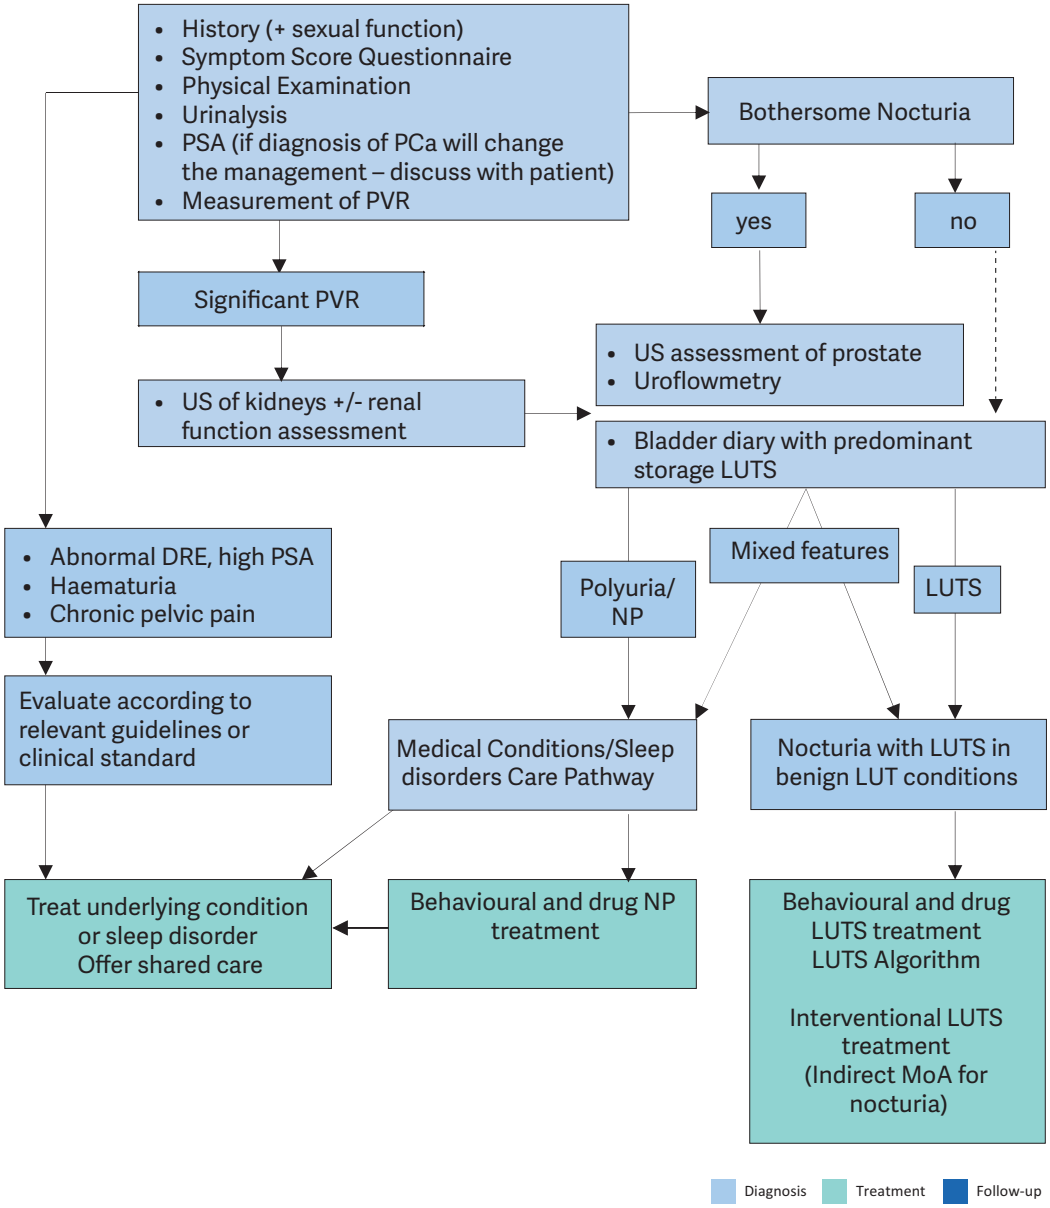
CATEGORY	Disproportionate urine production (at all times, or during sleep)	Low volume of each void (at all times, or overnight)
Behavioural	Inappropriate fluid intake	"Bladder awareness" due to secondary sleep disturbance
Systemic	Water, salt and metabolite output	
Sleep disorder	Variable water and salt output	"Bladder awareness" due to primary sleep disturbance
LUTD		Impaired storage function and increased filling sensation

*5.5.1 **Diagnostic assessment***

Evaluation is outlined in Figure 5;

1. Evaluate for LUTD according to the relevant guidelines. The severity and bother of individual LUTS should be identified with a symptom score, supplemented by directed questioning if needed. A validated bladder diary is mandatory.
2. Review whether behavioural factors affecting fluid balance and sleep are contributing.
3. Review of medical history and medications, including directed evaluation for key conditions, such as renal failure, diabetes mellitus, cardiac failure, and obstructive sleep apnoea. If systemic factors or sleep disorders are potentially important, consider involving appropriate medical expertise (see Figure 6). This is appropriate where a known condition is sub optimally managed, or symptoms and signs suggest an undiagnosed condition.

Figure 5. Evaluation of Nocturia in non-neurogenic Male LUTS.



Assessment must establish whether the patient has polyuria, LUTS, a sleep disorder or a combination. Therapy may be driven by the bother it causes, but non-bothersome nocturia may warrant assessment with a frequency volume chart (indicated by the dotted line) depending on history and clinical examination since potential presence of a serious underlying medical condition must be considered.
FVC = frequency volume chart; DRE = digital rectal examination; NP = nocturnal polyuria; MoA = mechanism of action; PVR = post-void residual; PSA = prostate-specific antigen; US = ultrasound.

*5.5.2 **Medical conditions and sleep disorders Shared Care Pathway***

Causative categories for nocturia comprise [568]:

1. bladder storage problems;
2. 24-hour polyuria (> 40 mL/kg urine output over a 24-hour period);
3. nocturnal polyuria (NP; defined as excessive production of urine during the individual's main sleep period, i.e. nocturnal output exceeding 20% of 24-hour urine output in the young, or 33% of urine output in people > 65 [3]);
4. sleep disorders;
5. mixed aetiology.

Potentially relevant systemic conditions are those which impair physiological fluid balance, including influences on the levels of free water, salt, other solutes, and plasma oncotic pressure; endocrine regulation e.g., by antidiuretic hormone; natriuretic peptides; cardiovascular and autonomic control; renal function; neurological regulation, e.g., circadian regulation of the pineal gland, and renal innervation. As nocturia is commonly referred to the specialty without full insight into cause, the urologist must review the likely mechanisms underlying a presentation with nocturia and instigate review by relevant specialties accordingly. Thus, the managing urologist needs to evaluate nocturia patients in a context where additional medical expertise is available (Table 3). They should not proceed along any LUTD management pathway unless a causative link with LUTD is justifiably suspected, and systemic or sleep abnormalities have been considered.

In patients with non-bothersome nocturia, the medical evaluation (history and physical examination) should consider the possibility of early stages of systemic disease, and whether there is possibility of earlier diagnosis or therapy adjustment.

Some important potentially treatable non-urological causes of nocturia include obstructive sleep apnoea, congestive cardiac failure, poorly controlled diabetes mellitus and medications (e.g., diuretics, or lithium).

Table 3: Shared care pathway for nocturia, highlighting the need to manage potentially complex patients using relevant expertise for the causative factors

UROLOGICAL CONTRIBUTION	SHARED CARE	MEDICAL CONTRIBUTION
Diagnosis of LUTD • Urological/LUTS evaluation • Nocturia symptom scores • Bladder diary		**Diagnosis of conditions causing NP** • Evaluate patient's known conditions • Screening for sleep disorders • Screening for potential causes of polyuria*
Conservative management Behavioural therapy • Fluid/sleep habits advice • Drugs for storage LUTS • Drugs for voiding LUTS • ISC/catherisation • Increased exercise • Leg elevation • Weight loss Interventional therapy • Therapy of refractory storage LUTS • Therapy of refractory voiding LUTS	**Conservative management** • Antidiuretic • Diuretics • Drugs to aid sleep	**Management** • Initiation of therapy for new diagnosis • Optimised therapy of known conditions * Potential causes of polyuria NEPHROLOGICAL DISEASE • Tubular dysfunction • Global renal dysfunction CARDIOVASCULAR DISEASE • Cardiac disease • Vascular disease ENDOCRINE DISEASE • Diabetes insipidus/mellitus • Hormones affecting diuresis/natriuresis NEUROLOGICAL DISEASE • Pituitary and renal innervation • Autonomic dysfunction RESPIRATORY DISEASE • Obstructive sleep apnoea BIOCHEMICAL • Altered blood oncotic pressure

ISC = intermittent self catheterisation

*5.5.3 **Treatment for Nocturia***

5.5.3.1 Antidiuretic therapy

The antidiuretic hormone arginine vasopressin (AVP) plays a key role in body water homeostasis and control of urine production by binding to V2 receptors in the renal collecting ducts. Arginine vasopressin increases water re-absorption and urinary osmolality, so decreasing water excretion and total urine volume. Arginine vasopressin also has V1 receptor mediated vasoconstrictive/hypertensive effects and a very short serum half-life, which makes the hormone unsuitable for treating nocturia/nocturnal polyuria.

Desmopressin is a synthetic analogue of AVP with high V2 receptor affinity and no relevant V1 receptor affinity. It has been investigated for treating nocturia [569], with specific doses, titrated dosing, differing formulations, and options for route of administration. Most studies have short follow-up. Global interpretation of existing studies is difficult due to the limitations, imprecision, heterogeneity and inconsistencies of the studies.

A SR of randomised or quasi-randomised trials in men with nocturia found that desmopressin may decrease the number of nocturnal voids by -0.46 compared to placebo over short-term follow-up (up to three months); over intermediate-term follow-up (three to twelve months) there was a change of -0.85 in nocturnal voids in a substantial number of participants without increase in major adverse events [570].

Another SR of comparative trials of men with nocturia as the primary presentation and LUTS including nocturia or nocturnal polyuria found that antidiuretic therapy using dose titration was more effective than placebo in relation to nocturnal voiding frequency and duration of undisturbed sleep [566]. Adverse events include headache, hyponatremia, insomnia, dry mouth, hypertension, abdominal pain, peripheral edema, and nausea. Three studies evaluating titrated-dose desmopressin in which men were included, reported seven serious adverse events in 530 patients (1.3%), with one death. There were seventeen cases of hyponatraemia (3.2%) and seven of hypertension (1.3%). Headache was reported in 53 (10%) and nausea in fifteen (2.8%) [566]. Hyponatremia is the most important concern, especially in patients > 65 years of age, with potential life-threatening consequences. Baseline values of sodium over 130 mmol/L have been used as inclusion criteria in some research protocols. Assessment of sodium levels must be undertaken at baseline, after initiation of treatment or dose titration and during treatment. Desmopressin is not recommended in high-risk groups [566].

Desmopressin oral disintegrating tablets (ODT) have been studied separately in the sex-specific pivotal trials CS41 and CS40 in patients with nocturia [571, 572]. Almost 87% of included patients had nocturnal polyuria and approximately 48% of the patients were > 65 years. The co-primary endpoints in both trials were change in number of nocturia episodes per night from baseline and at least a 33% decrease in the mean number of nocturnal voids from baseline during three months of treatment. The mean change in nocturia episodes from baseline was greater with desmopressin ODT compared to placebo (difference: women = -0.3 [95% CI: -0.5 to -0.1]; men = -0.4 [95% CI: -0.6 to -0.2]). The 33% responder rate was also greater with desmopressin ODT compared to placebo (women: 78% vs. 62%; men: 67% vs. 50%).

Analysis of three published placebo-controlled trials of desmopressin ODT for nocturia showed that clinically significant hyponatraemia was more frequent in patients aged ≥ 65 years than in those aged < 65 years in all dosage groups, including those receiving the minimum effective dose for desmopressin (11% of men aged ≥ 65 years vs. 0% of men aged < 65 years receiving 50 mcg; 4% of women ≥ 65 aged years vs. 2% of women aged < 65 years receiving 25 mcg). Severe hyponatraemia, defined as ≤ 125 mmol/L serum sodium, was rare, affecting 22 of 1,431 (2%) patients overall [573]. In a cases series including men aged of more than 60 treated with 50 mcg ODT, only 12/80 men had hyponatremia (non-severe) after one week. Hyponatraemia persistence was noted in 4/12 cases after reduction to 25 mcg [574].

Low-dose desmopressin ODT has been approved in Europe, Canada and Australia for the treatment of nocturia with ≥ 2 episodes in gender-specific low doses 50 mcg for men and 25 mcg for women; however, it initially failed to receive FDA approval, with the FDA citing uncertain benefit relative to risks as the reason. Following resubmission to the FDA in June 2018 desmopressin acetate sublingual tablet, 50 mcg for men and 25 mcg for women, was approved for the treatment of nocturia due to nocturnal polyuria in adults who awaken at least two times per night to void with a boxed warning for hyponatremia.

Desmopressin acetate nasal spray is a new low-dose formulation of desmopressin and differs from other types of desmopressin formulation due to its bioavailability and route of administration. Desmopressin acetate nasal spray has been investigated in two RCTs including men and women with nocturia (over two episodes per night) and a mean age of 66 years. The average benefit of treatment relative to placebo was statistically significant but low, -0.3 and -0.2 for the 1.5 mcg and 0.75 mcg doses of desmopressin acetate, respectively. The number of patients with a reduction of more than 50% of nocturia episodes was 48.5% and 37.9%, respectively compared with 30% in the placebo group [575]. The reported adverse event rate of the studies was rather low, and the risk of hyponatremia was 1.2% and 0.9% for desmopressin acetate 1.5 mcg and 0.75 mcg, respectively. Desmopressin acetate nasal spray was approved by the FDA in 2017 for the treatment of nocturia due to nocturnal polyuria, but it is not available in Europe.

Practical considerations: A complete medical assessment should be made, to exclude potentially non-urological underlying causes, e.g., sleep apnoea, before prescribing desmopressin in men with nocturia due to nocturnal polyuria. The optimal dose differs between patients, in men < 65 years desmopressin treatment should be initiated at a low dose (0.1 mg/day) and may be gradually increased up to a dosage of 0.4 mg/day every week until maximum efficacy is reached. Desmopressin is taken once daily before sleeping. Patients should avoid drinking fluids at least one hour before and for eight hours after dosing. Low dose desmopressin may be prescribed in patients > 65 years. In men ≥ 65 years or older, low dose desmopressin should not be used if the serum sodium concentration is below normal: all patients should be monitored for hyponatraemia. Urologists

should be cautious when prescribing low-dose desmopressin in patients under-represented in trials (e.g., patients > 75 years) who may have an increased risk of hyponatraemia.

5.5.3.2 Medications to treat LUTD

Where LUTD is diagnosed and considered causative of nocturia, relevant medications for storage (and voiding) LUTS may be considered. Applicable medications include; selective α1-adrenergic antagonists [576], antimuscarinics [577-579], 5-ARIs [580] and PDE5Is [581]. However, effect size of these medications is generally small, or not significantly different from placebo when used to treat nocturia [566]. Data on OAB medications (antimuscarinics, beta-3 agonist) generally had a female-predominant population. No studies specifically addressing the impact of OAB medications on nocturia in men were identified [566]. Benefits with combination therapies were not consistently observed.

5.5.3.3 Other medications

Agents to promote sleep [582], diuretics [583], non-steroidal anti-inflammatory agents (NSAIDs) [584] and phytotherapy [585] were reported as being associated with response or QoL improvement [566]. Effect size of these medications in nocturia is generally small, or not significantly different from placebo. Larger responses have been reported for some medications, but larger scale confirmatory RCTs are lacking. One RCT has compared melatonin+tamsulosin compared to placebo+tamsulosin and found no difference on IPSS change [586]. Agents to promote sleep do not appear to reduce nocturnal voiding frequency but may help patients return to sleep.

Summary of evidence	**LE**
No clinical trial of pathophysiology-directed primary therapy has been undertaken.	4
No robust clinical trial of behavioural therapy as primary intervention has been undertaken.	4
Antidiuretic therapy reduces nocturnal voiding frequency in men with baseline severity of two or more voids per night.	1b
There is an increased risk of hyponatremia in patients 65 years of age or older under antidiuretic therapy.	1b
Antidiuretic therapy increases duration of undisturbed sleep.	1b
Alpha 1-blocker use is associated with improvements in undisturbed sleep duration and nocturnal voiding frequency, which are generally of only marginal clinical significance.	2
Antimuscarinic medications can reduce night-time urinary urgency severity, but the reduction in overall nocturia frequency is small or non-significant.	2
Antimuscarinic medications are associated with higher incidence of dry mouth compared with placebo.	2
5α-reductase inhibitors reduce nocturia severity in men with baseline nocturia severity of two or more voids per night.	2
A trial of timed diuretic therapy may be offered to men with nocturia due to nocturnal polyuria. Screening for hyponatraemia should be undertaken at baseline and during treatment.	1b

Recommendations	**Strength rating**
Treat underlying causes of nocturia, including behavioural, systemic condition(s), sleep disorders, lower urinary tract dysfunction, or a combination of factors.	Weak
Discuss behavioural changes with the patient to reduce nocturnal urine volume and episodes of nocturia and improve sleep quality.	Weak
Offer desmopressin to decrease nocturia due to nocturnal polyuria in men < 65 years of age.	Weak
Offer low dose desmopressin for men > 65 years of age with nocturia at least twice per night due to nocturnal polyuria.	Weak
Screen for hyponatraemia at baseline, day three and day seven, one month after initiating therapy and periodically during treatment. Measure serum sodium more frequently in patients > 65 years of age and in patients at increased risk of hyponatraemia.	Strong
Discuss with the patient the potential clinical benefit relative to the associated risks from the use of desmopressin, especially in men > 65 years of age.	Strong
Offer α1-adrenergic antagonists for treating nocturia in men who have nocturia associated with LUTS.	Weak

Offer antimuscarinic drugs for treating nocturia in men who have nocturia associated with overactive bladder.	Weak
Offer 5α-reductase inhibitors for treating nocturia in men who have nocturia associated with LUTS and an enlarged prostate (> 40 mL).	Weak
Do not offer phosphodiesterase type 5 inhibitors for the treatment of nocturia.	Weak

5.6 Management of male urinary incontinence

The aim of the following section is to provide evidence-based recommendations for the management of male UI.

5.6.1 Epidemiology and Pathophysiology

Urinary incontinence is defined as an unintentional loss of urine and is reported to have a prevalence of 11% in men aged 60 to 64 years old to 31% in men ≥ 85 years and to affect up to 32% of men with LUTS [587-589]. Urinary incontinence can be further classified into three types: SUI, UUI and mixed urinary incontinence (MUI). Overflow UI, post-micturition dribble, nocturnal enuresis, and total incontinence are specific forms of UI that are outside the current scope of this guideline. An overview of the epidemiology and pathophysiology of male UI is given in table 4.

Table 4: Epidemiology and pathophysiology overview of male UI [589-593].

Type	Definition	Causes and associated factors	Pathophysiology	Clinical presentation
Stress UI: prevalence < 10%	Urine loss during movement, on effort or in general during increased abdominal pressure.	• Benign Prostatic Obstruction surgery • Neurogenic condition • Pelvic surgery • Radical prostatectomy • Urethral surgery	Sphincter deficiency	**Symptoms:** UI during physical activity, exercises, e.g. during coughing, sneezing,no leakage during sleep, no nocturnal enuresis **Voiding diary/Pad test:** with activity **Cough stress test:** leakage can coincide with coughing
Urgency UI: prevalence 40-80%	Urine loss concomitant or immediately following an urgency episode.	• Ageing process • Anorectal dysfunction/GI disorders • Behavioural factors (fluid intake and caffeine consumption) • BPO • Idiopathic • Intrinsic bladder diseases (cystitis, fibrosis, interstitial cystitis) • Metabolic syndrome [594] • Neurogenic conditions • UTIs	• Detrusor overactivity (neurogenic or not) • Urothelial stimulation • Increased afferent signalling • Others (pelvic organ cross talk, bladder wall ischemia etc.)	**Symptoms:** usually associated with, increased frequency and nocturia **Voiding diary:** urgency, frequency and nocturia, incontinence

Mixed UI: prevalence 10-30%	Any combination of SUI and UUI.	Causes of both SIU and UUI	Combination of SUI and UUI	**Symptoms:** UI on effort and with a sense of urgency **Voiding diary:** variable **Cough stress test:** may show leakage with coughing

BPO = benign prostatic obstruction; GI = gastrointestinal; SUI = stress urinary incontinence; UI = urinary incontinence; UTI = urinary tract infection; UUI = urgency urinary incontinence

*5.6.2 **Diagnostic Evaluation***

Medical history and physical examination of males with UI is the same as for male LUTS (Figure 2) and should allow UI to be categorised into SUI, UUI or MUI and to identify other types of UI (overflow UI, nocturnal enuresis), or those who need rapid referral to an appropriate specialist (e.g. pelvic diseases, neurological conditions).

Specific validated questionnaires, such as the ICIQ-UI-SF, can help to quantify UI severity; however, a detailed description of the different urinary symptoms questionnaires and PROMs is beyond the scope of this guideline. For more information on available questionnaires see the 7th International Consultation on Incontinence (ICI) review on patient reported outcomes assessment [595].

Voiding diaries are a standardised method of measuring symptom severity, including frequency and extent of UI episodes, voided volume and 24-hour or nocturnal total urine volume [43].

Pad tests can be used to quantify severity of UI and to monitor patient's response to treatment although the usefulness of these tests in differentiating between the different types of incontinence or predicting outcome of treatment is uncertain. Despite this, early post-operative testing with pad tests may predict future continence in men after radical prostatectomy [596, 597].

Urodynamic testing

Urodynamic studies allows for an objective characterisation of the type of UI and the identification of additional storage and/or voiding dysfunctions [598]

UDS in patients with UI following BPO surgery

Sphincter weakness is the most common finding in incontinent men after BPO surgery. However, data coming mostly from case series and reviews, show that besides sphincter incompetence, other LUTD, assessed via UDS, play an incident role in post BPO surgery incontinence.

Urodynamics has been performed in a retrospective study on 125 patients with incontinence after surgery for BPO. Sphincter insufficiency was the most common finding. However, also decreased detrusor compliance and DO have emerged as a cause of incontinence on urodynamic examination. Interestingly, both impaired detrusor contraction and DO alone were responsible for UI in 4 to 14% of patients [599].

UDS in patients with UI following radical prostatectomy

Also in this case, UI, is mainly due to sphincter deficiency. However, a SR on urodynamic findings in UI patients following radical prostatectomy, showed that while intrinsic urethral sphincter deficiency was reported as the sole cause of UI following radical prostatectomy in 8-71% of cases, it was variably associated with detrusor dysfunction in 0–88% of cases. In details, sphincter weakness was associated with DO in 0–100% of patients, with reduced bladder compliance in 18-58%, and with both DO and reduced bladder compliance in 4-64%. Interestingly, incontinent patients who did not complain of sphincter impairment showed detrusor dysfunction as follows: DO in 0-4%, reduced bladder compliance in 1-12%, DO plus impairment of bladder compliance in 1-7% [600].

UDS in patients with storage symptoms

In a retrospective evaluation of 668 urodynamic studies involving men with symptoms of urgency with or without urgency UI, DO was documented in 258 patients (38.6%) and 293 patients (43.9%) had evidence of BOO during PFS. The symptom UI correlated with the presence of DO [601].

The aforementioned evidence emphasises how urodynamic examination serves to clarify the origin of incontinence and the presence of any other associated LUTS. Unfortunately, the level of the evidence for the impact of UDS in the evaluation/management/outcome prediction of male patients with UI remains low [602] and does not allow us to produce any recommendations.

Therefore, UDS should be considered in selected patients with UI or persistent/*de novo* LUTS/UI after surgery, mainly when invasive treatments are considered [603].

Post-void residual volume measurement can be applied with caution to men with non-neurogenic UI, as the prevalence, severity, and clinical application of PVR in men with UI is uncertain. However, a post-void residual measurement helps to distinguish overflow incontinence from other UI types [604].

Urethrocystoscopy can be performed in selected patients to exclude urethral or bladder neck strictures. Some tests have been proposed to evaluate any sphincter function e.g., repositioning tests but with poor reliability. The examination of the bladder helps to exclude tumours, stones, diverticula, that may exacerbate UI [605].

Imaging (US, MRI, CT scan) can improve the understanding of the anatomical and functional abnormalities that may cause UI and thus help its management [606].

Urinalysis: Reagent strip ('dipstick') urinalysis may indicate UTI, proteinuria, haematuria, or glycosuria, requiring further tests as recommended according to other EAU Guidelines, e.g., Guidelines on urinary tract cancers and urological infections [48-51].

Summary of evidence	**LE**
Validated specific symptom score questionnaires and voiding diaries assist in the screening for and categorisation of UI.	3
Pad test can be used to quantify the presence and severity of UI, as well as a patient's response to treatment.	3
There is limited evidence that urodynamics and PVR affect treatment choice in men with uncomplicated UI.	3

Recommendation	**Strength rating**
Take a complete medical history including symptoms and co-morbidities, medications, and a focused physical examination in the evaluation of men with urinary incontinence (UI).	Strong
Use a validated symptom score questionnaire, bladder diary and pad-test to assess UI.	Strong
Measure post-void residual in the assessment of UI.	Strong
Perform urodynamics for UI when considering invasive treatment.	Weak

*5.6.3 **Conservative treatment***

5.6.3.1 Simple clinical interventions

5.6.3.1.1 Lifestyle interventions

Examples of lifestyle factors that may be associated with UI include obesity, smoking, level of physical activity and diet. Modification of these factors may improve UI, but most of the evidence for these interventions come from studies with predominately female study populations. However, as many of these interventions are now generalised public health measures their recommendation is in line with general medical practice [607-609]. Current evidence does not allow to adequately personalise lifestyle interventions according to the type of UI.

Modification of fluid intake, particularly restriction, is a strategy commonly used by people with UI to relieve symptoms. Advice on fluid intake given by healthcare professionals should be based on 24-hour fluid intake and urine output measurements. From a general health point of view, it should be advised that fluid intake should be sufficient to avoid thirst and that low or high 24-hour urine output should be investigated [607, 610, 611]. A cross-sectional population survey found no statistical association between caffeine intake and UI [612]. Conversely, an RCT showed that reduction of caffeine intake, associated with behavioural therapy, resulted in reduced urgency but not UI compared to behavioural therapy alone [613].

5.6.3.1.2 Treatment of co-morbidities

Urinary incontinence, especially in the elderly, has been associated with multiple co-morbid conditions [614]. It is possible that improvement of associated disease may reduce the severity of urinary symptoms. However, this is often difficult to assess as patients frequently suffer from more than one condition. Interventions may be combined and individualised, making it impossible to decide which alteration in an underlying disease has affected a patient's UI.

In patients with existing UI, particularly the elderly, it may be difficult or impossible to distinguish between the effects of medication, co-morbidities or ageing on UI. Although changing drug regimens for underlying diseases may be considered as a possible early intervention, there is limited evidence of benefit [615]. There is also a risk that stopping or altering medication may result in greater harm than benefit.

5.6.3.1.3 Constipation

One RCT, with a majority female population, found that a multimodal intervention in elderly patients, involving assisted toileting, fluid intake, etc., reduced the occurrence of UI and constipation, while behavioural therapy appeared to improve both [616]. However, there is no evidence to show whether treating constipation improves UI, although both constipation and UI appear to be improved by certain behavioural interventions.

5.6.3.1.4 Containment

Containment includes the use of absorbent pads, urinary catheters, external collection devices and penile clamps. A SR of six RCTs comparing different types of pads found that pads filled with super absorbent material were better than standard pads [617]. For men with light UI, a randomised crossover trial found that a leaf-shaped type of pad was preferred to rectangular pads [618].

A Cochrane review compared different types of long-term indwelling catheters and found no evidence that one catheter material or type of catheter was superior to another [619]. A SR of non-randomised studies found no differences in UTI outcome or Upper Urinary Tract (UUT) changes between use of suprapubic or urethral catheter drainage; however, patients with suprapubic catheters were less likely to have urethral complications [620]. For people using intermittent catheterisation, a Cochrane review found no evidence that one type of catheter or regimen of catheterisation was better than another [621].

An RCT in 56 men with post-prostatectomy incontinence (PPI) compared sheath drainage system, body-worn urinal, penile clamp, and absorbent pads. It was found that the three devices and absorbent pads have different strengths and limitations that make them more (or less) suitable for particular activities. Most men prefer to use a combination of devices and pads to meet their lifestyle needs. Hinge-type penile clamp was good for short vigorous activities as it was the most secure, least likely to leak and most discreet, although almost all men described it as uncomfortable or painful [622].

Summary of evidence	**LE**
There is limited evidence that lifestyle interventions e.g., weight reduction, smoking cessation or diet modification improves UI in males.	3
There is limited evidence that improving co-morbidities or changing drug regimens for underlying disease improves UI in males.	3
Pads and/or penile sheaths are palliative options for management of both SUI and UUI.	1b

Recommendations	**Strength rating**
Offer lifestyle advice that may improve urinary incontinence (UI) to patients; however, patients should be informed that the evidence for these interventions is lacking.	Weak
Review any medication associated with the development or worsening of UI.	Weak
Use pads and/or penile sheaths as a palliative option for the management of UI.	Weak

5.6.3.2 Behavioural and Physical therapies

Behavioural and physical therapies encompass all treatments which require a form of self-motivated personal retraining by the patient and include techniques that are used to augment this effect. Usually in clinical practice, these will be introduced as part of a package of care including lifestyle changes, patient education, and possibly cognitive therapy as well. Further details for behavioural treatments are outlined in section 5.1.2 of these guidelines.

5.6.3.2.1 Prompted or timed voiding

With prompted voiding, carers rather than the patient, initiate the decision to void. Two SRs confirmed a positive effect on continence outcomes for prompted voiding in comparison to standard care [623, 624]. Timed voiding is defined as fixed, pre-determined, time intervals between toileting, applicable for those with or without cognitive impairment. A Cochrane review of timed voiding, included two RCTs, found inconsistent improvement in continence compared with standard care in cognitively impaired adults [625].

5.6.3.2.2 Bladder training

Bladder training goals are to correct faulty habit patterns of frequent urination, improve control over bladder urgency, prolong voiding intervals, increase bladder capacity, reduce incontinent episodes, and restore patient confidence in controlling bladder function. The ideal form or intensity of a BT program for UI is unclear. It is also unclear whether BT can prevent the development of UI. The addition of BT to anticholinergic therapy did not improve UI compared to antimuscarinics alone but it did improve frequency and nocturia [626]. In seven RCTs, BT was compared to drug therapy alone, and showed only a benefit for oxybutynin in cure and improvement of UI [626].

5.6.3.2.3 Pelvic floor muscle training

A 2015 Cochrane review concluded that there was no overall benefit at twelve months post-surgery for men who received post-operative pelvic floor muscle training (PFMT) for the treatment of PPI and that the benefits of conservative treatment of PPI remain uncertain [627]. However, a subsequent SR and meta-analysis showed that PFMT either alone or in combination with biofeedback and/or electrical stimulation was effective for treating PPI, significantly reducing the time to continence recovery [628]. A further meta-analysis demonstrated that the addition of guided programs using biofeedback and/or pelvic floor muscle electric stimulation (PFES) significantly improved continence recovery rates at one- and three-month intervals post-surgery compared to PFMT alone [629].

Pelvic floor muscle training as soon as possible after surgery (I.e., between seven and ten days after the withdrawal of the urethral catheter) [630].

An RCT demonstrated that even a single-session of pre-operative PFMT with biofeedback from a dedicated pelvic floor physiotherapist, has beneficial effects on post-prostatectomy UI in the short term after surgery and is effective in improving LUTS related QoL in the long term [631, 632]

Two subsequent SRs in patients who underwent robotic-assisted radical prostatectomy demonstrated that the addition of PFMT to the post-operative management plan shorten the time to continence recovery [633, 634].

Two RCTs have shown that written instructions alone offer similar levels of improvement to supervised PFMT [635, 636]. One RCT found that PFMT was helpful in men who had been incontinent for at least one year after prostatectomy, and who had had no previous therapy [637].

One RCT compared PFMT to no treatment in men undergoing TURP. There was no demonstrable difference in the incidence of post-operative incontinence up to twelve months [638]. On the other hand, an RCT in men who underwent HoLEP, demonstrated that PFMT when started pre-operatively promoted early recovery of continence [639].

Other RCTs demonstrated that like PFMT, increased pelvic floor muscle strength and quicker return to continence may be achieved with the Pilates method [640], the oscillating rod [641], a combination of biofeedback with electrostimulation [642] and whole-body vibration training [643]. Furthermore, quicker return to continence and improved QoL may be achieved, even with extended and continuing nursing care [644]

5.6.3.2.4 Electrical stimulation

The majority of evidence on electrical stimulation refers to women with SUI and many are generally low quality, with a variety of stimulation parameters, treatment regimens and outcome parameters [638].

An RCT of 70 PPI men receiving surface or intra-anal electrostimulation reported a significant reduction in UI in terms of grams of urine loss and a significant improvement in QoL from baseline, but no statistically significant difference between treatment arms [645].

A Cochrane review of six RCTs on electrical stimulation in men with UI concluded that there was some evidence that electrical stimulation enhanced the effect of PFMT in the short-term but not after six months. Electrical stimulation was also more effective than sham stimulation at six, but not twelve months; however, there were more adverse effects including pain and discomfort with electrical stimulation [646].

Electromagnetic stimulation has been promoted as a treatment for UI, but only weak evidence of the short- and long-term effects has been reported in SRs [647, 648].

A more recent SR found insufficient evidence to suggest that electrical stimulation is beneficial for male patients with post-prostatectomy UI [649].

5.6.3.2.5 Posterior tibial nerve stimulation

Posterior tibial nerve stimulation (PTNS) has been studied as a treatment of UI, especially UUI. Electrical stimulation of the posterior tibial nerve delivers electrical stimuli to the sacral micturition centre via the S2-S4 sacral nerve plexus. Stimulation is done either percutaneously using a fine, 34-G, needle, inserted just above the medial aspect of the ankle (P-PTNS) or transcutaneously using surface electrodes (T-PTNS). Percutaneous-PTNS treatment cycles typically consist of twelve weekly treatments of 30 minutes and T-PTNS treatment cycles typically consists of self-administered, twenty-minute daily sessions, after adequate education.

A female-predominant sham controlled RCT, assessed the effectiveness of PTNS in OAB population. There were 22.8% and 20% males in the treatment and sham arms, respectively [650]. Overactive bladder symptoms improved significantly in 54.5% of patients in the PTNS arm compared to 20.9% in the sham arm. A non-inferiority RCT comparing T-PTNS compared to P-PTNS, reported significant improvements in daytime frequency, urgency and UUI episodes without significant difference between treatment arms after twelve weeks of therapy [651]. A SR on T-PTNS in idiopathic and neurogenic female-predominant (males < 10%) population, reported significant improvement in OAB symptoms in 48-93% of patients and cure of UUI episodes in 25-45% [652].

For PTNS, mild pain and discomfort at the puncture site is the most common adverse event [653]. Small haematomas, swelling, leg tingling and vasovagal reaction to needle placement have also been reported [650]. Treatment adherence is generally high at 89.7% [651]. Contra-indications include a cardiac pacemaker and skin disease at the site of stimulation.

There is some evidence that PTNS may benefit male patients with OAB, but due to too insufficient data, no recommendation on PTNS in males can be made at this time. However, considering the safety of this therapy, it can be offered to male patients as an alternative option prior to more invasive treatments.

Summary of evidence	**LE**
Prompted voiding, either alone or as part of a behavioural modification programme, improves continence in elderly, care-dependent people.	1b
The combination of bladder training with antimuscarinic drugs does not result in greater improvement of UI but may improve frequency and nocturia.	1b
There is conflicting evidence on whether the addition of BT, electrostimulation or biofeedback increases the effectiveness of PFMT alone.	1b
Pre-operative PFMT does not confer additional benefit to men undergoing radical prostatectomy.	1b
Electrical stimulation may add benefit to PFMT up to six months.	2
There is limited evidence for the effectiveness of PTNS in male population.	2
There is no evidence that PTNS cures UUI in male population.	2

Recommendations	**Strength rating**
Implement prompted voiding for patients with urinary incontinence (UI) where appropriate.	Strong
Offer bladder training as a complementary treatment for UI.	Weak
Offer pelvic floor muscle training alone or in combination with biofeedback and/or electrostimulation to men undergoing radical prostatectomy to speed recovery from UI.	Weak

5.6.4 ***Pharmacological management***

5.6.4.1 Drugs for urgency urinary incontinence

Muscarinic receptor antagonists [654-657] and beta-3 agonist [308-310, 658-661] are currently the first-line pharmacological treatments for UUI. The mechanism of action, efficacy, and safety and tolerability profiles of both classes of drugs are discussed in detail in sections 5.2.3 and 5.2.4, respectively.

5.6.4.2 Drugs for stress urinary incontinence

A SR of eight studies evaluating the efficacy of duloxetine in postprostatectomy SUI reported that duloxetine resulted in a mean dry rate of 58% (25–89%), mean improvement in pad number of 61% (12–100%), and mean improvement in one-hour pad weight of 68% (53–90%), at short-term follow-up (mean one to nine months) [662]. However, mean adverse event rates were high, and treatment was discontinued in 38% of cases. The most common adverse events included: fatigue, somnolence and nausea and were reported in 18% of patients [662]. The overall certainty of the evidence was low due to study heterogeneity and methodological limitations. Further RCTs with long-term follow-up are required. Duloxetine is currently prescribed in an off-label setting.

Summary of evidence	**LE**
Antimuscarinic monotherapy can significantly improve urgency, UUI, and increased daytime frequency.	1b
Mirabegron is superior to placebo and as efficacious as antimuscarinics for improvement of UUI.	1b
Duloxetine led to a short-term improvement in post-prostatectomy SUI symptoms and QoL improvement; however, a significant proportion of men discontinued treatment.	1b

Recommendations	**Strength rating**
Offer antimuscarinic drugs or mirabegron to adults with urgency urinary incontinence who failed conservative treatment.	Strong
Offer duloxetine to men with stress urinary incontinence.	Weak
Inform patients about the possible adverse events of duloxetine and that its use is off label for this indication in Europe.	Strong

5.6.5 ***Surgical treatment for stress urinary incontinence***

5.6.5.1 Bulking agents in men

Mechanism of Action: Urethral bulking agents work by adding bulk and improving the coaptation of a damaged sphincter zone. They represent a treatment option for men with either small volume leak or for those unfit for more invasive treatment options [663].

Efficacy: A Cochrane review on surgical treatment of PPI identified only one RCT that fulfilled the inclusion criteria. This trial randomised 45 men to Macroplastique injection or artificial urinary sphincter (AUS) implantation and compared their outcomes at 48 months [663]. Significant improvement was reported in both groups for men with minimal incontinence, but in men with total incontinence there was a significant difference in continence rates favouring AUS implantation (72% vs. 23%) [664]. A SR of eight studies (n=142) in men using Macroplastique, Opsys, Durasphere and Urolastic, showed short-term improvement, and reported dry rates between 0-83% [663]. A propensity score-matched analysis of 104 men with PPI, compared submucosal injection of Macroplastique to transobturator male sling (TiLOOP male) [665]. At twelve months follow-up, the reported failure free rates were 15.4% and 76.9%, the daily use of 0-1 pads was 21.2% and 67.3% and the satisfaction rate was 3.8% and 71.2%, respectively. Several small cohort studies of several different bulking agents have not shown any benefit.

A narrative review including data from 25 articles, reports a success rate with all bulking procedures of 54.3%, with 37.5% of symptoms improvement and almost 30% of dryness [666].

In a SR and meta-analysis, three studies addressed bulking agents. Two of them, involving a total of 384 participants, showed a pooled short-term cure rate of 26.1% and a single study on 68 subjects reported a 10.3% long term cure rate. Short- and long-term reoperation rates were not described [667].

Tolerability and safety: Bulking agent associated dysuria and haematuria are frequently reported to be transient and self-resolving [663]. The risk of urinary retention requiring clean intermittent self-catheterisation (CISC), or long-term catheter use is minimal [668]. However, they may provoke allergic reactions [669] and carry a potential risk for migration [670] to proximal and distal lymph nodes [671]. Overall, post procedural urinary retention rates range between 3-17%, with rare need for temporary catheterisation, while post-operatory UTIs ranged from 6-7% [666].

Practical considerations: Bulking agents have shown low cure rates but remain an option for men unfit for more invasive treatment options.

Summary of evidence	LE
There is very limited evidence that bulking agents are effective for the treatment of PPI.	2

Recommendation	Strength rating
Do not offer bulking agents to men with post-prostatectomy incontinence.	Weak

5.6.5.2 Male Slings

Male slings have been introduced to treat mild-to-moderate PPI. However, the definitions of mild and moderate UI are unclear. The majority of studies define cure as 'no pad use' or 'one security pad per 24-hours'. Some authors used more strict criteria such as 'urine loss of less than 2 g per 24-hour pad test' [672].

5.6.5.2.1 Non-adjustable slings

Mechanism of Action: Non-adjustable male slings are positioned under the urethra and fixed by a retropubic or transobturator approach. The tension is adjusted during the surgery, and it cannot be re-adjusted post-operatively. Synthetic slings restore continence in males either by urethral compression and/or by repositioning the bulb of urethra [673, 674].

Efficacy: A SR and meta-analysis involving 33 prospective cohorts and one RCT comparing sling to AUS, reported that both options are effective in improving UI and QoL [675]. Following sling insertion, the overall cure rate was 60% (95% CI: 0.51-0.67) and 56% (95% CI: 0.44-0.68) for sling and AUS respectively. The 24-hour pad use was -3.33 (95% CI: -4.33 to -2.34) and -3.75 (95% CI: -4.56 to -2.93) for slings and AUS, respectively. Similar findings were reported by a network meta-analysis that showed comparable efficacy between slings and AUS [676].

The MASTER Trial, a non-inferiority RCT comparing the outcomes of continence surgery in men with bothersome urodynamic SUI, using a very strict definition of UI after prostate surgery, reported that at twelve-months continence rates were 87% for male sling vs. 84.2% for AUS (95% CI: -11.6-4.6, P_{NI}=0.003]), confirming non-inferiority [677]. The subgroup analysis suggested that male sling is inferior to AUS for men with greater incontinence at baseline (pad weight > 250g); however, the difference did not reach statistical significance.

For the re-positioning sling (AdVance™ and AdVanceXP©), a mean subjective cure rate of 49% (8.6 - 73.7%) after mean follow-up of three years has been reported for 136 patients [678]. A prospective multicentre cohort study, with 60-month follow-up, in men with AdVanceXP demonstrated a constant continence outcome over time with a 57.6% cure rate, 25.4% improvement rate and 16.9% failure rate. These findings were verified in an additional study which reported cure rates of 66.7% and 71.7%, improvement rates of 26.5% and 24.4% and failures rates of 6.9% and 13.3% at 24- and 48-months, respectively [679]. A retrospective comparative study showed that both options are safe and effective in the treatment of male SUI [680].

With the transobturator compressive I-Stop TOMS male sling, 38% of men were dry at twelve months, but this reduced to 23% and 15% after four and five years, respectively [681].

Tolerability and safety: A SR and meta-analysis of 1,170 men with SUI and male sling, reported that the predictors of failure are prior radiation, severity of incontinence and previous surgeries [682]. Pelvic radiotherapy has also been reported in other studies as a negative prognostic factor [683]. A comparison among radiated vs. non-radiated men who had AdVanceXP reported a greater degree of post-operative improvement in the non-radiated group (49.6% vs. 22.2%) as well as greater satisfaction rates (95% vs. 64%) [684]. The most common complication with male slings is pain and local superficial wound infection [685]. Chronic pain has been observed in 1.3% of men who had non-adjustable slings [685]. Post-operative transient voiding dysfunction occurred in 4.3-10.3%, mostly as *de novo* urgency or urinary retention, while erosions and chronic pain were uncommon (0-0.4%), as was explantation [103, 678, 679, 686, 687].

Practical considerations: Fixed male slings are considered safe and improve continence, but their efficacy is limited in men with severe incontinence or previous radiotherapy.

5.6.5.2.2 Adjustable slings in males

Mechanism of Action: Adjustable slings in males are those for which the tension of the sling can be adjusted post-operatively. Three main systems have been used in men: the Remeex® system [688], the Argus® system [689] and the ATOMS® system [690].

Efficacy: There is one small RCT for adjustable slings in males [691]. Most studies consist of prospective or retrospective case series, with variable follow-up and different definitions of success [688, 690-694]. A SR reported objective cure rates varying between 17-92% after adjustable sling implantation [685].

For the Remeex® system, only two studies, with conflicting findings, have been published. One study followed nineteen patients for nearly seven years and reported 70% success, with no explants, infections, or erosions [688]. The second study followed fourteen patients for 25 months. Only 36% of patients were satisfied and multiple re-adjustments were needed. Mechanical failure was reported in 21% [692].

Data on the Argus® system has been reported for 404 men, but only few series have reported on more than 40 patients, with the longest follow-up being 35-months. Success rates varied between 17-93%, with a mean of 73.0% reporting subjective cure [693, 694]. A head-to-head comparison between the two Argus systems reported similar efficacy outcomes at 44 months, but Argus T was associated with a higher inguinal pain and explantation rate [695]. A small study of 22 men with PPI randomised to AdVance or Argus T reported superior 24-hour pad test results and of patient satisfaction levels for Argus T at eighteen-months follow-up [691].

A SR of the ATOMS system reported the pooled evidence from 1,393 patients with a 67% dryness, 90% improvement after adjustment and 16.4% complication rate [690]. The expulsion rate was 5.75%. Another SR and meta-analysis with 3,059 patients reported that ATOMS was superior to ProACT in mean dryness rate (68% vs. 55%), overall improvement (91% vs. 80%), satisfaction rate (87% vs. 56%), mean number of filing adjustments (2.4 vs. 3.5) and post-operative pad use per day (1.1 vs. 2.1) [696].

Tolerability and Safety: The most frequent complications in adjustable male slings are pain, erosions, and infections [685]. Pain at the implant site was usually only temporary, but chronic pain has been reported in 1.5% of men [693, 694]. The number of implants requiring re-adjustment is reported between 8-38.6% [694, 697, 698]. Explantation rates range from 10-15.8% and erosion rate is estimated around 10% [682]. The most common reasons for explantation are device infection (4.1-8%), erosions (4-12%), and urethral perforations (2.7-16%). A SR reported a device explantation rate of 5% vs. 25% and a major complication rate of 4.2% vs. 10.4% for ATOMS and ProACT, respectively [696].

Practical considerations: There is no evidence that adjustability offers additional benefit as RCTs are lacking; therefore, no recommendation can be made at this time. Explantation rate seems superior to fixed male sling based on external comparisons.

5.6.5.2.3 Autologous slings

The strategy of intra-operative placement of an autologous vas deferens sling below the vesico-urethral anastomosis during robotic-assisted radical prostatectomy (RARP) has been explored with the intention to improve early return of continence. Two RCTs [699, 700] showed an advantage of sling vs. no sling at one-month follow-up, and another study [701] showed an advantage of a 6-branch vs. a 2-branch sling at one month follow-up. However, a larger RCT (n=195), showed that continence rate and near-continence rate were similar between groups at six months with 66% vs. 65% and 86% vs. 88%, respectively [702].

Summary of evidence	**LE**
There is limited short-, medium- and long-term evidence that fixed transobturator male slings cure or improve PPI in patients with mild-to-moderate incontinence.	1b
Men with severe incontinence, previous radiotherapy or transurethral surgery may have less benefit from fixed transobturator male slings.	2
There is limited evidence that adjustable male slings can cure or improve SUI in men.	3
There is no evidence that adjustability offers additional benefit over other types of slings.	3
Explantation rate with adjustable male slings seems superior to fixed male sling based on external comparisons.	4
There is no evidence that intra-operative placement of an autologous sling during RARP improves return of continence at six months.	1b

Recommendations	Strength rating
Offer non-adjustable transobturator slings to men with mild-to-moderate* post-prostatectomy incontinence.	Weak
Inform men that severe incontinence, prior pelvic radiotherapy or transurethral surgery may worsen the outcome of non-adjustable male sling surgery.	Weak

** The terms "mild" and "moderate" PPI remain undefined.*

5.6.5.3 Compression devices in males

5.6.5.3.1 Artificial urinary sphincter

Mechanism of action: The AUS is the standard treatment for moderate-to-severe male SUI. The AMS 800 three component system with inflatable cuff, control pump and pressure regulating balloon is the device with the longest follow-up and the greatest level of evidence [703]. The ZSI 375 is a two-component device, inflatable cuff, and control pump, allowing an easier implantation process [704]. Other AUS devices have been launched e.g., the Victo and Br-SL-AS 904 systems but robust evidence regarding their efficacy and safety is pending [705].

Efficacy A meta-analysis of 33 cohort studies and one RCT, reported significant improvement after AUS implantation in overall cure rates (56%) and reductions in pad used per 24-hours (-3.75) [675]. Several observational studies reported on functional outcomes after AMS 800. Social continence rates (0-1 pads used daily) ranged from 55-76.8% [706-708]. A 77.2% continence rate and 89.5% subjective satisfaction rate have been reported after a median follow-up of > fifteen years in 57 men who had undergone AUS placement [709]. A prospective cohort study of 40 patients with a mean follow-up of 53 months, showed that from all urodynamic parameters only low bladder compliance had a negative impact on outcome [710].

However, another retrospective study showed that no urodynamic factors adversely altered the outcome of AUS implantation [711].

Some multicentre studies have confirmed older statements that surgeon's experience and higher surgical volume is associated with better outcomes and a lower revision rate after AUS implantation [712, 713].

The data regarding ZSI 375 is limited. A retrospective, non-randomised trial across several centres in Europe, reported an 84.4% success rate (19.3% dry rate and 65.1% improved 0-1 pads per day) after 43 months [704]. A 72% success rate was reported at seven years follow-up for 45 patients who underwent placement of the ZSI 375 device in France [714].

A retrospective study on 168 patients receiving AUS (AMS 800 AUS system) placements carried out by a single surgeon from 2008 to 2016 at a high-volume academic institution evaluated the causes of AUS failure at a median follow-up from initial placement of 2.7 year. Overall, 63 patients (37.5%) experienced AUS failure requiring device explant/revision. Pressure-regulating balloon malfunction, cuff malfunction, pump malfunction, urethral atrophy, urethral erosion, and infection occurred in 36.5%, 7.9%, 6.3%, 22.2%, 19.0% and 12.7% of all AUS failures, respectively. History of previous pelvic radiotherapy, urethral stricture, urethral sling placement and coronary artery disease were independent predictors of all-cause AUS failure [715].

A retrospective review of all cases of AUS implantation performed between 2005 and 2020 in sixteen different French centres including patients with primary implantation whose indication was moderate to severe SUI after radical prostatectomy (n= 417) or BPO surgery (n=50) found similar social continence rates (zero or one pad per day) at three months between the groups (79% vs. 72%) [716].

Tolerability and safety: Artificial urinary sphincter complications include device infection/erosion (8.5%), mechanical failure (6.2%) and urethral atrophy (7.9%) [717]. In multivariate analysis, radiation therapy was independently associated with risk of urethral atrophy, as were older age and a longer time interval between prostate cancer treatment and AUS surgery [708]. Urethral erosion is associated with previous irradiation and penoscrotal approach [718]. The reported revision rates at three years for any reason were 10-29.1% [706, 718-720]. The risk of urethral erosion after ZSI 375 AUS is 8.2-13.3% and risk of mechanical failure is 2.2-2.5% [704].

A retrospective database comparison found significantly higher complication rates in patients have been reported to be significantly higher in patients undergoing AUS implantation due to UI following BPO surgery compared to patients with post-prostatectomy UI (8% vs. 18%, p=0.044). The same was found for the Clavien-Dindo type 2 complication rate (20.6% vs. 44.4%, p=0.026) [716].

Practical Considerations: Artificial urinary sphincter is efficacious and improves the QoL of men with PPI. To minimise complications, it is advised to refer patients to specialised centres experienced in AUS implementation. Men considering insertion of an AUS should be fully informed that the success of the intervention relies on their ability to operate the pump. Treating physicians should keep in mind that operating the AUS may become difficult in men who develop cognitive impairment or lose manual dexterity. Artificial urinary sphincter has a limited lifespan and 'maintenance' re-operations are common in the long-term. These re-interventions should not be classified as complications [703].

5.6.5.3.2 Non-circumferential compression device (ProACT®)

Mechanism of action: The ProACT® system consists of two devices. Each device includes the balloon, the bi-lumen tubing, and the volume-adjustment port. The devices are introduced by a trocar via two small perineal incisions and are placed under fluoroscopic guidance on each side of the bladder neck, close to the vesico-urethral anastomotic site. The balloons can be filled, and their volume can be adjusted post-operatively using a hypodermic needle injected through the intra-scrotal port.

Efficacy: A SR and meta-analysis of nineteen studies including 1,264 patients reported a 60.2% dry rate, significant reduction in number of pads used per day (-3.1) and greatly improved QoL scores for ProACT® [721]; however, the level of heterogeneity among the included studies was high. A comparison between ATOMS and ProACT®, showed that the former is associated with higher improvement and satisfaction rates and fewer complications [696]. A quasi-randomised trial comparing ProACT® with bone-anchored male slings found that both resulted in similar improvements in SUI (68% vs. 65%, respectively) [722]. A questionnaire study showed that 50% of patients were still significantly bothered by persistent incontinence following ProACT® [723]. A subgroup analysis of radiotherapy patients reported worst outcomes as compared to patients not receiving radiotherapy (46% vs. 68% success rate) as well as a higher percentage of urethral erosion for ProACT® [724].

Tolerability and safety: The most common intra-operative complication during ProACT® implantation is perforation of the bladder and/or urethra. A meta-analysis estimated a perforation rate of 5.3% [721]. The estimated overall revision rate is 22.2%, and the main causes are erosion (3.8%), device leaking (4.1%) and migration (6.5%) [721]. Other prospective series have shown that adverse events were frequent, leading to an explantation rate of 11-58% [722, 723, 725-727].

Practical Considerations: ProACT® has a satisfactory rate of success and seems to be a reasonable alternative for the treatment of male UI; however, it is associated with high complication rates.

Summary of evidence	**LE**
Primary AUS implantation is effective for cure of SUI in men.	1b
Prior pelvic radiotherapy is likely to have a negative impact on the outcomes of AUS implantation.	3
The non-circumferential compression device (ProACT®) is effective for treatment of PPI SUI; however, it is associated with a high failure and complication rate leading to frequent explantation and particularly after pelvic radiation therapy.	2b
The rate of explantation of the AUS due to infection or erosion remains high (up to 24% in some series).	3
Explantation rate with adjustable male slings seems superior to fixed male sling based on external comparisons	4

Recommendations	**Strength rating**
Offer artificial urinary sphincter (AUS) to men with moderate-to-severe stress urinary incontinence.	Strong
Implantation of AUS or ProACT© for men should only be offered in expert centres.	Weak
Warn men receiving AUS or ProACT© that, although cure can be achieved there is a high risk of complications, mechanical failure, and the need for explantation.	Strong
Do not offer non-circumferential compression device (ProACT©) to men who have had pelvic radiotherapy.	Weak

5.6.6 *Surgical treatment for urgency urinary incontinence*

5.6.6.1 *Bladder wall injection of botulinum Toxin-A*

Mechanism of action: The primary mechanism of action of BoNT-A is through the inhibition of neurotransmitter release from cholinergic neurons [556]. OnabotulinumtoxinA (onabotA; BOTOX®) 100 U is licenced in Europe to treat OAB with persistent or refractory non-neurogenic UUI in adults [728, 729].

Efficacy: An RCT of OAB-wet patients whose symptoms were not adequately managed with anticholinergics and who receive either bladder wall injections of onabotA (100 U) or saline reported a 50% reduction in UUI episodes/day whilst the number of micturitions/day reduced by more than two in patients receiving onabotA [730]. A total of 22.9% of the patients in the onabotA arm were fully dry, vs. 6.5% in the saline arm.

A SR and meta-analysis comparing the efficacy of onabotA, mirabegron and anticholinergics in adults with idiopathic OAB reported that patients who received onabotA (100U) achieved greater reduction in UUI episodes, surgery, micturition frequency and the highest odds of achieving dryness as well as >50% reduction from baseline UUI episodes per day [731].

A randomised, placebo-controlled pilot study, assessing the effect of onabotA for the treatment of refractory OAB symptoms after prostatectomy reported significantly improved QoL and ICIQ scores and improvements in daily frequency in patients receiving onabotA compared to placebo [732]. A retrospective trial assessed onabotA efficacy in 65 non-obstructed men with refractory OAB and reported significant improvement in UDI-6 score (-4.2) and IIQ-7 (-6.0) scores, compared to baseline [733].

In a retrospective, single-centre cohort study of onabotA treatment for OAB in 120 patients lead to lower CISC rates in male patients after prior de-obstructive surgery than in surgery-naïve patients (28.6% CISC in the group without prior surgery, 7.5% in the TURP subgroup, and 4.2% in the radical prostatectomy subgroup) [734].

A phase IIIb trial randomised solifenacin-naive patients (10% males) with refractory OAB to onabotA, solifenacin or placebo, and showed that patients receiving onabotA had significantly greater changes in UUI episodes (-3.19) compared to solifenacin (-2.6) and placebo (-1.33) [735].

A network meta-analysis (male population range 9.8-40.2%) which compared onabotA to mirabegron demonstrated that onabotA was associated with improved outcomes in frequency episodes per day (-0.43,[-1.22-0.37]) and in UUI episodes per day (-0.46, [-1.46-0.53]) [736].

Tolerability and safety: Urinary retention and UTIs are the two most common adverse events after onabotA injection. Other reported adverse events include haematuria, dysuria and post-treatment pain [737]. Compared to mirabegron, onabotA is associated with higher risk for UTI and treatment emergent adverse events [736]. A retrospective analysis compared the use of CISC after onabotA injection, among men who had previous prostatectomy vs. those without prior surgery [734]. A 7.5% catheterisation rate after TURP, 4.2% rate after radical prostatectomy and 28.6% rate in men without prior prostate surgery was reported.

Practical Considerations: BoNT-A injections is a recommended treatment option for men with refractory UUI. Despite the lack of a universally accepted injection protocol, gender specific studies and absence of studies in BPO patients, BoNT-A seems superior to medical therapy. It is associated with, higher UTIs and urinary retention risk coupled with the need for repeated injections. A dedicated series in male population, focused on treatment persistence, has shown a high discontinuation rate (68.8%) [738]. Patients treated for OAB with onabotA treatment that have not undergone prior de-obstruction are more likely to develop retention and subsequent CISC.

Summary of evidence	**LE**
A single treatment session of onabotA (100 U) injected in the bladder wall is more effective than placebo at curing and improving UUI/OAB symptoms and QoL.	1b
There is no evidence that repeated injections of onabotA have reduced efficacy, but discontinuation rates are high.	3
There is an increased risk of urinary retention and UTI with onabotA injections.	2

Recommendations	Strength rating
Offer bladder wall injections of onabotulinumtoxinA (100 U) to patients with overactive bladder/urgency urinary incontinence refractory to medical therapy.	Weak
Warn patients of the limited duration of response, risk of urinary tract infection and the possible prolonged need for clean intermittent self-catheterisation (ensure that they are willing and able to do so).	Strong

5.6.6.2 Sacral nerve stimulation (neuromodulation)

Mechanism of action: Sacral neuromodulation (SNM) delivers low amplitude electrical impulses to the sacral nerve roots via an electrode implanted adjacent to the third sacral nerve root and connected to an attached pulse generator implanted in the buttock. It works by modulating neural activity thus stabilising bladder electrical activity through an unknown mechanism. It is a two-stage process: in the first stage, a tined lead electrode is placed percutaneously near the S3 (or if not found, near the S4) root and linked to an external stimulator to assess the response. If symptoms reduced more than 50%, patients are candidates for the second stage which is the full implant.

Efficacy: Several trials assess the clinical effectiveness of SNM. All RCTs suffer from the limitation that patients and assessors cannot be blinded to the treatment allocation since all recruited subjects had to respond to a test phase before randomisation. In addition, the percentage of male population in these trials is around 10%. A meta-analysis compared the effectiveness of SNM to onabotA and reported no significant difference in successfully treated cases at six-month follow-up (RR 0.93; 95% CI: 0.63-1.39) [739].

Tolerability and safety: Main complications after SNM are pain at the implant site (13-42%), lead migration (4.0-21%), leg or back pain (3.0-18%) and wound infection (5.7-6.7%). Surgical revision is required in 29-33% of patients due to device malfunction, battery or device replacement or lead migration [740].

Practical Considerations: SNM represents an alternative to onabotA in patients with refractory OAB, as it has been shown good success rates and an acceptable safety profile.

Summary of evidence	LE
Sacral nerve neuromodulation is effective after failed conservative treatment for OAB/UUI, but no sham controls have been used.	2a

Recommendation	Strength rating
Offer sacral neuromodulation to patients who have urgency urinary incontinence refractory to medical therapy and are willing to undergo surgical treatment.	Weak

5.6.6.3 Cystoplasty/urinary diversion

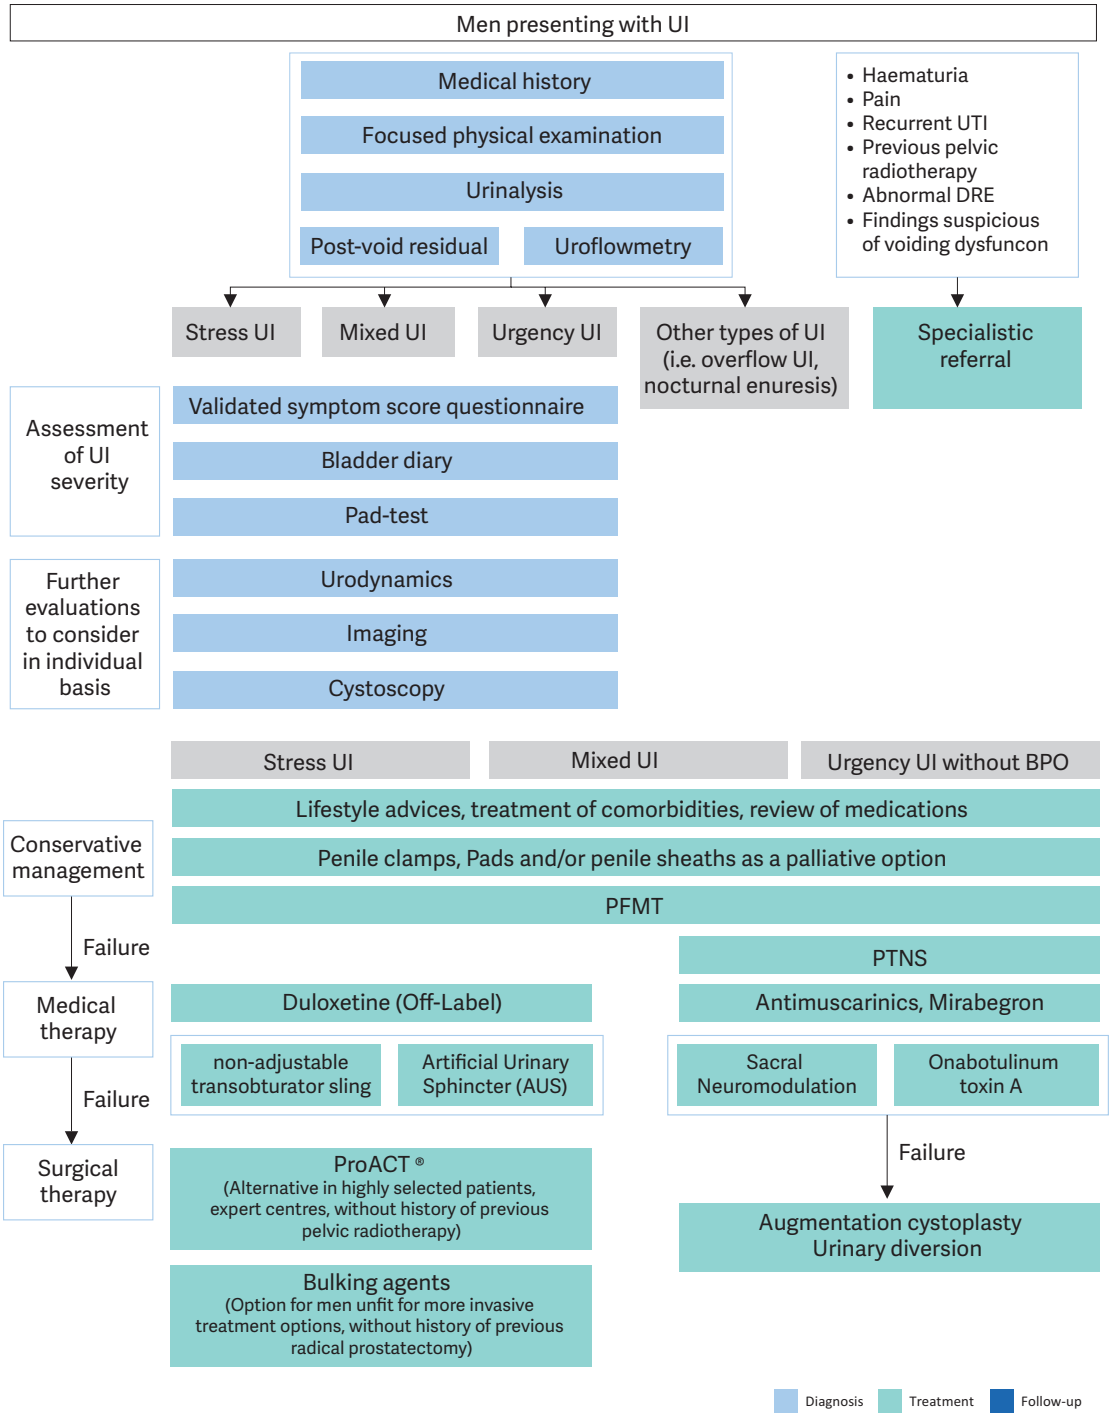
Mechanism of action: Augmentation cystoplasty involves the interposition of a detubularised segment of bowel into the bivalved bladder wall, aiming to increase bladder capacity and reduce OAB related symptoms. Urinary diversion remains a reconstructive option for patients with intractable UUI after multiple pelvic procedures, radiotherapy or pelvic pathology leading to irreversible sphincteric incompetence or fistula formation.

Efficacy: There are no RCTs comparing bladder augmentation to other treatments for patients with refractory OAB/UUI. In a large study with three years follow-up augmentation cystoplasty resulted in a post-operative continence rate of 93% in idiopathic detrusor overactivity patients, 78% in neurogenic overactivity and up to 90% when an AUS was implanted, respectively [741]. The largest case series of bladder augmentation in an idiopathic population included only women [742]. At an average follow up of 75.4 months only 53% were continent and satisfied with the surgery, whereas 25% had occasional leaks and 18% continued to have disabling UUI. A small prospective mixed gender trial reported high patient satisfaction rates with augmentation cystoplasty vs. onabotA therapy [743]. A small study comparing ileal with colonic conduits concluded that there were no differences in the relative risks of UUT infection and uretero-intestinal stenosis [744]. However, there are no studies that have specifically examined these techniques in the treatment of intractable OAB/UUI [744]. Therefore, careful consideration on which operation is undertaken will depend on thorough pre-operative counselling, access to stoma/continence nurses as well as patient factors to allow for fully informed patient choice.

Tolerability and safety: Cystoplasty and urinary diversion are major urological operations. The early post-operative complications include infection, bowel obstruction, bleeding, and cardiorespiratory complications. Long-term complications include metabolic disturbances (hyperchloraemic metabolic acidosis if ileum is used), change in bowel habits, increased mucus production, stone formation, bladder perforation and rarely bladder cancer [745]. Following augmentation cystoplasty or diversion, the majority of patients will depend on self-catheterisation for bladder emptying. Patients with urinary conduit will depend on lifelong urine bags.

Practical Considerations: Augmentation cystoplasty and urinary diversion represent realistic treatment options for men with refractory OAB. However, both options involve a major operation, with a non-negligible long-term complication rate and a lifelong reliance on catheterisation or urine bags.

Figure 6. Evaluation and Management of Urinary Incontinence in non-neurogenic Male LUTS



DRE = digital-rectal examination; UI = urinary incontinence; UTI = urinary tract infection; PFMT = pelvic floor muscle training; PTNS = posterior tibial nerve stimulation; BPO = benign prostatic obstruction.

Summary of evidence	LE
There is limited evidence of the effectiveness of augmentation cystoplasty and urinary diversion in treatment of idiopathic OAB.	3
The need to perform CISC following augmentation cystoplasty is high.	3
Augmentation cystoplasty and urinary diversion are associated with high risks of short- and long-term complications.	3
There is no evidence comparing the efficacy or adverse effects of augmentation cystoplasty to urinary diversion.	3

Recommendations	Strength rating
Offer augmentation cystoplasty to patients with overactive bladder (OAB)/urgency urinary incontinence (UUI) who have failed all other treatment options and are able and willing to perform self-catheterisation.	Weak
Inform patients undergoing augmentation cystoplasty of the high risk of complications; the risk of having to perform clean intermittent self-catheterisation and the need for life-long surveillance.	Strong
Only offer urinary diversion to patients who have failed less invasive therapies for the treatment of OAB/UUI, who will accept a stoma.	Weak

5.7 Management of underactive bladder

5.7.1 *Epidemiology and Pathophysiology*

Various definitions of underactive bladder (UAB) and detrusor underactivity (DU) can be identified in the current literature. DU appears as the most consistent concept, is based on urodynamics, and is defined by the International Continence Society as *"a contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or failure to achieve complete bladder emptying within a normal time span"* [17]. Underactive bladder is a terminology that should be reserved for describing symptoms and clinical features related to DU. A tentative definition has been proposed as *"a symptom complex suggestive of detrusor underactivity and usually characterized by prolonged urination time with or without a sensation of incomplete bladder emptying, usually with hesitancy, reduced sensation on filling, and a slow stream"* [746].

The prevalence of DU in the general population is unknown, as men with DU are either asymptomatic or have non-specific LUTS. In clinical studies of men with non-neurogenic LUTS referred for video-urodynamic studies, the prevalence of DU has been reported to be 10% [747, 748] ranging up to 48% in the elderly (≥ 70 years) [749]. Detrusor underactivity is a chronic condition, but its natural history in untreated men has shown a plateau-like course with few symptomatic and urodynamic changes over time [750].

Healthy voluntary bladder muscle contraction requires a functional detrusor muscle, intact efferent and afferent innervation, and integrated central neural control mechanisms. Dysfunction of any of these essential components can lead to DU, which may be the consequence of various pathological processes, suggesting a multifactorial pathophysiology.

Neurogenic. Neurogenic DU may be the consequence of peripheral or central nervous system disease. This aetiology is covered in the EAU Guidelines on Neuro-Urology [751].

Myogenic. Several conditions can affect the myocytes or their extracellular matrix, resulting in attenuated detrusor contraction. Bladder outflow obstruction and diabetic cystopathy are common causes of myogenic DU. However, many aspects of the pathophysiology of myogenic DU that relate to BOO and diabetic cystopathy are mainly based on animal studies and the clinical picture in any individual patient is probably multifactorial in nature [752, 753]. Some SRs have addressed the role of chronic BOO on bladder dysfunction in humans. Aside from the impact on smooth muscle cells, multiple other consequences were identified including modifications on the extracellular matrix, and damage to the urothelium, suburothelium and bladder innervation. To date, BOO-related DU pathophysiology remains poorly understood [754].

Iatrogenic. Patients may experience DU following pelvic surgery (e.g., radical prostatectomy or extended rectal surgery) and/or radiation therapy [752]. Pharmacological treatments (e.g., drugs with anticholinergic effects or opioids) may also be involved in the impairment of detrusor contractility [752].

Idiopathic. Given the higher prevalence of DU in the elderly, it has been hypothesised that ageing would be a major contributor. However, available data do not provide strong evidence to support the assertion that detrusor contractile function declines with common ageing [752].

5.7.2 ***Diagnostic Evaluation***

5.7.2.1 Medical history and physical examination

A review of medical history, including co-morbidities and current medications, can identify potential causes of UAB. The history should also include a thorough evaluation of LUTS, which should be classified into storage, voiding and post-micturition symptoms. There is no pivotal symptom to identify patients with UAB. The clinical presentation ranges from asymptomatic cases to symptomatic chronic urinary retention. Since UAB is a disorder of the voiding phase, voiding symptoms are to be the predominant ones, but they may be associated with storage symptoms, particularly in case of incomplete bladder emptying or other concomitant bladder dysfunctions [755].

Clinical diagnosis is even more difficult when patients have other conditions that may affect the presentation of LUTS, such as known or suspected BOO/BPO. In this setting, there is no validated tool to ascertain the respective roles of DU and BOO on voiding symptoms.

The Bristol group was the first to attempt to identify systematically which of the LUTS are most closely related to UAB [756]. Men with UAB reported a statistically significantly higher occurrence of decreased and/or interrupted urinary stream, hesitancy, feeling of incomplete bladder emptying, palpable bladder, feeling of incomplete bowel emptying, absent and/or decreased sensation, and always straining to void compared with men with normal pressure-flow studies. Several authors have proposed predictive models based on the patient's LUTS to distinguish individuals with an UAB from patients with normal pressure-flow studies or BOO [757, 758]. However, there is no conclusive evidence that one prognostic model is more accurate than another, and there is no published external validation of these models.

5.7.2.2 Questionnaires

There is no specific validated questionnaire for the diagnosis of UAB. Physicians can refer to validated questionnaires for male LUTS, but their clinical benefit to monitor symptom changes and treatment in patients with UAB is uncertain [759].

5.7.2.3 Uroflowmetry

Some authors have proposed to distinguish UAB from BOO based on uroflowmetry parameters, not only on Q_{max}, but on flow patterns and combinations of scores [760, 761]. The diagnostic accuracy of the developed models remains to be established and external validation is lacking.

5.7.2.4 Ultrasound scan and post-void residual measurement

Ultrasound findings have been evaluated as non-invasive predictors of DU. In a single-centre prospective study including 143 adult males with LUTS, detrusor wall thickness ≤ 1.23 mm and bladder capacity > 445 mL was associated with urodynamically proven DU, with sensitivity and specificity of 42% and 100%, respectively [762].

Detrusor underactivity is often associated with prolonged bladder emptying time and/or post-void residual urine. However, while high PVR value have been associated with presence of DU, no consensus cut-off has been identified to diagnose DU and it is unlikely that one will ever exist [763].

5.7.2.5 Urodynamics

Underactive bladder is a clinical diagnosis based on sign and symptoms and DU is a term that should be reserved for a urodynamic diagnosis [764]. Invasive urodynamics is the only widely accepted method for diagnosing DU [755]. However, current data do not allow for a consensus definition of the urodynamic criteria to be used for the diagnosis of DU. Three algorithms, which are all based on computer-urodynamic investigation and quantification of detrusor pressure during voiding, have been suggested to quantify detrusor power [763]:

- Griffiths' Watt factor: quantification of detrusor power with a formula consisting of detrusor pressure during voiding, contraction speed, and bladder volume at each point of micturition, expressed as W/m2. Detrusor power varies during voiding, single calculations are usually offered on urodynamic evaluation sheets, for example, maximum detrusor power (W_{max}) or detrusor power at maximum flow (WQ_{max}). However, it remains controversial which of the calculations and what threshold value should be used. Expert opinion suggested using a W_{max} threshold value of 7.0 W/m2 [763].
- Schafer's detrusor-adjusted mean PURR factor (DAMPF): detrusor power can grossly be quantified as very weak, weak, normal, or strong if linearised passive urethral resistance (linPURR) is drawn into the Schafer

nomogram. The length of linPURR determines detrusor strength.

- Bladder contractility index (BCI): quantification of detrusor power/contractility can be derived from Schafer's linPURR lines and calculated by the formula: BCI=pdetQ_{max} + 5Q_{max}. BCI>150 describes strong contractility, 100-150 normal contractility, and <100 weak contractility. Currently the BCI is the most widely used in the literature and clinical trials.

None of these models are validated and their concordance for the diagnosis of DU is uncertain [765, 766], preventing a consensus to be reached on the optimal method for diagnosing DU. Furthermore, detrusor contraction strength is only one aspect of voiding efficiency, and future models will need to encompass several aspects of assessing detrusor contraction (e.g., strength, durability) as well as how the bladder empties.

*5.7.3 **Conservative management***

In general, the treatment of UAB should focus on symptom relief, avoiding complications (such as infections) and improving or at least maintaining QoL. It involves a pragmatic approach ensuring timely bladder drainage by trying to improve bladder contraction and/or decrease urethral resistance [763].

5.7.3.1 Behavioural interventions

There are no randomised studies or large high-quality studies available investigating the effect of behavioural interventions in male patients with UAB. The main goal is to reduce bothersome symptoms and prevent complications of incomplete bladder emptying (such as recurrent UTI) while avoiding invasive treatments. Asymptomatic patients at risk of UAB should be informed of this, (like diabetes mellitus or after pelvic surgery/ radiotherapy) as diagnosis is delayed due to loss in bladder sensation and enlarged bladder capacity. In patients with sensory impairment, timed or scheduled voiding schemes can be recommended. In patients with bothersome frequency, double or triple voiding as well as Valsalva or the Credé maneuver can reduce PVR and may improve their symptoms however no clinical trial has proven efficacy or harm of these measures in the non-neurogenic male population.

A descriptive cohort investigated male patients with DU started on conservative treatment (not further defined) and the need for clean intermittent catheterisation (CIC) after five years. They concluded that male patients with non-neurological DU can remain stable without the need to initiate CIC. No urodynamic risk factors for CIC were detected [767].

5.7.3.2 Pelvic floor muscle relaxation training with biofeedback

Successful voiding is initiated by relaxation of the pelvic floor and urinary sphincter. A failure of at least one of these mechanisms can result in voiding dysfunction as well as inhibition of detrusor contraction, which is called the guarding reflex [768]. Therefore, physiotherapy with pelvic floor muscle relaxation is usually a first line therapy for voiding dysfunction but no RCT in male adults investigates its effect on UAB. Evidence is derived mostly from paediatric studies. One RCT in children compared the effect of standard urotherapy (diet, adapted fluid intake and timed voiding + toilet training) with animated biofeedback therapy versus urotherapy alone in children with proven DU. Improvement was seen in PVR, recurrent UTI and urodynamic parameters, like flow curve and maximum flow rate, in both treatment groups, but improvement was significantly better at all stages in children receiving biofeedback [769].

5.7.3.3 Clean intermittent self-catheterisation (see section 5.6.3.1.4)

In patients with persistently elevated PVR, clean intermittent catheterisation (CIC) is the preferred method for complete and timely bladder drainage. No data exist on the maximum accepted PVR but after 300 mls the risk of UTIs increases [770]. Clean intermittent self-catheterisation is preferred over indwelling catheters, as it might reduce the risk of complications like UTI, bacterial colonisation, bladder stones and overflow incontinence. However, this technique demands a certain level of manual dexterity and cognition if performed by individuals themselves or it can be performed by a caregiver or second person, for example a partner. More details can be found in section 5.6.3.1.4.

5.7.3.4 Indwelling catheters

Indwelling catheters should be avoided in the long-term unless other treatment options are not indicated, and the patient is unwilling or unable to perform CIC and there is no one else that can perform it for them. In this case, suprapubic catheters are preferred over urethral catheters due to the risk of traumatic hypospadias [620]. For further details see section 5.6.3.1.4.

5.7.3.5 Intravesical electrical stimulation

Intravesical electrotherapy (IVES) is an electrical stimulation technique that stimulates the A-delta mechanoreceptor afferents thereby reinforcing bladder contractions. Therapy consists of daily sessions of

stimulation with ten to fifteen sessions considered as a trial period. Afferent circuits should be intact together with a healthy detrusor muscle. A recently published RCT in a mixed-gender population with neurogenic predominant UAB, reported improvement at four weeks after IVES compared to sham in PVR (-97ml vs. -10.5ml, $p < 0.01$), in bladder voiding efficiency (+13.3 vs. 0.0, $p<0.01$) and in Q_{max} (+1.3 vs. +0.2, $p < 0.04$) [771]. One small retrospective study with a mixed population (eleven women - five men) showed some improvement in voiding after IVES in two-third of the study population [772]. Other evidence is mainly derived from small studies in children [755]

5.7.3.6 Extracorporeal Shock Wave Therapy

Extracorporeal Shock Wave therapy (ESWT) improves neovascularisation and tissue regeneration and theoretically could improve detrusor contractility. A small placebo controlled-RCT reported significant improvements in PVR and UAB-Q scores at 4th week but not at 12th week of follow up [773, 774].

Summary of evidence	**LE**
Behavioural interventions can be attempted in men with UAB and high PVR. Avoid increasing intrabdominal pressure, with Valsalva or Credé, in those with poorly compliant bladders.	3
Pelvic floor muscle relaxation techniques can help with voiding dysfunction.	4
Clean intermittent catheterisation is first line therapy in men with UAB and high PVR over 300ml.	3
Indwelling catheters (urethral or suprapubic) are associated with a range of complications as well as an enhanced risk of UTI.	3
If indwelling catheters are the treatment choice, then the suprapubic route is favoured over urethral due to risk of traumatic hypospadias.	3

Recommendations	**Strength rating**
Initiate clean intermittent self-catheterisation if there is risk of upper tract damage or PVR is > 300ml.	Weak
Offer indwelling transurethral catheterisation or suprapubic cystostomy only when other modalities for urinary drainage have failed or are unsuitable.	Weak

5.7.4 ***Pharmacological management***

5.7.4.1 Parasympathomimetics

For the mechanism of action of parasympathomimetics, see section 5.2.3.

A SR and meta-analysis were performed in both male and female patients with UAB evaluating twelve RCTs on the use of both subgroups (muscarinic agonists and acetylcholinesterase inhibitors) of parasympathomimetics [775, 776]. The meta-analysis showed a small benefit in some patients with (post-procedure) urinary retention with no increase in adverse events, but without improvement of PVR. However, the results of this SR are confounded by the low number of small studies, weak data, high heterogeneity and a very short-term follow up. Therefore, based upon the available literature, no strong evidence-based conclusions can be drawn on the role of parasympathomimetics as an effective pharmaceutical treatment for UAB.

5.7.4.2 Alpha-adrenergic blockers

One alternative to improve bladder emptying and micturition is by reducing outflow resistance in patients with UAB. Although there is a lack of high quality RCTs, some evidence exists that lowering outflow resistance improves voiding functions and bothersome symptoms in men with UAB. A single-blind prospective RCT investigated 119 patients with UAB treating them with a cholinergic drug, an alpha-adrenergic blocker or both. They showed both a significant improvement in symptoms as well as PVR and flow rate in patients treated with combination therapy compared to monotherapy [777]. A study evaluated the effects of tadalafil (a PDE5 inhibitor) and silodosin on voiding function in male patients with non-neurogenic DU. After propensity score matching, they showed improvement of both QoL and UDS parameters and voiding parameters in both subgroups [757]. Overall, the clinical rigor required to provide evidence-based support for the use of this class of medications in treating UAB is still lacking.

5.7.4.3 Prostaglandins

Prostaglandins are involved in the modulation of bladder function. There are five subtypes, of which prostaglandins E2 and F2a appear to be predominant in stimulating detrusor contractions. A Cochrane review analysing three RCTs using intravesical instillation of PGE2 and PGF2a, suggests a reduction of postoperative

retention after catheter removal [778]. However due to methodological limitations of the included trials, the use in clinical practice remains uncertain. One placebo-controlled trial investigated the combination of intravesical PGE2 with bethanechol chloride in nineteen patients with UAB [779]. Although they showed a reduction in PVR compared to placebo, clinical relevance is questioned. Overall, the efficacy of the prostaglandin agents in treating UAB is not established.

5.7.4.4 Other drugs

As previously stated, treatment with PDE5 inhibitors (such as tadalafil) showed improvement of both QoL and UDS parameters and voiding parameters in male patients with UAB [757]. For more information on PDE5s, please see section 5.2.5.

Summary of evidence	LE
Evidence on the effect of parasympathomimetics on clinical or urodynamic parameters of UAB is lacking. Possible serious adverse effects should be considered before administration.	4
There is limited evidence about effectiveness of alpha-adrenergic blockers in men with UAB.	4
The efficacy of the prostaglandin agents in treating UAB is not established.	4

Recommendations	Strength rating
Do not routinely recommend parasympathomimetics for treatment of men with underactive bladder.	Strong
Offer alpha-adrenergic blockers before more-invasive techniques.	Weak

5.7.5 ***Surgical treatment for underactive bladder***

Surgical options for male patients with non-neurogenic UAB/DU include benign prostatic surgery and sacral neuromodulation [165, 780-786].

5.7.5.1 Surgery for benign prostatic obstruction

A SR evaluated the outcomes of surgery for benign prostatic obstruction in men with pre-operative DU or acontractile detrusor [165]. Mean total IPSS variation following surgery was reported to range from -3 to -19.5 points. A >3 points improvement in terms of total IPSS score was evident in fourteen studies included into the SR [165]. Mean IPSS QoL score variation ranged from -0.9 to -3 points [165]. Mean maximum urinary flow (Q_{max}) improvement ranged from +1.4 to +11.7 mL/s. Mean PVR improvement ranged from -16.5 to -736 mL [165].

Direct comparisons between patients with DU versus without DU provided conflicting results [165]. A study found that post-operative outcomes one month after photoselective laser vaporisation prostatectomy (PVP) were worse in patients with DU compared to patients without DU [40]. In men with pre-operative DU, mean total IPSS score improved from 12.0 to 15.2, mean Q_{max} improved from 4.8 ml/sec to 8.2 ml/sec, and mean PVR improved from 918.3 mL to 325.9 mL. In patients without pre-operative DU mean total IPSS improved from 17.5 to 9.7, mean Q_{max} improved from 6.9 ml/sec to 17.6 ml/sec, and mean PVR improved from 225.0 mL to 99.2 mL [783]. A statistically significant difference ($p \leq 0.05$) was observed in terms of mean IPSS, mean Q_{max}, and mean PVR when comparing patients with and without pre-operative DU at one month follow-up [783].

Similarly, another study found that patients with DU had smaller decrease in terms of median total IPSS (-6.5 vs. -11) and a smaller increase in the Q_{max} (+3.5 mL/s vs. +8.2 mL/s) after PVP than did those without DU [782]. In details, in men with DU median total IPSS score improved from 17.5 to 9.5, median Q_{max} improved from 9.7 ml/sec to 13.8 ml/sec and median PVR improved from 28 mL to 11.5 mL. In patients without pre-operative DU median IPSS improved from 20.5 to 8, median Q_{max} improved from 10 ml/sec to 17.9 ml/sec, and median PVR improved from 27.5 mL to 9 mL [782]. Statistical analysis found a significant differences between the two groups at follow-up evaluations only in terms of Q_{max} (p: 0.023).

Other authors failed to find differences in terms of symptom improvement and success rates between patients with and without pre-operative DU [165]. Mean Bladder Contractility Index (BCI) improvement was reported to range from 4 to 44.6 [165].

A retrospective study found that 81.7% of patients with DU or acontractile detrusor undergoing TURP or TUIP achieved a satisfactory treatment outcome defined as improved QoL and voiding efficiency of >50% [784]. Among these patients, mean BCI significantly increased from 16.4 to 61.0 and 69.4% of them had recovery of detrusor function within 3 months [784].

A prospective case series found that 78% of patients with DU or acontractile detrusor and concurrent BPO undergoing holmium laser enucleation of the prostate exhibited significant return of bladder contractility, determined by the presence of a sustained, volitional detrusor contraction at six months follow-up [785]. Of note, 94.7% of patients were voiding spontaneously with acceptable PVR volume, whereas 5.3% required CIC post-operatively [785].

Factors influencing the surgical outcomes have been investigated: older age, lack of obstruction, concomitant detrusor overactivity, lower detrusor contractility and use of transurethral resection of the prostate or photovaporisation instead of holmium laser enucleation of the prostate (HoLEP) were associated with worse outcomes [165].

A retrospectively investigated the effect of DU on the efficacy of TURP by comparing the subjective and objective parameters preoperatively and three months post-operatively between severe (BCI < 82), mild (82 ≤ BCI < 100), and absent DU (BCI ≥ 100) in two obstruction groups (20 ≤ Bladder Outlet Obstruction Index (BOOI) < 40 and BOOI ≥ 40) [786]. Successful improvement after the operation were defined according to the criteria developed by Homma *et al.* [786]. In patients with pre-operative BOOI ≥ 40 the successful improvement rates for the IPSS, IPSS-Storage, IPSS-Voiding, QoL and free Q_{max} were 60.6%, 54.5%, 54.5%, 63.6% and 66.6% in patients with severe DU. The same figures in patients with BOOI ≥ 40 and mild DU were: 87.7%, 63.2%, 94.7%, 75.4%, and 75.4%, respectively. Finally, in patients with BOOI ≥ 40 and absent DU the successful improvement rates were 94.1%, 82.8%, 95.6%, 90.6%, and 71.4%, respectively.

In the 20 ≤ BOOI < 40 group, the successful improvement rates for the IPSS, IPSS-Storage, IPSS-Voiding, QoL and free Q_{max} in the severe DU patients were only 38.2%, 38.2%, 44.1%, 41.2% and 38.2%, respectively. The same figures in patients with mild DU were: 83.3%, 66.7%, 83.3%, 75.0%, and 41.7%, respectively. Finally, in patients with absent DU the successful improvement rates were 90.9%, 90.9%, 90.9%, 90.9%, and 81.8%, respectively.

Therefore, patients with varying degrees of benign prostate obstruction can benefit from TURP, but for patients with severe DU in the 20 ≤ BOOI < 40 group, TURP should be carefully considered only after adequate counselling [786].

Unfortunately, the few long-term data available seem to reveal poor durability of benefits [165].

5.7.5.2 Sacral neuromodulation

Sacral neuromodulation (SNM) has been reported to improve idiopathic urinary retention in women in long-term studies [787]. However, only scarce evidence exists in men with DU or acontractile detrusor. A multicentric, retrospective case series reported the outcomes of SNS in adults with a urodynamic-based diagnosis of DU and symptom duration of more than six months who failed to respond to first and second-line treatment options [781]. Patients with cognitive disabilities, BOO and those who had any contraindication for SNS were excluded. Overall, 35 males were included. Of these, 51.4% responded to the first stage and were candidates for the full implant. Overall, 72% of male patients had favourable responses after the full implantation. Voided volume, PVR, and the median Q_{max} improved in both sexes [781]. In men who underwent full implantation voided volume improved from 75.0 mL to 300.0 mL, PVR improved from 350.0 mL to 90.0 mL, and mean Q_{max} improved from 7.0 to mL/sec to 16.0 mL/sec. Evidence from another retrospective study suggests that residual detrusor contractility is more likely to respond to a trial of SNM compared to detrusor acontractility [788].

Summary of evidence	**LE**
In patients with DU or acontractile detrusor and concomitant benign prostatic obstruction, de-obstruction procedures are associated with improvements in bladder contractility index, mean total International Prostate Symptom Score, mean maximum urinary flow, and mean postvoid residual volume.	3
Older age, lack of bladder outflow obstruction, concomitant detrusor overactivity, lower bladder contractility and use of transurethral resection of the prostate or photo vaporisation instead of laser enucleation of the prostate are associated with worse post-operative outcomes after de-obstruction procedures.	3
Sacral neuromodulation provides statistically significant improvement in terms of voided volume, post-void residual, and median maximum flow rate in men with refractory DU and no BPO.	3

Recommendations	Strength rating
Counsel patients with evidence of detrusor underactivity (DU) or acontractile detrusor and concomitant benign prostatic enlargement about the potential subjective and objective benefits of benign prostatic surgery.	Weak
Offer men with DU and no benign prostatic obstruction, test phase sacral neuromodulation.	Weak

*5.7.6 **Follow-up***

The natural history and clinical evolution at long-term follow-up of men with UAB is not well documented. A small retrospective cohort evaluated recovery of detrusor contraction one year after (medical or surgical) treatment through video-urodynamic studies [789]. In this small cohort, bladder contractility recovery was seen in 43.9% of patients and an optimal bladder compliance cut-off value of < 80ml/cmH2O was predictive of better recovery. The interval between follow-up visits depends on patient characteristics, treatments given and the frequency of urinary complications. Two studies looked at the natural evolution of detrusor contractility with or without TURP for BOO [108, 750]. Although retrospective, they showed that detrusor contractility does not get worse with persisting BOO nor that it improves after performing a TURP. The underactive detrusor seems to remain under-active but does not deteriorate with time.

6. FOLLOW-UP

6.1 Watchful waiting (behavioural)

Patients who elect to pursue a WW policy should be reviewed at six months and then annually, provided there is no deterioration of symptoms or development of absolute indications for surgical treatment. The following are recommended at follow-up visits: history, bladder diary, IPSS/ICIQ-MLUTS, uroflowmetry, and PVR volume.

6.2 Medical treatment

Patients receiving α1-blockers, muscarinic receptor antagonists, beta-3 agonists, PDE5Is or the combination of α1-blockers and 5-ARIs or muscarinic receptor antagonists should be reviewed four to six weeks after drug initiation to determine the treatment response. If patients gain symptomatic relief in the absence of troublesome adverse events, drug therapy may be continued. Patients should be reviewed at six months and then annually, provided there is no deterioration of symptoms or development of absolute indications for surgical treatment. The following are recommended at follow-up visits: history, IPSS/ICIQ-MLUTS, uroflowmetry, and PVR volume. Frequency volume charts or bladder diaries should be used to assess response to treatment for predominant storage symptoms or nocturnal polyuria.

Patients receiving 5-ARIs should be reviewed after twelve weeks and six months to determine their response and adverse events. The following are recommended at follow-up visits: history, IPSS/ICIQ-MLUTS, uroflowmetry and PVR volume. Men taking 5-ARIs should be followed up regularly using serial PSA testing if life expectancy is greater than ten years and if a diagnosis of PCa could alter management. A new baseline PSA should be determined at six months, and any confirmed increase in PSA while on 5-ARIs should be evaluated.

In patients receiving desmopressin, serum sodium concentration should be measured at day three and seven, one month after initiating therapy and periodically during treatment. If serum sodium concentration has remained normal during periodic screening follow-up screening can be carried out every three months subsequently. However, serum sodium concentration should be monitored more frequently in patients ≥ 65 years of age and in patients at increased risk of hyponatremia. The following tests are recommended at follow-up visits: serum-sodium concentration and FVC. The follow-up sequence should be restarted after dose escalation.

6.3 Surgical treatment

After prostate surgery, patients should be reviewed four to six weeks after catheter removal to evaluate treatment response and adverse events. If patients have symptomatic relief and are without adverse events, no further re-assessment is necessary. The following tests are recommended at follow-up visit after four to six weeks: IPSS/ICIQ-MLUTS, uroflowmetry, erectile and ejaculatory function and PVR volume.

Summary of evidence	LE
Follow-up for all conservative, medical, or operative treatment modalities is based on empirical data or theoretical considerations, but not on evidence-based studies.	4

Recommendations	Strength rating
Follow-up all patients who receive conservative, medical, or surgical management.	Weak
Define follow-up intervals and examinations according to the specific treatment.	Weak

8. CONFLICT OF INTEREST

All members of the EAU Non-neurogenic Male LUTS Guidelines Panel have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publicly accessible through the European Association of Urology website: http://uroweb.org/guideline. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative and travel and meeting expenses. No honoraria or other reimbursements have been provided.

9. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Paris April 2024. ISBN 978-94-92671-23-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, the Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

Lower urinary tract symptoms (LUTS) encompass storage, voiding and post-micturition symptoms [1]. Storage symptoms include frequency, urgency, nocturia and urinary incontinence (UI) (stress UI [SUI], urgency UI [UUI], and mixed UI [MUI]). Voiding symptoms include hesitancy, intermittency, slow stream, straining, splitting or spraying of the urinary stream and terminal dribble. Post-micturition symptoms include post-void dribbling and feeling of incomplete bladder emptying. Lower urinary tract symptoms are often broadly classified into clinical syndromes/entities such as overactive bladder (OAB), underactive bladder (UAB), UI, nocturia, dysfunctional voiding, or genitourinary fistulae.

Lower urinary tract symptoms are common in women [2-5] and cause a great deal of distress and embarrassment [6], as well as significant costs to both individuals and society [7]. Estimates of prevalence vary according to the definition and population studied. However, there is universal agreement about the importance of the problem in terms of human suffering and economic cost [7].

1.1 Aim and objectives

These Guidelines from the European Association of Urology (EAU) Working Panel on Non-neurogenic Female LUTS are written by a multidisciplinary group, primarily for urologists, but are likely to be referred to by other professional groups. The guidelines aim to provide sensible and practical evidence-based guidance on the clinical problems associated with female LUTS rather than an exhaustive narrative review. Such reviews for UI and other LUT syndromes are already available from the International Consultation on Incontinence (ICI) [8] and other sources. Therefore, these EAU Guidelines do not describe the causation, basic science, epidemiology and psychology of LUTS/UI in detail. The focus of these guidelines is on assessment and treatment, reflecting clinical practice, and they do not consider women with LUTS caused by neurological disease, or LUTS occurring in children, as these are covered by complementary EAU Guidelines [9, 10].

The current guidelines provide:

- A clear description of the assessment and treatment of common clinical problems. This can provide the basis for both individual patient management and for planning and designing clinical services.
- A brief but authoritative summary of the current state of evidence on clinical topics, complete with references to the original sources.
- Clear guidance in those areas of practice for which there is little or no high-quality evidence.

The guideline has seen a significant expansion of scope from UI to non-neurogenic female LUTS in recent years. The primary consideration here is to include the significant population of women with functional urological conditions not necessarily associated with UI that were hitherto not accounted for in previous guidelines. Secondary considerations are to align more cohesively with the existing Non-neurogenic Male LUTS Guidelines. As a consequence of the anatomical and physiological differences between the male and female LUT, the prevalence, pathophysiology, diagnostic approach and management of male and female LUTS differ widely. For that reason, the EAU Guidelines Office decided to provide gender-specific guidelines on LUTS and UI.

1.2 Panel composition

The EAU Non-neurogenic Female LUTS Panel consists of a multidisciplinary group of experts, including urologists, a uro-gynaecologist, a urodynamic scientist, a physiotherapist, a nurse practitioner in Continence Care, and patient advocates. All experts involved in the production of this document have submitted potential conflict of interest statements that can be viewed on the EAU website: https://uroweb.org/guidelines/non-neurogenic-female-luts/panel.

1.3 Available publications

A quick reference document (Pocket Guidelines) is available in print. This is an abridged version that require consideration together with the full-text versions. All documents are accessible through the EAU website: https://uroweb.org/guideline/non-neurogenic-female-luts/.

1.4 Publication history

The first EAU Urinary Incontinence Guidelines were published in 2001. The guidelines have been modified since to broaden its scope specifically to include other female LUTS as of 2021. All sections of the 2023 Female LUTS Guidelines have been fully updated. The next update of the Female LUTS Guidelines will be published in 2025.

2. METHODS

2.1 Introduction

For the 2023 Non-neurogenic Female Lower Urinary Tract Symptoms guidelines, databases searched included Medline, Embase, and the Cochrane Libraries, covering a time frame between 01 September 2021 and 20 February 2022, with a focus on high-level evidence only (systematic reviews (SR) and meta-analyses). A total of 345 unique records were identified, retrieved, and screened for relevance. Detailed search strategies are available: https://uroweb.org/guideline/non-neurogenic-female-luts/?type=appendices-publications.

For the 2023 edition of the guidelines a de novo systematic review was undertaken by the Panel on the subject of OAB syndrome [11]. The results from this publication have informed the corresponding sections of this guidelines update.

Recommendation within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences [12, 13]. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [14];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention.

Strong recommendations typically indicate a high degree of evidence quality and/or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [15].

Additional information can be found in the general Methodology section of this print, and online at the EAU website: https://uroweb.org/guidelines/policies-and-methodological-documents/.

A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review

The guidelines were extensively peer reviewed prior to publication in 2021.

2.3 Future goals

- Systematic review of underactive bladder (UAB) in women.

3. DIAGNOSIS

3.1 History and physical examination

Taking a thorough clinical history is fundamental to the process of clinical evaluation. Despite the lack of high-level evidence to support it, there is universal agreement that taking a history should be the first step in the assessment of anyone with LUTS. The history should include a full evaluation of LUTS, as well as sexual, gastrointestinal, and neurological symptoms. The history should help to categorise LUTS as storage, voiding and post-micturition symptoms, and classify UI as SUI, UUI, MUI or overflow incontinence; the latter being defined as “the complaint of UI in the symptomatic presence of an excessively (over-) full bladder (no cause identified)” [16].

The history should also identify patients who need referral to an appropriate clinic/specialist. These may include patients with associated pain, haematuria, history of recurrent urinary tract infection (UTI), pelvic surgery or radiotherapy, constant leakage suggesting a fistula (see Section 4.8), new-onset enuresis or suspected neurological disease. A neurological, obstetric, and gynaecological history may help to understand

the underlying cause and identify factors that may affect treatment decisions. Guidance on history-taking and diagnosis in relation to UTIs, neuro-urological conditions and chronic pelvic pain (CPP) can be found in the relevant EAU Guidelines [9, 17, 18]. Patients should also be asked about other co-morbidity as well as smoking status, previous surgical procedures, and current medications, as these may affect LUTS.

There is also little evidence from clinical trials that carrying out a clinical examination improves outcomes, but widespread consensus suggests that clinical examination remains an essential part of assessment of patients with LUTS. Examination should include abdominal examination, to detect an enlarged urinary bladder or other abdominal mass, and digital examination of the vagina and/or rectum. Pelvic examination in women includes assessment of oestrogen status, pelvic floor muscle (PFM) function and careful assessment of any associated pelvic organ prolapse (POP). A cough stress test is necessary to look for SUI. Among women with genital prolapse, the cough test was found to show good agreement with urodynamic studies (UDS) in the detection of SUI [19]. Urethral mobility and PFM contraction strength can also be assessed. A focused neuro-urological examination should also be routinely undertaken.

3.1.1 Summary of evidence and recommendation for history taking and physical examination

Summary of evidence	LE
History taking including symptoms and co-morbidity and focused physical examination are essential parts of the evaluation of women with LUTS.	4

Recommendation	Strength rating
Take a complete medical history including symptoms and co-morbidity and perform a focused physical examination for evaluation of women with LUTS.	Strong

3.2 Patient questionnaires

This section includes symptom scores, symptom questionnaires/scales/indices, patient-reported outcome measures (PROMs) and health-related quality of life (HRQoL) measures. The latter include generic or condition-specific measures. Questionnaires should have been validated for the language in which they are being used, and, if used for outcome evaluation, should have been shown to be sensitive to change. The US Food and Drug Administration (FDA) published guidance for industry on PROM instruments (questionnaires) in 2009 [20].

Although many studies have investigated the validity and reliability of urinary symptom questionnaires and PROMs, most of these studies included mixed populations (men and women). This limits the extent to which results and conclusions from these studies can be applied to particular LUT syndromes in women. Some questionnaires (ICIQ-FLUTS, QUID, 3IQ, ICIQ-SF) have potential to discriminate UI types in women [21-23]. Others have been developed to measure symptoms and bother in OAB (OABQ-SF, B-SAQ) and other specific conditions. A newly developed patient assessment tool, the OAB- Bladder Assessment Tool (OAB-BAT), was found to be a valid and reliable OAB PROM that includes symptoms, bother, impacts and satisfaction with treatment [24]. A systematic review included 22 studies that assessed eleven case-finding tools for OAB. All tools were found to have good sensitivity and specificity for OAB or incontinence symptoms. The B-SAQ was the only tool in this SR to include screening for “red- flag” symptoms such as haematuria and pain, and it has also been validated in a primary care setting [25]. Some questionnaires are responsive to change and may be used to measure outcomes, although evidence for this is inconsistent [26, 27].

A SR including 73 studies assessed 27 specific and six generic instruments that measure quality of life (QoL) in women with UI. In this review, the incontinence questionnaire (IQoL) was found to be the most psychometrically robust disease-specific tool for use in English-speaking women with UI. It had the highest level of evidence for sufficient internal consistency, test-retest reliability, measurement error and hypothesis testing for construct validity. It is also the most translated instrument. Evidence on the performance of generic QoL tools for this population is limited [28]. There is no evidence to indicate whether use of QoL or condition-specific questionnaires has an impact on outcome of treatment.

Detailed description of the different urinary symptoms questionnaires and PROMs is beyond the scope of these guidelines. For more information, we recommend the 6th ICI review on PROM assessment [29]. To date, there is not one questionnaire that fulfils all requirements for assessment of women with LUTS. Clinicians must evaluate the tools that exist, for use alone or in combination, for assessment and monitoring of treatment outcome [30]. The questionnaires can be found on the following websites: www.iciq.net, https://eprovide.mapi-trust.org, www.pfizerpcoa.com, www.ncbi.nlm.nih.gov.

3.2.1 Summary of evidence and recommendation for patient questionnaires

Summary of evidence	LE
Validated condition-specific symptom scores assist in the screening for and categorisation of LUTS.	3
Validated symptom scores measure the severity of UI and LUTS.	3
Both condition-specific and general health status questionnaires measure current health status and change following treatment.	3
Patient questionnaires cannot replace a detailed patient consultation and should only be used as part of a complete medical history.	4

Recommendation	Strength rating
Use a validated and appropriate questionnaire as part of the standardised initial assessment and follow-up of female LUTS.	Strong

3.3 Bladder diaries

Measurement of the frequency and severity of LUTS is an important step in the evaluation and management of LUT dysfunction. Bladder diaries are a semi-objective method of quantifying symptoms, such as frequency of UI events, number of nocturia episodes, etc. They also quantify urodynamic variables, such as voided volume, 24-hour urine volume or nocturnal total urine volume.

Discrepancy between diary recordings and the patient rating of symptoms, e.g., frequency of UI, can be useful for patient counselling. Fluid intake and voided volume measurement can be used to support diagnoses and management planning, for example in OAB, and for identifying 24-hour or nocturnal polyuria. Diaries can also be used to monitor treatment response and are widely used in clinical trials. In patients with severe UI, a bladder diary is unlikely to accurately report 24-hour urine output.

Consensus terminology is now well-defined and widely accepted [1, 31]. However, the terms micturition diary, frequency/volume chart, bladder diary and voiding diary, have been used interchangeably for many years, but only bladder diaries include information on fluid intake, times of voiding, voided volumes, UI episodes, pad usage, degree of urgency and severity of UI recorded for at least 24 hours. When reviewing the evidence, all synonymous search terms have been included.

Two studies have demonstrated the reproducibility of diaries in both men and women [32, 33]. Other studies have shown the feasibility, reliability, and validity of the bladder diary [34, 35]. Further studies have demonstrated variability of diary data within a 24-hour period and compared voided volumes recorded in diaries with those recorded by uroflowmetry [36, 37]. Another study found that keeping a bladder diary had a therapeutic benefit [38].

A number of observational studies have demonstrated a close correlation between data obtained from bladder diaries and standard symptom evaluation [39-42]. The optimum number of days required for bladder diaries appears to be based on a balance between accuracy and compliance [43, 44]. Diary durations between three and seven days are routinely reported in the literature.

3.3.1 Summary of evidence and recommendations for bladder diaries

Summary of evidence	LE
Bladder diaries of three to seven days duration are reliable tools for objective measurement of mean voided volume, day- and night-time frequency, urgency episodes, UI episode frequency fluid intake and pad usage.	2b
Bladder diaries are sensitive to change and are a reliable outcome measure.	2b

Recommendations	Strength rating
Ask patients with LUTS to complete a bladder diary as part of the standardised assessment of female LUTS.	Strong
Use a bladder diary with a duration of ≥ 3 days.	Strong

3.4 Urinalysis and urinary tract infection

Reagent strip (dipstick) urinalysis may indicate proteinuria, haematuria or glycosuria, or suggest UTI requiring further assessment. Please refer to the Urological Infections Guidelines for diagnosis and treatment of UTI [17].

Urine dipstick testing is a useful adjunct to clinical evaluation in patients in whom urinary symptoms are suspected to be due to UTI. Urinalysis negative for nitrite and leukocyte esterase may exclude bacteriuria in women with LUTS [45], and should be included, with urine culture when necessary, in the evaluation of all patients with LUTS. Urinary incontinence or worsening of LUTS may occur during UTI [46] and existing UI may worsen [47]. The rate and severity of UI were unchanged after eradication of asymptomatic bacteriuria in nursing home residents [48].

3.4.1 Summary of evidence and recommendations for urinalysis

Summary of evidence	LE
Urinalysis negative for nitrite and leukocyte esterase may exclude bacteriuria in women with LUTS.	3
Urinary incontinence may be a symptom during UTI, and LUTS may increase during UTI.	3
The presence of UTI worsens existing symptoms of UI.	3
Elderly nursing home patients with UI do not benefit from treatment of asymptomatic bacteriuria.	2

Recommendations	Strength rating
Perform urinalysis as a part of the initial assessment of patients with LUTS.	Strong
If an urinary tract infection is present with LUTS, reassess the patient after treatment.	Strong
Do not routinely treat asymptomatic bacteriuria in elderly patients with the aim of improving UI.	Strong

3.5 Post-void residual volume

Post-void residual (PVR) volume is the amount of urine that remains in the bladder after voiding. It is a measure of voiding efficiency, and results from a number of contributing factors. The detection of significant PVR volume is important because it may worsen symptoms and, may be associated with UTI, upper urinary tract (UUT) dilatation and renal insufficiency. Both bladder outlet obstruction (BOO) and/or detrusor underactivity (DU) can potentially contribute to the development of significant PVR volume. Post-void residual volume can be measured by catheterisation or ultrasound (US).

Most studies investigating PVR volume have assessed mixed populations including those with neurogenic UI, so results should be applied with caution to women with non-neurogenic LUTS. Studies investigating the best method of measuring PVR volume [48-53] conclude that US measurement of PVR volume is preferable to catheterisation due to its favourable risk–benefit profile.

The prevalence of significant PVR volume among patients with LUTS is uncertain, partly because of the lack of a standard definition of an abnormal PVR volume. Some authors have suggested that it is reasonable to consider a PVR volume > 100 mL to be significant, although many women may remain asymptomatic and hence it is imperative to consider the clinical context. There is no consensus on what constitutes a significant PVR volume in women [54-59], therefore the Panel prefers the use of bladder voiding efficiency (BVE) - the proportion of the total bladder volume that is voided by the patient. Bladder voiding efficiency can be calculated as a percentage: BVE = voided volume (VV)/(VV+PVR) × 100. This may be a more reliable parameter to evaluate poor voiding [46].

3.5.1 Summary of evidence and recommendations for post-void residual volume

Summary of evidence	LE
Women with lower urinary tract symptoms exhibit a higher PVR volume compared to asymptomatic women.	2

Recommendations	Strength rating
Measure post-void residual (PVR) volume in patients with LUTS during initial assessment.	Strong
Use ultrasound to measure PVR volume.	Strong
Monitor PVR volume in patients receiving treatments that may cause or worsen voiding dysfunction.	Strong
Provide bladder voiding efficiency as an additional parameter when measuring PVR volume.	Weak

3.6 Urodynamics

Urodynamic testing is widely used as an adjunct to clinical diagnosis, in the belief that it may help to provide or confirm diagnosis, predict treatment outcome, or facilitate discussion during counselling. The simplest form of urodynamic evaluation is uroflowmetry. The maximum flow rate (Q_{max}), the volume voided and the shape of the curve in addition to the PVR volume (see above) are the most important parameters to be assessed [29]. The bladder should be sufficiently full because of the volume dependency of Q_{max} [60, 61]. A minimum voided volume of 150 mL is advised in men, but there is little evidence to suggest a volume threshold in women. It is relevant to ask the patient whether or not the voiding is representative.

Invasive urodynamic tests are sometimes performed prior to invasive treatment of LUTS. These tests include multichannel cystometry and pressure–flow studies, ambulatory monitoring and video-urodynamics, and different tests of urethral function, such as urethral pressure profilometry. The International Continence Society (ICS) and the United Kingdom Continence Society (UKCS) provide standards to optimise urodynamic test performance and reporting [62, 63]. A characteristic of a good urodynamic study is that the patient's symptoms are replicated, recordings are checked for quality control, and results interpreted in the context of the clinical problem, remembering that there may be physiological variability within the same individual [62]. Non-invasive alternatives for measurement of detrusor pressure and BOO include transabdominal wall near-infrared spectroscopy and US detrusor wall thickness analysis, but as yet, these techniques have not been adopted into routine clinical practice [29].

Further condition-specific information regarding the role of urodynamic testing in OAB, SUI, BOO and UAB can be found in respective sections of these guidelines.

3.6.1 Variability

In common with most physiological tests there is variability in urodynamic results. This has consequences for the reproducibility, diagnostic accuracy, and predictive value of urodynamic testing. ICS Good Urodynamic Practice Guidelines state [62] that, at least in the case of cystometry and pressure–flow studies, one set of measurements suffices, but only if the patient's symptoms have been replicated but some studies contradict this [64, 65]. There is also conflicting evidence about the reproducibility of maximum urethral closure pressure (MUCP) measurement [64, 65]. Valsalva leak point pressure (VLPP) measurement is not standardised and there is minimal evidence about its reproducibility. No studies on the reproducibility of ambulatory monitoring in non-neurological patients have been published [29].

3.6.2 Diagnostic accuracy

Clinical diagnosis and cystometric findings sometimes do not correlate [66, 67] and asymptomatic women may have abnormalities on urodynamic testing. The diagnostic accuracy of urethral pressure profilometry [68] and urethral retro-resistance pressure measurement in SUI is poor [29]. Valsalva leak point pressure did not reliably assess UI severity in a cohort of women selected for surgical treatment of SUI [69]. Urethral pressure reflectometry may have greater diagnostic accuracy but its clinical role remains unclear [70]. Ambulatory urodynamics may detect unexpected physiological variance from normal more often than conventional cystometry does, but the clinical relevance of this is also uncertain [71, 72].

A pressure–flow study, that is, the simultaneous measurement of flow rate and detrusor pressure during voiding, can reveal whether a poor flow rate and PVR volume are due to BOO, DU or a combination of both. Also, it may provide information on the degree of pelvic floor relaxation and thus diagnose dysfunctional voiding. Several proposals to define BOO in women have been made. These definitions are based on detrusor pressure, either $P_{det}Q_{max}$ or the maximum value $P_{det.max}$, and the Q_{max} value, either during the pressure-flow study or during uroflowmetry. These measures are sometimes combined with the findings during fluoroscopic imaging (see Section 4.5.4.8) [73, 74]. Unlike the situation in men, there is no widely accepted threshold for BOO diagnosis in women. Bladder contraction strength parameters are derived from detrusor pressure and flow rate during a pressure-flow study or from stop tests [74], but again, validation is poor. Although these parameters estimate the strength of the contraction, they ignore its speed and persistence (see Section 4.4.3.2) [75]. A video-

urodynamic study can be useful to detect the site of obstructed voiding, which may be anatomical or functional [76]. Also, video-urodynamics may detect bladder diverticulum or gross reflux as a pressure-absorbing reservoir.

*3.6.3 **Predictive value***

Performing urodynamic evaluation is only useful if it leads to more effective clinical care and better outcomes. A Cochrane review of eight randomised controlled trials (RCTs) showed that use of urodynamic tests in women with UI increased the likelihood of prescribing drugs but did not increase the likelihood of undergoing surgery. However, there was no evidence that this altered the clinical outcome [77]. Most RCTs addressed the utility of urodynamic tests on SUI only, including women with uncomplicated SUI. A meta-analysis including four RCTs comparing surgical outcomes in women with self-reported SUI (or stress-predominant MUI) who were investigated via urodynamics with women who had office evaluation only, found that there was no difference in cure and complication rates [78]. In contrast, a large retrospective multicentre study found that only 36% of patients were defined as uncomplicated according to the definitions used in large RCTs [79]. The urodynamic observations were not consistent with the pre-urodynamic diagnosis in 1,276 out of 2,053 patients (62.2%). Voiding dysfunctions were urodynamically diagnosed in 394 patients (19.2%) and planned surgery was cancelled or modified in 304 of 1,582 patients (19.2%) in whom data were available, due to the urodynamic findings [80]. A large UK multi-centre RCT is underway designed to evaluate the effectiveness and cost-effectiveness of invasive urodynamic investigations in management of women with refractory OAB symptoms [81].

The predictive value of urethral function tests remains unclear. In observational studies, there was no consistent correlation between the results of these tests and subsequent success or failure of SUI surgery [40-42, 82]. The same was true in a secondary analysis of an RCT [83].

The presence of preoperative detrusor overactivity (DO) in women with stress-predominant MUI has been associated with postoperative UUI but did not predict overall treatment failure following mid-urethral sling (MUS) surgery or colposuspension [83]. The urodynamic diagnosis of DO has no predictive value for treatment response in studies on antimuscarinics, onabotulinumtoxinA and sacral nerve stimulation (SNS) in patients with OAB symptoms [84, 85]. Augmentation cystoplasty aims to abolish DO, improve bladder compliance, and increase functional bladder capacity but there is no evidence to guide whether or not preoperative urodynamics are predictive of outcome. Most clinicians would, however, consider preoperative urodynamics as essential prior to contemplating augmentation cystoplasty.

A pressure–flow study is capable of discriminating BOO from DU as a cause of voiding dysfunction. The predictive value of parameters derived from such a study for voiding dysfunction after a surgical procedure for SUI is, however, low. A low preoperative flow rate and a low detrusor voiding pressure have been shown to correlate with voiding dysfunction after a tension-free vaginal tape (TVT) and an autologous fascial sling procedure, respectively [86-88]. Bladder contraction strength parameters combining flow rate and detrusor pressure only poorly predicted voiding dysfunction after autologous fascial sling [89]. Post-hoc analysis of two high-quality surgical trials of TVT, Burch colposuspension and autologous fascial sling showed that no preoperative urodynamic parameter predicted postoperative voiding dysfunction in a selected population of women with low preoperative PVR volume [90, 91].

The Panel recognises that it may be valuable to use urodynamic test results to select the optimum management strategy; however, there is inconsistent evidence regarding the predictive value of such tests. When urodynamics and clinical assessment (i.e., by history and examination) are in disagreement, there needs to be a careful re-evaluation of the clinical symptoms and investigation results to ensure that the diagnosis is correct before invasive treatments are contemplated. Expert opinion recognises urodynamic testing as the most comprehensive analysis of LUT function and the primary aim of urodynamics includes reproduction of the patient's symptoms. The information one obtains from urodynamics may be very valuable to discuss and manage expectation regarding invasive treatment.

*3.6.4 **Summary of evidence and recommendations for urodynamics***

Summary of evidence	**LE**
Urodynamics provide comprehensive analysis of LUT function underlying different clinical conditions.	4
Most urodynamic parameters show variability within the same session and over time.	3
Different techniques of measuring urethral function may have good test–retest reliability, but do not consistently correlate to other urodynamic tests or to the severity of UI.	3

There may be inconsistency between history and urodynamic results.	3
Urodynamic diagnosis of DO does not influence treatment outcomes in patients with OAB.	1a
Preoperative urodynamics in women with uncomplicated, clinically demonstrable SUI does not improve the outcome of surgery for SUI.	1b
There is no consistent correlation between the results of urethral function tests and subsequent success or failure of SUI surgery.	3
There is no consistent evidence that preoperative DO is associated with surgical failure of MUS in women.	3
The presence of preoperative DO may be associated with persistence of urgency postoperatively in women undergoing surgery for SUI.	3

Recommendations	**Strength rating**
Adhere to good urodynamic practice standards as described by the International Continence Society when performing urodynamics in patients with LUTS.	Strong
Do not routinely carry out urodynamics when offering treatment for uncomplicated stress urinary incontinence.	Strong
Do not routinely carry out urodynamics when offering first-line treatment to patients with uncomplicated overactive bladder symptoms.	Strong
Perform urodynamics if the findings may change the choice of invasive treatment.	Weak
Do not use urethral pressure profilometry or leak point pressure to grade severity of urinary incontinence.	Strong

3.7 Pad testing

Measurement of urine loss using an absorbent pad worn over a set period of time or during a protocol of physical exercise can be used to quantify the presence and severity of UI, as well as provide objective evidence of response to treatment.

The clinical utility of pad tests in woman with UI has been assessed in three SR's [92-94]. One SR included eighteen studies and concluded that 1-hour pad test was more accurate but less reproducible when compared to the longer duration pad tests. A 1-hour pad test using a standardised exercise protocol and a diagnostic threshold of 1.4 g shows good specificity but lower sensitivity for symptoms of SUI and MUI. A 24-hour pad test using a threshold of 4.4 g is more reproducible but is difficult to standardise, with variation according to activity level [95].

A pad test with a specific short graded exercise protocol also has diagnostic value but a negative test should be repeated with the degree of provocation increased [96]. The usefulness of pad tests in quantifying severity and predicting outcome of treatment is uncertain [92, 97, 98]. Pad tests are responsive to change following successful treatment [99]. Pad testing using a standardised bladder volume (50% of cystometric capacity) was suggested to allow for a more reliable assessment of UI in a small study of 25 women [100]. There is no evidence that one type of pad test is superior to another.

3.7.1 Summary of evidence and recommendations for pad testing

Summary of evidence	**LE**
A pad test can diagnose UI accurately.	2
Standardisation of bladder volume and degree of provocation improves reproducibility.	2
Twenty-four hours is sufficient duration for home-based testing balancing diagnostic accuracy and adherence.	1a
Change in leaked urine volume on pad tests can be used to measure treatment outcome.	2
Pad tests can be a useful tool in the research setting and are an optional investigation in clinical practice.	4

Recommendations	Strength rating
When a pad test is performed, use a standardised duration and activity protocol.	Strong
Use a pad test when quantification of urinary incontinence is required, especially to assess response to treatment.	Weak

3.8 Imaging

In clinical practice, imaging is used to understand the relationship between anatomy and function. Ultrasound and magnetic resonance imaging (MRI) have largely replaced X-ray imaging in the evaluation of the pelvic floor. Ultrasound is sometimes preferred to MRI because of its ability to produce three-dimensional (3D) and 4D (dynamic) images at lower cost and wider availability.

There is no need for UUT imaging unless a high-pressure bladder, severe POP or chronic urinary retention is suspected or diagnosed, or abnormal renal function tests are observed. In cases of suspected UI caused by an UUT anomaly or uretero-vaginal fistula, UUT imaging (urography, computed tomography [CT]) may be indicated [101].

*3.8.1 **Ultrasound***

Ultrasonography of the LUT plays a role in the differential diagnosis of women with LUTS and in cases presenting with haematuria.

Ultrasonography has been used in the evaluation of UI and pelvic floor since the 1980s. Different imaging approaches, such as abdominal, transvaginal, transrectal, perineal and transurethral are described. The bladder neck and urethra are easily visible, and measurements can be done at rest and during straining, coughing and pelvic floor contraction. The parameters assessed in the diagnosis of SUI, for example, include bladder neck mobility or descent, urethro-vesical angle, and urethral rotation [102, 103]. Ultrasonography can be used to assess PFMs and their function. Contraction of PFM results in displacement of pelvic structures that can easily be imaged on US. Integrity of the levator ani muscle can be determined by 3D transperineal US. Ultrasound may also provide information on the anatomical changes of the LUT and pelvic floor associated with persistence of symptoms post-treatment [104]. The specific role of US is discussed in the condition-specific sections of these guidelines where applicable.

*3.8.2 **Detrusor wall thickness***

As OAB syndrome is linked to DO, it has been hypothesised that frequent detrusor contractions may increase detrusor/bladder wall thickness (DWT/BWT). No consensus exists as to the relationship between OAB and increased BWT/DWT [105], and there is no evidence that BWT/DWT imaging improves management of OAB. There is no widely accepted standardised bladder volume for bladder wall thickness measurement.

In a retrospective study including 227 women with symptoms of voiding difficulty (hesitancy, intermittency, and poor stream), 74 (32.6%) were diagnosed with voiding dysfunction on the basis of free uroflowmetry and residual urine. While controlling for the effect of DO, the relationships between DWT and different parameters of voiding function in pressure–flow studies and free uroflowmetry were examined. The results indicated that DWT was not associated with any urodynamic parameters that may indicate BOO [106].

*3.8.3 **Magnetic resonance imaging***

There is a general consensus that MRI provides good global pelvic floor assessment, including POP, defecatory function and integrity of the pelvic floor support [107]. However, there is a large variation in MRI interpretation between observers [108] and little evidence to support its clinical usefulness in the management of LUTS/UI. There is no conclusive evidence that MRI evaluation of POP is more clinically useful than vaginal examination. Studies have assessed the use of imaging to assess the mechanism of MUS insertion for SUI. One study suggested that MUS placement decreased mobility of the mid-urethra but not of the bladder neck [109]. Following MUS, a wider gap between pubic symphysis and sling (assessed by imaging) has been shown to correlate with a lower chance of cure of SUI [110].

3.8.3.1 Summary of evidence and recommendation for imaging

Summary of evidence	LE
There is no consistent evidence that routine urinary tract imaging is useful in the evaluation or management of LUTS.	3
There is no consistent evidence that BWT/DWT measurement is useful in the management of OAB.	3

Recommendation	Strength rating
Do not routinely carry out imaging of the upper urinary tract or lower urinary tract as part of the assessment of LUTS.	Strong

3.9 Urinary biomarkers and microbiome

Interest in the role of urinary biomarkers for the diagnosis of LUT dysfunction has increased in recent years. Nerve growth factor (NGF), brain derived neurotrophic factor (BDNF), prostaglandin E2, adenosin triphosphate (ATP) and purinergic receptors (P2X) in bladder tissue have been studied as biomarkers for OAB. Serum beta natriuretic peptide (BNP), urinary 6-sulfaoxymelatonin and C-reactive protein (CRP), melatonin, vasopressin levels have been studied in relation to nocturia. For SUI, urinary IL 12-70, urinary (uNGF) N-telopeptide of type I collagen (NTx) and urinary microbiota have been studied. Currently, studies investigating urinary biomarkers are methodologically limited often due to failing to control for confounding variables and results are conflicting [111].

Another area of discovery is the role of urinary microbiota in identifying and differentiating various types of UI and other LUT disease in women. A SR described studies showing differences in the types and relative proportions of bacteria such as *Lactobacillus, Gardnerella, and Atopobium vaginae*, among women with different types of UI compared with healthy controls. Urinary microbiota has also been shown to differ depending on women's response to anticholinergic treatment response [112]. Further research is needed before the place of urine microbiota assessment in the clinical pathway for women with LUTS is fully defined.

Further information on the diagnostic efficacy of biomarkers in OAB can be found in Section 4.1.3.

3.9.1 ***Summary of evidence and recommendation for urinary biomarkers***

Summary of evidence	LE
There is insufficient evidence on the diagnostic accuracy and validity of urinary biomarkers for LUT disease in women.	3
Differences in the urinary microbiota have been found to be associated with different types of LUT dysfunction in women, including UI, and with different responses to treatment.	3

Recommendation	Strength rating
Do not routinely use urinary biomarkers or estimation of the urinary microbiota in the diagnosis and management of LUT disease in women.	Strong

4. DISEASE MANAGEMENT

4.1 Overactive bladder

4.1.1 ***Epidemiology, aetiology, pathophysiology***

Overactive bladder syndrome is defined by the ICS as "*urinary urgency, usually accompanied by frequency and nocturia, with or without UUI, in the absence of UTI or other obvious pathology*" [113]. Overactive bladder is a chronic condition that can have debilitating effects on QoL. The hallmark urodynamic feature is DO but the diagnosis of OAB is exclusively based on symptoms.

The EPidemiology of InContinence (EPIC) study [114] was a cross-sectional telephone survey of adults conducted in five countries and demonstrated an overall prevalence of OAB symptoms of 11.8% (10.8% in men and 12.8% in women).

Various theories have been proposed to explain the pathophysiology of OAB, mainly relating to imbalances in inhibitory and excitatory neural pathways to the bladder and the urethra or sensitivity of bladder muscle receptors. However, no definite identifiable causes have been established.

*4.1.2 **Classification***

Overactive bladder is generally classified into wet and dry, based on the presence or absence of associated UI.

*4.1.3 **Diagnostic evaluation***

Evaluation of symptoms of OAB follows the general pathway of evaluation of women with LUTS.

4.1.3.1 Bladder diaries

Diaries are particularly helpful in establishing and quantifying symptoms of frequency, urgency and UI, and may be valuable in assessing change over time or response to treatment. Several observational studies have demonstrated a close correlation between data obtained from bladder diaries and standard symptom evaluation [39-42]. The optimum number of days required for bladder diaries appears to be based on a balance between accuracy and compliance. Diary duration of three to seven days is routinely used in the literature. For further information, please review Section 3.3.

4.1.3.2 Urodynamics

Urodynamics is essential in establishing the presence of DO, but its absence does not preclude diagnosis of OAB, which is based on symptoms alone.

A Cochrane review of seven RCTs showed that use of urodynamic tests increased the likelihood of prescribing drugs or avoiding surgery. However, there was no evidence that this influence on decision-making altered the clinical outcome of treatment [77]. A sub-analysis of an RCT comparing fesoterodine to placebo [85] showed that the urodynamic diagnosis of DO was not predictive of treatment response.

4.1.3.3 Summary of evidence and recommendations regarding OAB diagnosis

Summary of evidence	**LE**
Bladder diaries of three to seven days' duration may be helpful in quantifying symptoms of OAB and assessing response to treatment.	3
Urodynamic diagnosis of DO does not influence treatment outcomes in patients with OAB.	1a

Recommendations	**Strength rating**
Request that patients complete at least a three-day bladder diary at initial evaluation for overactive bladder (OAB).	Strong
Do not routinely carry out urodynamics when offering first-line treatment to patients with uncomplicated OAB symptoms.	Strong

4.1.3.4 Urinary biomarkers

A SR and meta-analysis indicated that uNGF, BDNF to creatinine ratio and uNGF to creatinine ratio were all increased in female OAB patients compared to healthy controls, whereas no difference was found for the PGE2/Cr and ATP/Cr ratios [115]. The current data is inadequate to assess any other potential biomarkers, in the diagnosis or management of OAB in female patients.

*4.1.4 **Disease management***

4.1.4.1 Conservative management

In clinical practice, it has long been the convention that non-surgical therapies are recommended first because they usually carry the lowest risk of harm. While this remains true for non-pharmacological conservative treatments [e.g., pelvic floor muscle training (PFMT)], increasing concerns regarding the adverse events of some pharmacological treatments used to treat OAB (e.g., anticholinergic drugs), particularly regarding cognitive function, have emerged and patients should be fully counselled regarding this potential risk.

4.1.4.1.1 Addressing associated medical co-morbidities

Lower urinary tract symptoms, especially in elderly patients, are associated with multiple co-morbid conditions including:

- cardiac failure;
- chronic renal failure;
- diabetes;
- chronic obstructive pulmonary disease;
- neurological disease;
- general cognitive impairment;
- sleep disturbances, e.g., sleep apnoea;
- depression;
- metabolic syndrome.

If a change in co-morbidity or a new treatment for any associated co-morbidity has been linked to a deterioration in LUTS then this should be reviewed.

One study involving middle-aged women with type 1 diabetes mellitus showed that 10% had UUI. The study showed no correlation between early intensive insulin treatment of type 1 diabetes mellitus vs. conventional insulin treatment and the occurrence of UUI. The same study found no difference in the prevalence of UI in these patients later in their lives [116].

4.1.4.1.2 Adjustment of other medication

Although LUTS are listed as adverse effects of many drugs, this mainly derives from uncontrolled individual patient reports and post-marketing surveillance. Few controlled studies used the occurrence of LUTS as a primary outcome or were powered to assess the occurrence of statistically significant LUTS, or worsening rates against placebo. In most cases, it is therefore not possible to be sure that any drug causes OAB/LUTS.

A structured scoping review failed to identify any studies addressing whether adjustment of specific medications could alter existing symptoms of OAB.

4.1.4.1.2.1 Summary of evidence and recommendations for conservative management of OAB

Summary of evidence	**LE**
There is a lack of evidence that improving any associated co-morbid condition improves OAB.	3
There is little evidence that adjustment of specific medications for associated co morbid conditions can alter existing symptoms of OAB.	3

Recommendations	**Strength rating**
Take a history of current medication use from all patients with overactive bladder (OAB).	Strong
Review any new medication associated with the development or worsening of OAB symptoms.	Strong

4.1.4.1.3 Urinary containment

Urinary containment is important for people with OAB wet when active treatment does not cure the problem, is delayed, or when it is not available or possible. Some individuals may prefer urinary containment rather than active treatment with its associated risks. Containment includes the use of absorbent pads, urinary catheters, external collection devices and intravaginal devices. Detailed literature summaries can be found in the current International Consultation on Urological Diseases (ICUD) monograph [8] and in a European Association of Urology Nurses guidance document [117].

A SR of five RCTs comparing different types of pads found that pads filled with superabsorbent material were better than standard pads but evidence that disposable pads in preventing skin problems, were better than washable pads was inconsistent [118]. A series of three crossover RCTs examined performance of different pad designs for differing populations [119]. For women with light UI, disposable insert pads (within washable pouch pants) were most effective. In adults with moderate/severe UI, disposable pull-up pants were more effective for women.

A Cochrane review summarised three RCTs comparing different types of long-term indwelling catheters and found no evidence that one catheter material or type of catheter was superior to another [120]. A SR of non-randomised studies found no differences in UTI outcome or UUT changes between use of suprapubic or urethral catheter drainage; however, patients with suprapubic catheters were less likely to have urethral complications [121].

Catheter-related bladder discomfort may be significant in women. Anticholinergics have been proposed to prevent or reduce this issue, but most of the evidence comes from clinical trials in the postoperative period, and the results are conflicting [122-125]. One retrospective study including 40 women (most of them neurogenic) with long-term bladder catheters found intravesical botulinum toxin injections helped to prevent bladder pain and discomfort and catheter bypass/leakage. Patients reported an improvement in QoL and a significant 83% reduction in urine leakage [126].

A Cochrane review summarising five trials comparing bladder washout policies in adults with indwelling urinary catheters found inconsistent evidence of benefit [127].

A Cochrane review summarising eight trials of whether antibiotic prophylaxis was beneficial for adults using clean intermittent self-catheterisation (CISC) or indwelling catheterisation found it reduced the incidence of symptomatic UTI but possible harms were not assessed [128]. A multicentre RCT from the UK involving patients practising CISC reported that prophylaxis reduced UTI incidence and was well-tolerated, but development of antibiotic resistance was a concern [129].

4.1.4.1.3.1 Summary of evidence and recommendations for urinary containment

Summary of evidence	**LE**
Pads are effective in containing urine.	1b
Antibiotic prophylaxis may help reduce incidence of UTI in patients who have an indwelling catheter or use CISC, but at the cost of increasing antimicrobial resistance.	1a

Recommendations	**Strength rating**
Ensure that women with overactive bladder (OAB) and/or their carers are informed regarding available treatment options before deciding on urinary containment alone.	Strong
Offer incontinence pads and/or containment devices for management of OAB wet, either for temporary symptom control or when other treatments are not planned.	Strong
Offer prophylactic antibiotics to patients on clean intermittent self-catheterisation or on indwelling catheter with recurrent urinary tract infection only after discussion regarding the risk of increasing antimicrobial resistance.	Strong

4.1.4.1.4 Lifestyle interventions

Examples of lifestyle factors that may be associated with UI include obesity, smoking, level of physical activity, regulation of bowel habit, and fluid intake. Modification of these factors may improve symptoms of OAB.

4.1.4.1.4.1 Caffeine intake

A scoping review of fourteen interventional and twelve observational studies reported that reduction in caffeine intake may reduce symptoms of urgency, but the certainty of evidence was low, with significant heterogeneity in study populations [130].

4.1.4.1.4.2 Fluid intake

Modification of fluid intake, particularly restriction, is a strategy commonly used by people with OAB. Any advice on fluid intake given by health care practitioners (HCPs) should be based on 24-hour fluid intake and urine output measurements as retrieved from the bladder diary. From a general health point of view, it should be advised that fluid intake should be sufficient to avoid thirst and that an abnormally low or high 24-hour urine output should be investigated. The few published RCTs involving women provide inconsistent evidence [131-133]. In most studies, the instructions for fluid intake were individualised and it was difficult to assess participant adherence. An RCT showed that a reduction in fluid intake by 25% improved symptoms in patients with OAB but did not improve UI [133]. Personalised fluid advice compared to generic advice made no difference to continence outcomes in people receiving anticholinergics for OAB, according to an RCT comparing drug

therapy alone to drug therapy with behavioural advice [134]. Patients should be warned of the potential consequences of fluid restriction such as worsening of constipation or development of UTI.

4.1.4.1.4.3 Weight loss

Being overweight or obese has been identified as a risk factor for LUTS in epidemiological studies [135, 136]. There is evidence that the prevalence of both UUI and SUI increases proportionately with body mass index (BMI) [137]. However, the evidence base largely relates to obesity and SUI rather than UUI and OAB. Therefore, no definite inference can be drawn between obesity and the prevalence of OAB.

4.1.4.1.4.4 Smoking cessation

Smoking cessation is a general public health measure and has been shown to be weakly associated with improving urgency, frequency, and UI [138, 139]. The effect of smoking cessation on LUTS was described as uncertain in a health technology assessment review [140].

4.1.4.1.4.5 Summary of evidence and recommendations for lifestyle interventions

Summary of evidence	**LE**
Reduction of caffeine intake may reduce symptoms of frequency and urgency.	2
Reduction in fluid intake by 25% may help improve symptoms of OAB but not UI.	1b
Personalised fluid intake advice when added to pharmacotherapy provides no additional benefit in patients with OAB.	2
Obesity is a risk factor for UI in women, but the relationship to other OAB symptoms remains unclear.	1b
There is weak evidence that smoking cessation improves symptoms of OAB.	3

Recommendations	**Strength rating**
Advise adults with OAB that reducing caffeine intake may improve symptoms of urgency and frequency, but not incontinence.	Strong
Review type and amount of fluid intake in patients with OAB.	Weak
Encourage overweight and obese adults with overactive bladder (OAB)/urinary incontinence to lose weight and maintain weight loss.	Strong
Provide smoking cessation strategies to patients with OAB who smoke.	Strong

4.1.4.1.5 Behavioural and physical therapies

Behavioural and physical therapies are often introduced as part of a package of care including lifestyle changes and patient education.

4.1.4.1.5.1 Prompted voiding and timed voiding

The term ‘prompted voiding’ implies that carers, rather than the patient, initiate the patient going to void with the aim of preventing or reducing UI. This applies largely to an assisted care setting. A SR (nine RCTs including mostly women with UI), comparing prompted voiding to standard care, suggested evidence of short-term benefit for management of UI [141].

Timed voiding is defined as fixed, predetermined, time intervals between voids and is applicable for those with or without cognitive impairment. A Cochrane review of timed voiding included four RCTs and found inconsistent improvement in continence compared with standard care in cognitively impaired adults [142].

4.1.4.1.5.2 Bladder training

Bladder training (BT) is a programme of patient education along with a scheduled voiding regimen with gradually increasing intervals. Specific goals are to correct faulty patterns of frequent urination, improve control over bladder urgency, prolong voiding intervals, increase bladder capacity, reduce incontinent episodes and restore patient confidence in controlling bladder function. The ideal form or intensity of a BT programme for OAB/UI is unclear.

A comparison of anticholinergic treatment with BT in one Cochrane review with seven RCTs showed inconsistent results in terms of cure rates but reported significantly more patients improved with anticholinergics [143]. The same review showed that the addition of anticholinergics to BT as part of behavioural modification resulted in more subjective improvement but no difference in objective outcomes.

Cognitive behavioural therapy involves the analysis of or change to a thought process related to the sensation of urgency or employment of a specified thought process during an episode of urgency. This includes mental distraction (the most common), relaxation and mindfulness practices. A SR on cognitive components of behavioural therapies for OAB concluded that they were neither well described nor rationalized. Behavioural therapy that includes cognitive component shows promise for OAB treatment, but its relative importance has not been well evaluated nor rigorously studied [144].

Another SR including 12 studies on the effect of cognitive behavioural therapy on women with UUI showed high level of evidence of its effectiveness on improving symptom severity and moderate level of evidence on QoL, psychological symptoms and patient satisfaction when compared with placebo. However, results were inconsistent with some studies showing no difference in objective parameters such as bladder capacity [145].

4.1.4.1.5.3 Pelvic floor muscle training

Pelvic floor muscle contraction can lead to simultaneous inhibition of urgency, detrusor contraction and incontinence [146]. Intensive and regular strength training of the PFMs over time increases both PFM contraction strength and endurance, and changes the morphology of the pelvic floor, which may yield more effective inhibition of the detrusor and help to stabilize the proximal urethra and improve urethral function. There is a lack of basic and mechanistic studies to confirm that change in pelvic floor morphology improves OAB symptoms.

A SR of eleven RCTs [147] including women with OAB compared the efficacy of PFMT vs. inactive control, usual care, other lifestyle modification or other intervention. Pelvic floor muscle training significantly reduced OAB symptoms (frequency and UUI) in five RCTs, while the remaining six reported no significant difference. Significant heterogeneity in protocols and outcomes was noted.

4.1.4.1.5.4 Electrical stimulation

The methods of delivery of electrical stimulation (ES) vary considerably. Electrical stimulation of the PFM can also be combined with other forms of conservative therapy, e.g., PFMT with and without biofeedback. Electrical stimulation is often used to assist women who cannot initiate contractions to identify their PFMs and in patients with OAB and UUI with the aim of inhibiting detrusor contraction. There is, however, a lack of basic and mechanistic studies to confirm this theory.

A SR of the effect of ES included 63 trials with 4,224 adults with OAB symptoms [148]. Moderate-quality evidence suggests that ES is more likely to improve OAB symptoms compared to sham control, no treatment, PFMT, and drug treatment. It was unclear if ES was more effective than placebo/sham for UUI. Insufficient or very low-quality evidence was available to determine the difference in the adverse event rates between ES and placebo/sham and the other active treatments.

A SR of nine studies compared the effects different techniques of electrical stimulation. Pooled analysis of three trials showed no difference between intravaginal stimulation and transcutaneous posterior tibial nerve stimulation (T-PTNS) in terms of urinary frequency, nocturia and QoL scores [149]. In the same review, pooled results from two studies which T-PTNS was compared with posterior tibial nerve stimulation (PTNS) showed no difference in urinary urgency, frequency and QoL scores [149].

4.1.4.1.5.4.1 Posterior tibial nerve stimulation

Electrical stimulation of the posterior tibial nerve delivers electrical stimuli to the sacral micturition centre via the S2–S4 nerve roots. Stimulation is percutaneous with a fine (34-G) needle, inserted just above the medial aspect of the ankle (P-PTNS). Transcutaneous stimulation is also available that delivers stimulation via surface electrodes that do not penetrate the skin. The optimal treatment schedule has not been determined, with daily and weekly regimens described [150].

A SR identified five RCTs (408 women) that compared PTNS with antimuscarinics. The PTNS techniques were significantly more effective than antimuscarinics in the reduction of UUI episodes with no significant difference in the reduction of overall symptoms score, frequency episodes or urgency episodes [11].

A SR of three studies comparing PTNS monotherapy with PTNS plus antimuscarinics, showed that the combination therapy added no statistically significant difference to PTNS monotherapy in the reduction of mean symptoms score, frequency episodes, nocturia episodes, or UUI episodes [11].

4.1.4.1.5.4.2 Percutaneous posterior tibial nerve stimulation

The reviewed studies included a SR, two twelve-week RCTs of P-PTNS compared with sham treatment [151-153], one RCT comparing PTNS to tolterodine, and a three-year extension trial utilising a maintenance protocol in patients with OAB [154, 155]. The results of studies of PTNS in women with OAB consistently showed significant and sustained improvement in symptoms from baseline, with similar improvement compared to treatment with tolterodine.

4.1.4.1.5.4.3 Transcutaneous posterior tibial nerve stimulation

A SR of thirteen trials (ten RCTs and three cohort studies) compared the efficacy of T-PTNS (duration four to twelve weeks) with sham treatment, anticholinergics, and exercise in treatment of adults with OAB symptoms [156]. Of note, the populations were adult women and men, and some studies included patients with neurogenic OAB. Meta-analysis was possible in two RCTs comparing T-PTNS with sham treatment and revealed mean reduction in total International Consultation on Incontinence modular questionnaire (ICIQ) Urinary Incontinence Short Form (ICIQ-UI-SF) associated with T-PTNS of −3.79 points.

A small RCT compared T-PTNS plus standard treatment (PFMT and BT) with PFMT and BT alone in older women [157]. Women in the T-TPNS group were more likely to achieve improvement.

A small RCT compared BT alone, BT plus P-PTNS and BT plus T-PTNS in women with idiopathic OAB. Both P-PTNS and T-PTNS were more effective than BT alone. These two tibial nerve stimulation methods had similar clinical efficacy but with slight differences: T-PTNS had shorter preparation time, less discomfort level and higher patient satisfaction than P-PTNS [158].

4.1.4.1.5.5 Acupuncture

A SR with meta-analysis of ten RCTs including 794 patients (590 women) reported that acupuncture might have an effect in reducing OAB symptoms compared to sham treatment [159]. The studies were of low quality and compared electro-acupuncture vs. sham acupuncture, or electro-acupuncture plus tolterodine vs. tolterodine alone.

4.1.4.1.5.6 Summary of evidence and recommendations for behavioural and physical therapies

Summary of evidence	**LE**
Prompted voiding, either alone or as part of a behavioural modification programme, improves continence in elderly, care-dependent, people in the short-term.	1b
Bladder training is effective for improvement of UUI in women, but efficacy appears to be lower than that of pharmacotherapy.	1b
Pelvic floor muscle training may improve symptoms of frequency of OAB in women.	1b
Electrical stimulation may improve symptoms of OAB in some women, but the type and mode of delivery of ES remains variable and poorly standardised.	1a
Posterior tibial nerve stimulation is more effective than antimuscarinics in reducing UUI episodes but with no difference in improving other OAB symptoms.	1a
A maintenance programme of P-PTNS has been shown to be effective for up to 3 years.	2a
Transcutaneous-PTNS appears to be effective in reducing OAB symptom compared to sham treatment.	1a
Transcutaneous -PTNS is not inferior to percutaneous -PTNS with regard to improvement in urinary urgency, frequency, and QoL scores.	1a

Recommendations	**Strength rating**
Offer prompted voiding to adults with overactive bladder (OAB) who are cognitively impaired.	Strong
Offer bladder training as a first-line therapy to adults with OAB/urge urinary incontinence (UUI).	Strong
Ensure that pelvic floor muscle training programmes are as intensive as possible.	Strong
Consider posterior tibial nerve stimulation as an option for symptomatic improvement of OAB/UUI.	Strong

4.1.4.2 Pharmacological management

4.1.4.2.1 Anticholinergic drugs

Anticholinergic (antimuscarinic) drugs are currently the mainstay of treatment for OAB. Different agents vary in their pharmacological profiles, such as muscarinic receptor affinity and other modes of action and in their pharmacokinetic properties, such as lipid solubility and half-life.

The Panel SR identified twelve studies (11,179 women) comparing antimuscarinics with placebo. Antimuscarinics were significantly more effective than placebo in improving mean symptom score on OABQ, reducing daily frequency episodes, reducing daily urgency episodes and UUI episodes, and increasing bladder functional capacity [11].

The SR established that antimuscarinics caused significantly higher adverse events than placebo including dry mouth, cognitive impairment, UTI and constipation [11].

Immediate-release (IR) anticholinergic preparations provide maximum dosage flexibility, including an off-label on-demand use. Immediate-release drugs have a greater risk of adverse effects than extended release (ER) formulations because of differing pharmacokinetics. A transdermal delivery system and gel developed for oxybutynin provide alternative formulations. On balance, IR formulations tend to be associated with more adverse effects compared to ER formulations [160].

A network meta-analysis of 128 RCTs including both genders comparing anticholinergics with placebo or other anticholinergics revealed that all anticholinergics, except imidafenacin, showed reasonable cure or improvement rates for OAB symptoms in both sexes [161]. Differences across the drugs in terms of alteration in symptoms were small.

Cure of UUI is deemed to be the most important outcome measure. Table 1 shows a summary of the findings from a SR of RCTs including only women [162]. All agents showed superiority compared to placebo, but the absolute size of the effect was small.

Table 1: Summary of cure and discontinuation rates of anticholinergic drugs from RCTs [163]

Drug	**No. of studies**	**No. of patients**	**RR (95% CI) (of curing UI)**	**NNT (95% CI) (to achieve one cure of UI)**
Cure of incontinence				
Fesoterodine	2	2,465	1.3 (1.1–1.5)	8 (5–17)
Oxybutynin (includes IR)	4	992	1.7 (1.3–2.1)	9 (6–16)
Propiverine (includes IR)	2	691	1.4 (1.2–1.7)	6 (4–12)
Solifenacin	5	304	1.5 (1.4–1.6)	9 (6–17)
Tolterodine (includes IR)	4	3,404	1.2 (1.1–1.4)	12 (8–25)
Trospium (includes IR)	4	2,677	1.7 (1.5–2.0)	9 (7–12)
Discontinuation due to adverse events				
			RR (95% CI) (of discontinuation)	**NNT (95% CI) (for one discontinuation)**
Darifenacin	7	3,138	1.2 (0.8–1.8)	
Fesoterodine	4	4,433	2.0 (1.3–3.1)	33 (18–102)
Oxybutynin (includes IR)	5	1,483	1.7 (1.1–2.5)	16 (8–86)
Propiverine (includes IR)	2	1,401	2.6 (1.4–5)	29 (16–77)
Solifenacin	7	9,080	1.3 (1.1–1.7)	78 (39–823)
Tolterodine (includes IR)	10	4,466	1.0 (0.6–1.7)	
Trospium (includes IR)	6	3,936	1.5 (1.1–1.9)	56 (30–228)

CI = confidence interval; IR = immediate release; NNT = number to treat; RR = relative risk; UI = urinary incontinence.

The cure rates for darifenacin were not included in the US Agency for Healthcare Research and Quality (AHRQ) review. Continence rates were 29–33% for darifenacin compared to 17–18% for placebo [163]. Transdermal oxybutynin showed a significant improvement compared with placebo and other oral formulations in the number of incontinence episodes and micturitions per day but cure of UI was not reported as an outcome [163]. Oxybutynin topical gel was superior to placebo for improvement of UUI, with a higher proportion of participants being cured [163, 164].

4.1.4.2.1.1 Comparison of different anticholinergic agents

Head-to-head comparison trials of the efficacy and adverse effects of different anticholinergic agents are of interest for decision-making.

Both a network meta-analysis and a SR revealed no superior anticholinergic preparation for cure or improvement [161, 165]. There were no clinically significant differences between anticholinergics for voiding and UI outcomes. No single anticholinergic agent improved QoL more than another [165].

Conflicting results were reported from another network meta-analysis of 53 RCTs that compared the efficacy and tolerability of solifenacin 5 mg/day with other oral anticholinergics in the treatment of adults with OAB symptoms [166]. Solifenacin 5 mg/day was significantly more effective than tolterodine 4 mg/day for reducing UUI episodes, but significantly less effective than solifenacin 10 mg/day for reducing micturition episodes. Solifenacin 5 mg/day showed significantly lower risk of dry mouth compared with other anticholinergics but no significant differences for the risk of blurred vision or constipation.

A further network meta-analysis with 128 RCTs including both genders showed that all anticholinergics were worse than placebo in terms of dry mouth with transdermal oxybutynin having the smallest difference [161].

Dry mouth is the most prevalent reported adverse effect. Extended-release formulations are associated with lower rates of dry mouth than IR preparations [165, 167]. Oxybutynin IR shows higher rates of dry mouth than tolterodine IR and trospium IR but lower rates of dry mouth than darifenacin, 15 mg daily [165, 167]. Overall, oxybutynin ER causes higher rates of dry mouth than tolterodine ER does, although the incidence of moderate or severe dry mouth is similar. Transdermal oxybutynin has a lower rate of dry mouth than oxybutynin IR and tolterodine ER but an overall higher rate of withdrawal due to adverse skin reactions [165]. Solifenacin 10 mg daily has higher rates of dry mouth than tolterodine ER [165]. Fesoterodine 8 mg daily has a higher rate of dry mouth than tolterodine 4 mg daily [168-170]. Similar discontinuation rates have been observed, irrespective of differences in the occurrence of dry mouth.

It is notable that nearly all the primary studies in this category were industry sponsored. In general, these studies have been designed to achieve regulatory approval. Upward dose titration is often included in the protocol for the experimental arm but not for the comparator arm. They have short treatment durations (twelve weeks) and a primary outcome of a change in OAB symptoms rather than a cure of, or an improvement in, UUI, which were generally analysed as secondary outcomes. The clinical utility of these trials in real-life practice is therefore debatable. Most trials were of low or moderate quality [165].

4.1.4.2.1.2 Anticholinergic drugs versus conservative treatment

More than 100 RCTs and high-quality reviews are available detailing relative efficacy of anticholinergic drugs and conservative treatment strategies [143, 165, 171-174]. Most of these were independent studies. The main focus of the reviews was to compare the different drugs used to treat UUI. A U.S. health technology assessment [172] found that the vast majority of trials were of a low or moderate quality.

4.1.4.2.1.2.1 Anticholinergic drugs in combination with other conservative treatment versus anticholinergic drugs alone

The combination of BT and solifenacin in female patients with OAB confers no additional benefit in terms of continence compared with solifenacin monotherapy [175]. A recent Cochrane review on the benefit of adding PFMT to other active treatments of UI in women showed insufficient evidence of any benefit in adding PFMT to drug treatment [176].

One SR identified thirteen RCTs comparing outcomes of antimuscarinic mono-therapy with combinations of antimuscarinics plus adjunct treatments including topical oestrogen, pregabalin, Stroller neurostimulation (SANS), PFMT, and behavioural therapy. Antimuscarinics alone were less effective than a combination of antimuscarinics plus another treatment modality in reducing urgency episodes, UUI episodes, frequency and nocturia episodes and in improving the mean symptoms score but no significant differences were found in rates of dry mouth, constipation or voiding dysfunction [11].

4.1.4.2.1.3 Anticholinergic drugs: adherence and persistence

Most studies on anticholinergic medication are short term (twelve weeks). Adherence in clinical trials is considered to be higher than in clinical practice [177]. Discontinuation rates were high for tolterodine at twelve months, and particularly high (68–95%) for oxybutynin. Two open-label extensions of RCTs of fesoterodine 8 mg showed adherence rates at two years of 49–84% [178, 179].

A longitudinal disease analyser database study has indicated an increasing discontinuation rate, following treatment with anticholinergics, from 74.8% at one year to 87% at three years [180].

Several of the RCTs tried to identify the factors associated with low/lower adherence or persistence of anticholinergics. These were identified as:

- low level of efficacy (41.3%);
- adverse events (22.4%);
- cost (18.7%), although higher adherence rates were observed when drugs were provided at no cost to patients [181].

Other factors associated with poor adherence included:

- immediate release formulations (lower persistence compared with ER formulations);
- age (lower persistence among younger adults);
- unrealistic expectations of treatment;
- gender distribution (better adherence/persistence in female patients);
- ethnic group (African–Americans and other ethnic minorities are more likely to discontinue or switch treatment).

4.1.4.2.1.4 Summary of evidence and recommendations for anticholinergic drugs

Summary of evidence	**LE**
Anticholinergic drugs are effective in improving OAB symptoms, decreasing UUI episodes, decreasing daily urgency and frequency episodes and increasing mean voided volumes, compared with placebo.	1a
Anticholinergic drugs caused higher adverse events than placebo including dry mouth, cognitive impairment, and constipation.	1a
Once daily (ER) formulations are associated with lower rates of adverse events compared to IR preparations.	1b
Transdermal oxybutynin is associated with lower rates of dry mouth than oral anticholinergic drugs but has a higher rate of withdrawal due to skin reactions.	1b
Higher doses of anticholinergic drugs are more effective to improve OAB symptoms but exhibit a higher risk of adverse effects.	1a
No anticholinergic drug is clearly superior to another for cure or improvement of OAB/UUI.	1a
The combination of antimuscarinics plus another treatment modality was more effective than antimuscarinics alone in improving OAB.	1a
Adherence to anticholinergic treatment is low and decreases over time because of lack of efficacy, adverse events and/or cost.	2a
Most patients will stop anticholinergic agents within the first three months.	2a

Recommendations	**Strength rating**
Offer anticholinergic drugs to woman with overactive bladder (OAB) who fail conservative treatment.	Strong
Consider extended-release formulations of anticholinergic drugs whenever possible.	Strong
If an anticholinergic treatment proves ineffective, consider dose escalation, offering an alternative anticholinergic formulation, or the use of mirabegron (alone or in combination with an anticholinergic).	Strong
Encourage early review (of efficacy and adverse effects) of patients on anticholinergic medication for OAB.	Strong

4.1.4.2.2 Beta-3 Agonists

Beta-3 adrenoceptors are the predominant beta receptors expressed on detrusor smooth muscle cells and their stimulation is thought to induce detrusor relaxation. Mirabegron was the first clinically available beta-3 agonist. Vibegron is another beta-3 agonist commercially available in some countries.

Mirabegron has undergone evaluation in industry-sponsored phase II and III trials [182-185]. Three SRs assessing the clinical effectiveness of mirabegron [182, 183, 186] reported that mirabegron at doses of 25, 50 and 100 mg results in significantly greater reduction in UI episodes, urgency episodes and micturition frequency than placebo, with no difference in the rate of common adverse events [183]. The dry rates in most of these trials are 35–40% for placebo and 43–50% for mirabegron. In all trials the significant differences were consistent only for improvement but not for cure of UI. Similar improvements in the frequency of UI episodes and micturition frequency were found whether or not patients had previously tried anticholinergic agents.

The most common adverse events in the mirabegron groups were hypertension (7.3%), nasopharyngitis (3.4%) and UTI (3%), with the overall rate similar to that with placebo [182, 185, 187].

A SR with meta-analysis of data pooled from three RCTs comparing vibegron (75 mg or 100 mg) with placebo in 2,120 patients with OAB revealed significant improvement of urgency episodes and UUI episodes and mean voided volume associated with vibegron [188]. The review also reported that vibegron showed a favourable safety profile. Another SR that included three high-quality RCTs compared vibegron with anticholinergic monotherapy (imidafenacin and tolterodine) concluding similar efficacy in terms of improvements in mean number of micturitions, urgency and UUI, but with less dry mouth [189].

4.1.4.2.2.1 Beta-3 agonists versus anticholinergics

One SR [190] assessed the outcomes of mirabegron in women with OAB. It included seven RCTs, three non-randomised comparative studies and eleven observational studies. The review reported no statistical difference between mirabegron and anticholinergics in decreasing OAB symptoms on voiding diaries and symptom questionnaires on short-term follow-up (up to twelve weeks). However, at one year follow-up, there was a statistically significant decrease in OAB symptoms in favour of mirabegron.

Another SR identified four studies on 371 women that compared beta-3 agonists with antimuscarinics. Pooled analysis for the studies showed that beta-3 agonists were significantly more effective than antimuscarinics in reducing nocturia episodes. No significant differences were found between antimuscarinics and beta-3 agonists in reduction of mean symptoms score, urgency episodes, frequency episodes, UUI episodes, or voided volumes [11].

Antimuscarinics caused higher rates of dry mouth than beta-3 agonists, but no significant difference was found in constipation rates [11].

Post hoc analyses of RCTs showed that clinical improvement in OAB severity translates into improvement in HRQoL and efficacy is maintained in patients with more severe UI [191, 192]. No risk of QTc prolongation [193] and no raised intraocular pressure [194] were observed up to the 100 mg dose; however, patients with uncontrolled hypertension or cardiac arrhythmia were excluded from these trials. There is no significant difference in the rate of adverse effects at different doses of mirabegron [187].

Equivalent adherence was observed for tolterodine and mirabegron at twelve months (5.5% and 3.6%), although the incidence of dry mouth was significantly higher in the tolterodine group [187]. In mirabegron-treated patients, improvement in objective outcome measures correlates directly with clinically relevant PROMs (Overactive Bladder questionnaire and Patient Perception of Bladder Condition) [191, 195]. Data from a large Canadian Private Drug Plan database suggest a higher adherence rate for mirabegron compared to anticholinergics [196].

An RCT in patients who had inadequate response to solifenacin monotherapy 5 mg demonstrated that combination treatment with mirabegron 50 mg had a higher chance of achieving clinically meaningful improvement in UI as compared to dose escalation of solifenacin [197].

4.1.4.2.2.2 Summary of evidence and recommendation for Beta-3 agonists

Summary of evidence	LE
Mirabegron and vibegron are better than placebo for improvement of OAB/UUI symptoms.	1a
Adverse event rates with mirabegron and vibegron are similar to those of placebo.	1a
Beta-3 agonists are as effective as antimuscarinics in the management of OAB but with lower dry mouth rates.	1a
Patients inadequately treated with solifenacin 5 mg may benefit more from the addition of mirabegron rather than dose escalation of solifenacin.	1b

Recommendations	Strength rating
Offer beta-3 agonists as an alternative to anticholinergics to women with OAB who fail conservative treatment.	Strong
Offer mirabegron as an additional therapy in patients who are inadequately treated with solifenacin 5 mg.	Weak

4.1.4.2.3 Anticholinergics and beta-3 agonists: elderly patients and cognition

Systematic reviews have included sections on the efficacy and safety of anticholinergics in elderly patients [163, 165] but an older SR found inconclusive evidence of the impact of anticholinergics on cognition [198].

Two more recent longitudinal cohort studies in patients using anticholinergic drugs showed deterioration in cognitive function, alteration in central nervous system metabolism and an association with brain atrophy [199, 200]. As most of the study periods are short (four to twelve weeks), the long-term impact of anticholinergic agents specifically approved for OAB treatment on specific patient cohorts are poorly understood [201-204].

- *Oxybutynin:* There is evidence that oxybutynin IR may cause/worsen cognitive dysfunction in adults [201, 203, 205, 206]. Whilst short-term trials showed no effect on recent memory or other cognitive functions [206], prospective studies showed cumulative cognitive deterioration associated with prolonged use (mean follow-up, 7.3 years) of anticholinergic medication including oxybutynin [199]. Another prospective cohort study including 376 nursing home residents aged 65 and older taking oxybutynin and tolterodine showed a decline in activity of daily living after a median follow-up of 141 days, in spite of concomitant treatment with cholinesterase inhibitors [207].

- *Solifenacin:* One pooled analysis [208] showed that solifenacin did not increase cognitive impairment in elderly patients. No age-related differences in the pharmacokinetics of solifenacin in different age groups were found, although more frequent adverse events in patients aged > 80 years were observed. No cognitive effect on healthy elderly volunteers was shown [209]. In a sub-analysis of a large trial, solifenacin 5–10 mg improved symptoms and QoL in people aged ≥ 75 years who had not responded to tolterodine [210]. In patients with mild cognitive impairment, aged ≥ 65 years, solifenacin showed no difference in efficacy between age groups and a lower incidence of most adverse effects compared to oxybutynin IR [206, 211].

- *Tolterodine:* No change in efficacy or adverse effects related to age has been reported, although a higher discontinuation rate was found for both tolterodine and placebo in elderly patients [201]. Two RCTs in elderly patients found similar efficacy and adverse effect profile to those in younger patients [212-215]. *Post hoc* analysis has shown little effect on cognition. One non-randomised comparison showed lower rates of depression in elderly participants treated with tolterodine ER compared to oxybutynin IR [216]. Duration of the RCTs was short (twelve weeks).

- *Darifenacin:* Two RCTs in the elderly population (one in patients with UUI and the other in volunteers) concluded that, compared with placebo, darifenacin was effective with no risk of cognitive change, measured as memory scanning tests [217, 218]. Another study on darifenacin and oxybutynin ER in elderly people concluded that the two agents had similar efficacy, but that cognitive function was more often affected in the oxybutynin ER arm [203].

- *Trospium chloride:* Trospium does not appear to cross the blood–brain barrier in healthy individuals due to its molecular characteristics (quaternary amine structure and hydrophilic properties). Two studies in healthy volunteers using electroencephalography showed no effect from trospium, while tolterodine caused occasional changes and oxybutynin caused consistent changes [219, 220]. No evidence as to the comparative efficacy and adverse effect profiles of trospium in different age groups are available. However, there is some evidence that trospium does not impair cognitive function in Alzheimer's disease patients if combined with cholinesterase inhibitors over a six month period [204], or in non-cognitively impaired patients over shorter periods (twelve weeks) [221] and that it is effective compared to placebo in the elderly [222].

- *Fesoterodine:* Pooled analyses of the RCTs of fesoterodine confirmed the efficacy of 8 mg but not 4 mg dose in patients aged > 75 years [178]. Adherence was lower in patients aged > 75 years but effects on mental status were not reported [170, 178, 223]. A more recent RCT showed efficacy of fesoterodine in vulnerable elderly people with no differences in cognitive function at twelve weeks [224].

- *Mirabegron:* Analysis of pooled data from three RCTs showed efficacy and safety of mirabegron in elderly patients [225].

4.1.4.2.3.1 Applicability of evidence to the general elderly population

It is not clear how much the data from pooled and subgroup analyses from large RCTs can be extrapolated to a general ageing population. Community-based studies of the prevalence of anticholinergic adverse effects may be the most helpful [226]. When starting anticholinergics in elderly patients, mental function should be assessed and monitored [227]. No consensus exists as to the best mental function test to detect changes in cognition [207, 228].

4.1.4.2.3.2 Anticholinergic burden

Several drugs have anticholinergic effects and, if another anticholinergic drug is prescribed, possible cumulative effects on cognition should be considered. Lists of drugs with anticholinergic properties are available from several sources [229].

Two SRs of largely retrospective cohort studies showed a consistent association between long-term anticholinergic use and cognitive dysfunction [230, 231]. Longitudinal studies in older people over two to four years have found increased rates of cognitive decline in patients on anticholinergics or drugs with anticholinergic effects [199, 200, 232, 233]. It is unclear whether there is a direct correlation between cognitive dysfunction caused by medication and the long-term risk of development of dementia.

4.1.4.2.3.3 Summary of evidence and additional recommendations for use of anticholinergic and beta-3 agonists in elderly patients

Summary of evidence	**LE**
Anticholinergic drugs are effective in elderly women suffering from OAB/UUI.	1b
Mirabegron has been shown to be efficacious and safe in elderly women suffering from OAB.	1b
In older women the cognitive impact of drugs with anticholinergic effects is cumulative and increases with length of exposure.	2
Oxybutynin may worsen cognitive function in elderly women.	2
Darifenacin, fesoterodine, solifenacin and trospium have not been shown to cause cognitive dysfunction in elderly women in short-term studies.	1b

Recommendations	**Strength rating**
Long-term anticholinergic treatment should be used with caution in elderly women, especially those who are at risk of, or have pre-existing cognitive dysfunction.	Strong
Assess anticholinergic burden and associated co-morbidity in women being considered for anticholinergic therapy for overactive bladder syndrome.	Weak

4.1.4.2.4 Oestrogens

Oestrogen treatment for UI has been tested using oral, transdermal, and vaginal routes of administration. Vaginal (local) treatment is primarily used to treat symptoms of vaginal atrophy in postmenopausal women. Available evidence is related mainly to SUI, and although some reviews include participants with UUI, it is difficult to generalise the results to women with predominantly OAB/UUI.

The association of LUTS with genitourinary syndrome of menopause (GSM) should be considered [234]. Genitourinary syndrome of menopause is a new term that describes various menopausal symptoms and signs associated with physical changes of the vulva, vagina and LUT. These include mucosal pallor/erythema, loss of vaginal rugae, tissue fragility/fissures, vaginal petechiae, urethral mucosal prolapse, introital retraction and vaginal dryness. There is evidence from a SR to suggest benefit from vaginal oestrogen therapy in GSM [235]. All vaginal oestrogens demonstrated superiority in objective and subjective end points of GSM compared with placebo. Only some trials demonstrated superiority vs. placebo in urogenital symptoms (UI, recurrent UTI, urgency, and frequency). No significant difference was observed between various doses and dosage forms of vaginal oestrogen products. Vaginal oestrogen showed superiority over vaginal lubricants and moisturisers for the improvement of objective clinical end points of vulvovaginal atrophy but not for subjective end points [235].

Available evidence suggests that vaginal treatment with oestradiol and oestriol is not associated with increased risk of thromboembolism, endometrial hypertrophy, and breast cancer that is seen with systemic administration [236-238].

4.1.4.2.4.1 Summary of evidence and recommendation for oestrogen therapy

Summary of evidence	**LE**
Vaginal oestrogen therapy may improve symptoms associated with GSM, of which OAB may be a component.	1a

Recommendation	**Strength rating**
Offer vaginal oestrogen therapy to women with LUTS and associated symptoms of genitourinary syndrome of menopause.	Weak

4.1.4.2.5 Placebo and nocebo

Placebo has a clear effect on the improvement of OAB signs and symptoms, and the overall placebo responses in various outcomes studied are statistically significant and, for some of the outcomes, possibly clinically significant. A recent SR including 57 studies with 12,901 patients showed a standardised mean difference of -0.45 for daily micturition episodes, -0.33 for daily nocturia episodes, -0.46 for UUI episodes, -0.50 for daily urgency episodes, -0.51 for daily incontinence episodes, and 0.25 for volume voided per micturition [239]. The same group published a SR with meta-analysis of data retrieved from 57 RCTs on the nocebo effect of pharmacotherapy in patients with OAB (up to 80% females). They reported dry mouth as the most common reported adverse event with mean rate of 4.9%, followed by constipation 2.6%. The authors concluded that HCPs should appreciate the possible positive and negative patient expectation regarding pharmacotherapy for OAB in order to optimise the individual outcomes [240]. The placebo response seems to be non-negligible in OAB, supporting the requirement for placebo control in RCTs.

4.1.4.3 Surgical management

4.1.4.3.1 Bladder wall injection of botulinum toxin A

OnabotulinumtoxinA (onabotA; BOTOX®) 100 U is licenced in Europe to treat OAB with persistent or refractory UUI in adults of both sexes [241, 242]. Surgeons should be aware that other doses of onabotA and other formulations of botulinum toxin A, abobotulinumtoxin A and incobotulinumtoxin A, are not licensed for use in OAB/UUI. Doses for onabotA are not transposable to the other brands of onabotulinumtoxinA. The continued efficacy of repeat injections is usual, but discontinuation rates may be high [243, 244]. The most important adverse events related to onabotA 100 U injection detected in the regulatory trials were UTI and an increase in PVR volume that may require CISC [245].

A SR included ten studies on 2,055 patients comparing intravesical onabotA injection with placebo. OnabotulinumtoxinA was more effective than placebo in improvement of mean symptoms score, reduction of mean urgency episodes, mean UUI episodes, mean frequency episodes, mean nocturia episodes [11]. No statistically significant difference was found between onabotA and placebo in change of mean voided volumes or maximum cystometric capacity.

OnabotulinumtoxinA was associated with significantly higher rates of voiding dysfunction compared to placebo at both 100 unit dose and 200 unit dose, and significantly higher rates of UTI both at 100-unit dose and 200-unit dose.

A Cochrane review reported no significant difference in PVR volume between the onabotA and placebo groups [246].

Quality of life was substantially improved in the onabotA arm, as shown by the > 2.5 times improvement in Incontinence Quality of Life Questionnaire (I-QOL) scores compared to baseline. Cohort studies have shown the effectiveness of bladder wall injections of onabotA in elderly and frail elderly people [247], although the success rate might be lower and the PVR volume (> 150 mL) higher in this group.

The median time to request retreatment in the pooled analysis of the two RCTs was 24 weeks [242, 245]. Follow-up over 3.5 years showed consistent or increasing duration of effect for each subsequent treatment, with a median of 7.5 months. Considerable differences were noted in patients' outcomes on secondary analysis [248].

Two RCTs on 545 patients compared onabotA injections with antimuscarinics. OnabotulinumtoxinA was significantly more effective in curing UUI, but no significant difference was noted in the reduction of mean UUI episodes. However, it was associated with significantly higher rates of voiding dysfunction than antimuscarinics, and UTIs [11].

Identification of DO in urodynamics does not appear to influence the outcome of onabotnA injections in patients with UUI [249].

4.1.4.3.1.1 Summary of evidence and recommendations for bladder wall injection of onabotulinumtoxinA

Summary of evidence	**LE**
A single treatment session of onabotA (100 U) injected in the bladder wall is more effective than placebo at curing and improving UUI/OAB symptoms and improving QoL.	1a
There is no evidence that repeated injections of onabotA have reduced efficacy, but discontinuation rates are high.	2a
There is a risk of voiding dysfunction, increased PVR volume and UTI with onabotA injections.	1a
The risk of bacteriuria after onabotA (100 U) injection is high but the clinical significance of this remains uncertain.	1b
OnabotulinumtoxinA is more effective in curing UUI but similarly effective in reducing mean UUI episodes compared with antimuscarinics.	1a
OnabotulinumtoxinA is associated with higher rates of voiding dysfunction than antimuscarinics.	1a

Recommendations	**Strength rating**
Offer bladder wall injections of onabotulinumtoxinA (100 U) to patients with OAB/UUI refractory to conservative therapy or drug treatment.	Strong
Warn patients of the limited duration of response, risk of UTI and possible prolonged need for clean intermittent self-catheterisation prior to offering treatment with onabotulinumtoxinA.	Strong

4.1.4.3.2 Sacral nerve stimulation

Sacral nerve stimulation (SNS) involves placing electrodes adjacent to the sacral nerve roots and delivering an electric current to the area via an attached battery implanted in the buttock. This delivers low-amplitude stimulation resulting in modulation of neural activity and stabilisation of bladder electrical activity through a mechanism that is, as yet, not fully understood. In most centres, test stimulation with a temporary or permanent electrode is performed to assess response, before undertaking permanent stimulator implantation. Currently, the only reliable predictor for treatment success in SNS is test stimulation. A SR did not find predictive factors of success due to low level of evidence of included studies (small, retrospective, and heterogeneous populations) [250].

All randomised studies suffer from the limitation that patients cannot be blinded to the treatment allocation since all recruited patients have to respond to a test phase before randomisation.

The ROSETTA trial randomised 386 women with refractory UUI to SNS (n = 194 women) or intradetrusor injection of onabotA (n = 192 women) [251]. At two years, the authors found no statistically significant difference between SNS and onabotA in improvement of mean symptom scores on OABq-SF or in reducing the mean UUI daily episodes. Patients reported significantly higher satisfaction with onabotA, but also significantly higher rates of recurrent UTIs than SNS (24% vs. 10%, respectively). On the other hand, SNS was associated with 9% removal rate and 3% revision rate at two-years follow-up.

The INSITE trial randomised 70 (94% women) patients to SNS implantation and 77 patients (92% women) to receive antimuscarinics [252]. At six months follow-up, results showed statistically significant higher success rate for SNS compared to antimuscarinics – success was defined as > 50% improvement in daily UUI or frequency episodes. Adverse events occurred in 30% and 27% of SNS and antimuscarinics trial arms, respectively, none were serious. SNS was associated with higher rates of UTIs and was associated with implant site infection and lead migration in 3.4% of cases each.

A Cochrane review [253] identified three RCTs that investigated SNS in patients with refractory UUI. The majority of studies compared a strategy of immediate implantation with delayed implantation. One study compared implantation to controls who stayed on medical treatment and received delayed implantation at six months. Fifty percent of the immediately implanted group had > 90% improvement in UUI at six months compared with 1.6% of the control group [254]. The effect on QoL measured by the SF-36, was unclear as it differed between the groups in only one of the eight dimensions. The other RCT achieved similar results, although these patients had already been included in the first report [255].

Another SR of studies including SNS with ≥ 6 months follow-up reported dry rates of 43–56% [256]. Adverse events occurred in 50% of implanted cases, with surgical revision necessary in 33–41% [257, 258]. In a sub-analysis of the RCT similar success rates were found in patients with or without urodynamic DO [259].

4.1.4.3.2.1 Summary of evidence and recommendation for sacral nerve stimulation

Summary of evidence	LE
Sacral nerve stimulation is more effective than continuation of failed conservative treatment for OAB/UUI, but no sham controls have been used.	1b
Sacral nerve stimulation is as effective as onabotA 200 U injection at 24 months.	1b
In patients who have been implanted, 50% improvement of UUI is maintained in ≥ 50% of patients and 15% may remain cured at four years.	3

Recommendation	Strength rating
Offer sacral nerve stimulation to patients who have overactive bladder/urge urinary incontinence refractory to anticholinergic therapy.	Strong

4.1.4.3.3 Laser treatment

A recent SR evaluated the use of vaginal lasers in the treatment of OAB in short term studies detailing minimal improvement [260]. No RCTs were included, the quality of reported studies were weak and long-term safety data were also lacking.

4.1.4.3.3.1 Summary of evidence and recommendation for laser treatment

Summary of evidence	LE
Vaginal laser therapy shows minimal OAB symptom improvement in the short term, with minimal complications, however, long-term efficacy and safety data is lacking.	3

Recommendation	Strength rating
Do not offer vaginal laser therapy to treat overactive bladder symptoms outside of a well-regulated clinical research trial.	Strong

4.1.4.3.4 Cystoplasty/urinary diversion

4.1.4.3.4.1 Augmentation cystoplasty

In augmentation cystoplasty (also known as clam cystoplasty), a detubularised segment of bowel is inserted into the bivalved bladder wall. Most of the evidence pertaining to cystoplasty comes from patients with neuropathic bladder dysfunction. One study did not find any difference between bivalving the bladder in the sagittal or coronal plane [261, 262]. The procedure can be done, with equal success by open or robotic techniques, although the latter takes more time [263].

There are no RCTs comparing bladder augmentation to other treatments for patients with OAB/UUI.

A large case series of bladder augmentation in a mixed population of idiopathic and neurogenic UUI included 51 women [264]. At an average follow-up of 74.5 months, only 53% were continent and satisfied with the surgery, whereas 25% had occasional leaks and 18% continued to have disabling UUI. The results for idiopathic DO (58%) were less satisfactory than for neurogenic UUI (90%). Malignant transformation was not reported in this series; however, it has been documented in other series and a SR [265-267]. Fewer than 60 cases have been reported worldwide, and almost all are exclusively beyond ten years after the original cystoplasty [268].

Adverse effects are common and have been summarised in a review with five to seventeen years follow-up of > 267 cases; 61 of which had non-neurogenic UUI [269]. Short-term complications include bowel obstruction (2%), infection (1.5%), thromboembolism (1%), bleeding (0.75%) and fistula (0.4%). In the long term, patients may require CISC to obtain adequate bladder emptying (38%). Other long-term effects include asymptomatic bacteriuria (70%), changes in bowel symptoms (25%), UTI (20%), metabolic disturbances (16%), urinary tract stones (13%), deterioration in renal function (2%), and bladder perforation (0.75%).

It is unclear if mucolytic agents reduce mucus accumulation. The only RCT comparing various mucolytic agents did not find significant benefits with the use of N-acetylcysteine, aspirin, or ranitidine. In one small study (n = 40), subcutaneous octreotide immediately before, and for fifteen days after surgery yielded significant reductions in mucus production, the need for bladder irrigation to clear blockages, and mean duration of hospital stay [270]. Before cystoplasty, all potential complications should be outlined, and before and after surgery, patients should be well supported by stoma/continence nurses.

Depending on the relative costs of onabotA and augmentation cystoplasty, the latter can be cost-effective within 5 years if the complication rate is low and duration of effect of onabotA is < 5 months [271].

4.1.4.3.4.2 Detrusor myectomy (bladder auto-augmentation)

Detrusor myectomy aims to increase bladder capacity and reduce storage pressure by incising or excising a portion of the detrusor muscle, to create a bladder mucosal bulge or pseudo-diverticulum. It was initially described as an alternative to bladder augmentation in children [272].

Two case series in adult patients with idiopathic and neurogenic bladder dysfunction demonstrated poor long-term results caused by fibrosis of the pseudo-diverticulum [273, 274]. This technique is rarely, if ever, used nowadays.

4.1.4.3.4.3 Urinary Diversion

Urinary diversion remains a reconstructive option for patients with intractable UI after multiple pelvic procedures, radiotherapy or pelvic pathology leading to irreversible sphincteric incompetence or fistula formation. Options include ileal conduit urinary diversion, orthotopic neobladder and heterotopic neobladder with Mitrofanoff continent catheterisable conduit. There is insufficient evidence to comment on which procedure leads to the most improved QoL.

A small study comparing ileal with colonic conduits concluded that there are no differences in the relative risks (RR) of UUT infection and uretero-intestinal stenosis. However, no studies have specifically examined these techniques for treatment of intractable OAB/UUI [261]. Therefore, careful consideration of which operation is undertaken depends on thorough preoperative counselling, access to stoma/continence nurses, as well as patient factors to allow for fully informed patient choice.

4.1.4.3.4.4 Summary of evidence and recommendations for cystoplasty/urinary diversion

Summary of evidence	LE
There is limited evidence of the effectiveness of augmentation cystoplasty and urinary diversion specifically for treatment of idiopathic OAB or UUI.	3
Augmentation cystoplasty and urinary diversion are associated with high risks of short- and long-term severe complications.	3
The need to perform CISC following augmentation cystoplasty is common.	3
There is no evidence comparing the efficacy or adverse effects of augmentation cystoplasty to urinary diversion.	3

Recommendations	Strength rating
Ensure patient counselling and life-long support both prior to and after major surgery as a treatment for overactive bladder (OAB) is provided by a specialist nurse or equivalent health care provider.	Strong
Offer augmentation cystoplasty to patients with OAB/urge urinary incontinence (UUI) who have failed all other treatment options and have been informed about all possible complications.	Weak
Inform patients undergoing augmentation cystoplasty of the high risk of clean intermittent self-catheterisation (ensure they are willing and able to do so) and that they will need life-long surveillance.	Strong
Do not offer detrusor myectomy as a treatment for UUI.	Weak
Only offer urinary diversion to patients who have failed less-invasive therapies for the treatment of OAB/UUI, who will accept a stoma and have been warned about the possible small risk of malignancy.	Weak

*4.1.5 **Follow-up***

Follow-up for women with OAB is guided by the type of treatment instituted and local service capacity. Standardisation of follow-up pathways can therefore be difficult. Here, we provide recommendations based on best practice and standards from clinical trials.

4.1.5.1 Recommendations for follow-up of patients with overactive bladder

Recommendations	Strength rating
Offer early follow-up to women who have been commenced on anticholinergic or beta-3 agonist therapy.	Strong
Offer repeat injections of onabotulinumtoxinA, as required, to women in whom it has been effective (refer to the manufacturer's guidance regarding the minimum timeframe for repeat injections).	Strong
Offer life-long surveillance to women who have a sacral nerve stimulation implant to monitor for lead displacement, malfunction, and battery wear.	Strong
Offer cystoscopic surveillance to women with an augmentation cystoplasty due to the small risk of malignancy.	Weak

4.2 Stress urinary incontinence

*4.2.1 **Epidemiology, aetiology, pathophysiology***

Stress urinary incontinence, defined as the involuntary loss of urine on effort or physical exertion, is a significant health problem worldwide with social and economic impact on women and society. It is estimated that the number of women in the USA with UI will have increased from 18.3 million in 2010 to 28.4 million in 2050 [275]. The prevalence of SUI appears to peak between 45 and 59 years of age [276].

Data regarding the association of UI with ethnicity are conflicting. In several studies, SUI is more common in white women than in women of African American or Asian American origin [277, 278]. Other factors positively associated with SUI include parity, obesity, previous hysterectomy or pelvic surgery, diabetes mellitus [279] and

pulmonary disease [280]. Physical activity level is another important factor that is positively correlated with SUI severity [281]. A meta-analysis including six studies with a total sample size of 3,678 cases showed that the risk for SUI in women with metabolic syndrome was three times those without [282].

Two common, often overlapping, mechanisms for SUI have been described: (1) urethral hypermobility resulting from loss of support of the bladder neck and urethra; and (2) weakness of the urinary sphincter itself (intrinsic sphincter deficiency), which can result from trauma, radiotherapy, previous pelvic or uro-gynaecological surgery, neurological disease, or ageing.

The mechanism behind urethral hypermobility as a cause of SUI is based on the "vaginal hammock" hypothesis [283]. The endopelvic fascia, which is attached to the upper (abdominal) side of the PFMs, links the muscles to the vagina and represents the "hammock", which can compress the urethra during rest and activity. This compression, combined with intrinsic urethral sphincter pressure, supports, and maintains the urethra in the correct and closed position, preventing involuntary loss of urine, despite any increases in intravesical pressure. Damage to the supporting tissues (particularly the arcus tendinous fasciae pelvis, the central part of the fascia) can result in urethral hypermobility. Consequently, rather than being compressed at times of increased intra-abdominal pressure, the urethra moves caudally, funnelling the bladder neck, and is no longer compressed, resulting in SUI [283, 284]. In general, almost all treatments are used for both subtypes of SUI, but in general most treatments are more successful in patients with some degree of urethral hypermobility than for isolated intrinsic weakness of the urinary sphincter [285].

*4.2.2 **Classification***

Patients with SUI can be classified as uncomplicated and complicated [286]. The Panel has reached a consensus on the definition to be used throughout this guideline document:

- Women with uncomplicated SUI: no prior surgery for SUI, extensive pelvic surgery, or pelvic radiotherapy; no neurogenic LUT dysfunction; no bothersome genitourinary prolapse; absence of voiding symptoms; and no medical conditions that affect the LUT. In cases where additional significant storage symptoms, especially OAB, are present, consider a possible diagnosis of MUI (see Section 4.3).
- Women with complicated SUI: previous surgery for incontinence or extensive pelvic surgery; history of pelvic irradiation; presence of anterior or apical POP; presence of voiding symptoms or neurogenic LUT dysfunction; significant OAB/UUI; congenital abnormalities such as bladder exstrophy. Neurogenic LUT dysfunction is reviewed in the EAU Guidelines on Neuro-Urology and will not be considered further in these guidelines [9]. The treatment of LUTS associated with genitourinary prolapse has been included in these guidelines (see Section 4.7).

*4.2.3 **Diagnostic evaluation***

4.2.3.1 History and physical examination

There is universal agreement that taking a history, should be the first step in the assessment of anyone with UI. When the history categorises UI as probable SUI the presence of complicated or uncomplicated SUI can also be determined. Those patients who require rapid referral to an appropriate specialist can also often be identified from the clinical history.

There is little evidence from clinical trials that carrying out a clinical examination improves clinical outcomes, but there is widespread consensus that it remains an essential part of the assessment of women with SUI. It should include abdominal examination, vaginal examination and careful assessment of any associated POP, examination of the perineum and evaluation of PFM strength, as well as a neuro-urological examination. An attempt to reproduce the SUI should be made. A standing cough test has greater sensitivity for diagnosis of SUI compared with a supine cough test [287]. Despite this, the ICS has proposed a standardisation of the female cough stress test that includes a supine/lithotomy position with 200–400 mL fluid in the bladder and one to four coughs [288].

4.2.3.1.1 Summary of evidence and recommendation for history and physical examination

Summary of evidence	**LE**
A standing cough stress test is more sensitive than a supine test.	1b

Recommendation	Strength rating
Take a full clinical history and perform a thorough physical examination including standardised cough stress test in all women presenting with stress urinary incontinence.	Strong

4.2.3.2 Patient questionnaires

Although many studies have investigated the validity and reliability of urinary symptom questionnaires and PROMs, most of these studies did not include homogeneous populations of adult women diagnosed with SUI. This limits the extent to which results and conclusions from these studies can be specifically applied to women with SUI. Some questionnaires are used for prevalence studies; others are responsive to change and may be used to measure outcomes, although evidence on their sensitivity is inconsistent [26, 27]. There is no evidence to indicate whether use of QoL or condition-specific questionnaires has an impact on treatment outcome. To date, there is not one questionnaire that fulfils all requirements for the assessment of women with SUI.

4.2.3.2.1 Summary of evidence and recommendation for patient questionnaires

Summary of evidence	LE
Validated condition-specific symptom scores assist in the screening for and categorisation of UI.	3
Validated symptom scores measure the severity and associated bother of SUI.	3
Both condition-specific and general health status questionnaires measure current health status and are responsive to change following treatment.	3

Recommendation	Strength rating
Use a validated and appropriate questionnaire as part of the standardised assessment of patients with stress urinary incontinence.	Strong

4.2.3.3 Post-void residual volume

It is important to evaluate PVR volume in patients with SUI; particularly in those who also have voiding symptoms or POP. The prevalence of a significant PVR volume in patients with SUI is uncertain, partly because of the lack of a standard definition of an abnormal PVR volume. Most studies investigating PVR volume have not included patients with SUI. In general, the data on PVR volume can only be applied with caution to adults with non-neurogenic SUI. In a cohort study of > 900 women with SUI, there was good correlation between PVR volume estimated by US and measured by catheterisation [59].

4.2.3.3.1 Summary of evidence and recommendations for post-void residual volume

Summary of evidence	LE
The majority of women with SUI do not have a significant PVR volume.	3
There is good correlation between PVR volume estimated using US and measured via catheterisation in women with SUI.	3

Recommendations	Strength rating
Measure post-void residual (PVR) volume, particularly when assessing patients with voiding symptoms or complicated stress urinary incontinence (SUI).	Strong
When measuring PVR volume, use ultrasound in preference to catheterisation.	Strong
Monitor PVR volume in patients scheduled for treatment that may cause or worsen voiding dysfunction, including surgery for SUI.	Strong

4.2.3.4 Urodynamics

The role of urodynamics in SUI evaluation remains poorly defined and is still under debate.

Invasive urodynamic tests are often performed prior to surgical treatment of SUI. Clinical diagnosis of incontinence and cystometric findings often do not correlate [66, 67]. The diagnostic accuracy of urethral pressure profilometry [68] and VLPP measurement in SUI is generally poor [289]. Measurement of MUCP correlates, albeit weakly, with incontinence severity [68], and there is conflicting evidence about its

reproducibility [64, 65]. Methods of recording MUCP cannot be compared meaningfully [290]. Valsalva leak point pressures are not standardised and there is minimal evidence about reproducibility. Valsalva leak point pressures did not reliably assess incontinence severity in a cohort of women selected for surgical treatment of SUI [69]. The predictive value of the tests regarding treatment outcome remains unclear.

A Cochrane review including seven RCTs showed that urodynamic tests increased the likelihood of avoiding surgery for SUI. However, there is no evidence that this influence on decision-making alters the clinical outcome of treatment within trial populations [77].

A high-quality RCT (n = 630) compared office evaluation alone and combined with urodynamics in women with clinically demonstrable SUI about to undergo surgery. While urodynamics changed the clinical diagnosis in 56% of women [291], there was no difference in severity of SUI or any secondary outcome at twelve months' follow-up after SUI surgery [79]. A similar study also found that omission of urodynamics in the preoperative work-up of SUI did not lead to inferior results [292]. Patients in whom urodynamics were discordant with clinical assessment (n = 109) were randomly allocated to receive either immediate surgery or individually tailored therapy based on the urodynamic findings. In this trial, performing immediate surgery, irrespective of the result of urodynamics, did not result in inferior outcomes [293]. An RCT, in which 145 women were randomised to retropubic or trans-obturator MUS, concluded that when patients were stratified according to preoperative VLPP (≤ or > 60 cm H_2O), it was not linked to outcome after both synthetic MUS procedures [294].

Another study reported conflicting evidence. Valsalva leak point pressures or MUCP in the lowest quartile was predictive in terms of synthetic MUS failure at twelve months [83].

The Panel recognises that it may be valuable to use urodynamic test results to help select the optimum surgical procedure, but the evidence outlined above suggests that performing urodynamics in patients with uncomplicated SUI, which can be diagnosed based on detailed clinical history and demonstrated at examination, is not necessary. The role of urodynamics in complicated SUI is still under debate [295]. However, the Panel consensus is that urodynamics should be carefully considered in cases of SUI with associated storage symptoms; cases in which the type of incontinence is unclear; cases in which voiding dysfunction is suspected; and cases with associated POP or prior surgery for SUI. This is in line with other guideline documents in this area [66].

4.2.3.4.1 Summary of evidence and recommendations for urodynamics

Summary of evidence	**LE**
Preoperative urodynamic testing in women with uncomplicated, clinically demonstrable, SUI does not improve surgical outcome for SUI.	1b
There is no consistent correlation between urethral function tests and subsequent success or failure of SUI surgery.	3
There is no consistent evidence that preoperative DO is associated with surgical failure of MUS in women.	3

Recommendations	**Strength rating**
Perform preoperative urodynamic tests in cases of SUI with associated storage symptoms, cases in which the type of incontinence is unclear, cases in which voiding dysfunction is suspected, and cases with associated pelvic organ prolapse or prior surgery for SUI.	Weak
Perform urodynamic tests if the findings may change the choice of invasive treatment.	Weak
Do not use urethral pressure profilometry or leak point pressure to grade severity of incontinence as they are primarily tests of urethral function.	Strong

4.2.3.5 Pad testing

Please refer to Section 3.7 for the diagnostic accuracy and predictive value of using pad testing to quantify the presence and severity of SUI. The summary of evidence and recommendations can be found in section 3.7.1.

4.2.3.6 Imaging

The role of imaging in SUI patients is limited. Many studies have evaluated imaging of bladder neck mobility by US and MRI and concluded that SUI cannot be identified by a particular pattern of urethro-vesical movement [296]. In addition, the generalised increase in urethral mobility after childbirth does not appear to be associated with de novo SUI [297]. Studies have assessed the use of imaging to investigate the mechanism of action of MUS inserted for SUI. One study suggested that MUS placement decreased mobility of the mid-urethra but not mobility of the bladder neck [109]. Following MUS surgery, a wider gap between symphysis and sling (assessed by imaging) has been shown to correlate with a lower chance of cure of SUI [110]. One study of 72 women post-synthetic sub-urethral MUS surgery has investigated the usefulness of trans-labial US to assess tape functionality. In this study different parameters were measured (distance from tape to urethra, position, and shape during Valsalva manoeuvre, etc.) and concluded that tape position relative to the patient's urethra seems to play a role in treatment outcome [298]. The general role of US in the evaluation and follow-up of women with SUI is unclear, and further research is needed to establish its place in the clinical pathway.

Several imaging studies have investigated the relationship between sphincter volume and function [299] and sphincter volume and outcome of surgery [300] in women. However, no imaging test has been shown to predict the outcome of treatment for SUI. Imaging of the pelvic floor can identify levator ani detachment and hiatus size, although there is little evidence of a relationship to clinical benefit after treatment of SUI.

4.2.3.6.1 Summary of evidence and recommendation for imaging

Summary of evidence	**LE**
Imaging can reliably be used to measure bladder neck and urethral mobility, although there is no evidence of clinical benefit for patients with UI.	2b

Recommendation	**Strength rating**
Do not carry out imaging of the upper or lower urinary tract as part of the routine assessment of stress urinary incontinence.	Strong

*4.2.4 **Disease management***

4.2.4.1 Conservative management

4.2.4.1.1 Obesity and weight loss

Being overweight or obese has been identified as one of the risk factors for LUTS and SUI in many epidemiological studies [136, 137]. There is evidence that the prevalence of both UUI and SUI increases proportionately with BMI [301]. The proportion of patients who undergo surgery for incontinence who are overweight or obese is higher than that of the general population [137]. On the other hand, young, elite athletes, and women who work-out for fitness show a high prevalence of UI/SUI [281, 302].

Three SRs concluded that weight loss was beneficial in improving UI [135, 136, 303]. Five further RCTs reported a similar beneficial effect on incontinence following surgical weight reduction programmes [304-308].

In a prospective study in 160 consecutive women who underwent bariatric surgery, surgically induced weight loss was associated with a significant improvement in pelvic floor disorders, including UI [309]. Similar results reported by prospective single-centre studies investigating the effect of weight loss induced by bariatric surgery revealed that bariatric surgery was associated with substantially reduced UI at eleven months and three years [310, 311].

4.2.4.1.1.1 Summary of evidence and recommendation for obesity and weight loss

Summary of evidence	**LE**
Obesity is one of the risk factors for LUTS and UI in women.	3
Non-surgical weight loss improves UI in overweight and obese women.	1a
Surgical weight loss improves UI in obese women.	1b

Recommendation	Strength rating
Encourage overweight and obese women with LUTS/stress urinary incontinence to lose weight and maintain weight loss.	Strong

4.2.4.1.2 Urinary containment

The evidence for urinary containment derives from the same literature as for containment in OAB-wet. The readers are therefore referred to Section 4.1.4.1.3. The summary of evidence and recommendations for urinary containment can be found in Section 4.1.4.1.3.1.

4.2.4.1.3 Pelvic floor muscle training

Pelvic floor muscle training is used to improve functional and morphological parameters of the pelvic floor, thus improving urethral stability.

An immediate effect of a single PFM contraction is narrowing of the levator hiatus area, increase of urethral closure pressure, and lifting of the bladder and rectum thus preventing occurrence of SUI [312-314]. In an RCT comparing intensive PFMT over a six-month period with no treatment, there were increased muscle strength and endurance, narrowing of the levator hiatus, reduced PFM length, increased muscle volume, and lifting of the bladder neck and rectal ampulla [315]. Pelvic floor muscle training may be used to prevent SUI, e.g., in childbearing women before birth, or as part of a planned recovery programme after childbirth. Most often, PFMT is used to treat existing SUI; sometimes in combination with observation and/or palpation of the muscle contraction by the therapist, or biofeedback (using an apparatus measuring the contraction either by electromyography, manometry, dynamometry, US or MRI). Electrical stimulation and vaginal cones are also used in treatment of SUI based on an assumption of the same mechanism of action.

4.2.4.1.3.1 Efficacy of pelvic floor muscle training

A Cochrane review compared PFMT with no treatment or inactive control treatment and found that women with SUI in the PFMT groups were eight times more likely to report cure [316]. The review also documented significant improvement in SUI and improvement in UI QoL. Pelvic floor muscle training reduced leakage by an average of one episode per day in women with SUI. Women with SUI in the PFMT groups lost significantly less urine in short (up to one-hour) pad tests. The comparison of short pad tests showed considerable heterogeneity, but the findings still favoured PFMT when using a random-effects model. Women in the PFMT group were also more satisfied with treatment and their sexual outcomes were better. Adverse events were rare and minor.

A Cochrane review concluded that there may be some additional effect of adding biofeedback to PFMT. However, this was based on RCTs with training frequency and attention favouring biofeedback [317]. In a recent RCT (61.3% had MUI) comparing the exact same training dosage and attention between groups, use of biofeedback did not yield any additional effect [318]. Group training is cost-effective in treatment of SUI/UI compared to individual treatment [319]. Another Cochrane review concluded that combination of individual assessment/education and group training was equally effective compared to individual treatment, but again the dosage and attention differed between comparison groups [320]. In a more recent RCT with the exact same training dosage and attention in individual and group training, group training was not inferior to individual treatment [319]. It is worth noting that all of the PFMT interventions in these reviews follow individual assessment and teaching before starting PFMT, and most interventions use some sort of measurement tool (biofeedback) in the assessment.

Both the Cochrane review and the ICI concluded that the use of vaginal cones to train the PFMs is more effective than no treatment, but it is inconclusive whether it is more or less effective than structured PFMT [316, 321, 322]. Some women are unable to maintain the cone inside, and some report discomfort and motivation problems and adherence may be low [321].

The Cochrane review [316], the ICI [322] and the National Institute for Health and Care Excellence (NICE) guidelines (2019) [66] all conclude that there is the highest level evidence (1a) to support PFMT in the treatment of SUI/MUI. All SRs conclude that PFMT is less effective if women with MUI and UUI are included in the studies and more effective with more intensive and supervised training. According to the NICE guidelines literature review, PFMT is as effective as surgery for around half of women with SUI, and due to the risks following surgery and absence of adverse effects of PFMT, they recommend three months of supervised PFMT as first-line treatment for SUI and MUI [66].

Pelvic floor muscle training was compared to synthetic MUS surgery in an RCT involving 460 women with moderate to severe SUI [323]. Crossover between treatment arms was allowed and 49% of women in the physiotherapy group and 11.2% of women in the surgery group crossed over to the alternative treatment.

Subjective improvement was reported by 90.8% of women in the surgery group and 64.4% of women in the physiotherapy group at twelve months [323].

4.2.4.1.3.2 Efficacy of electrical stimulation

There is lack of consensus regarding the use of ES to treat SUI. For subjective cure of SUI, a Cochrane review found moderate-quality evidence that ES is probably better than no active treatment [324]. Similar results were found for cure or improvement of SUI, but the quality of evidence was low. There is uncertainty as to whether there is a difference between ES and sham treatment in terms of subjective cure alone because of the very low quality of evidence. For subjective cure or improvement, ES may be better than sham treatment. Any comparison between ES and PFMT and other treatments is hampered by low-quality evidence. One assessor blinded RCT found that PFMT was significantly better than either the use of vaginal cones or electrical stimulation. Only PFMT showed improvement in PFM strength and SUI measured by pad test and leakage episodes compared to control [325]. Adverse effects such as pain and discomfort have been reported, and ES is not tolerated by all women [324].

In an RCT, 132 women assessed by vaginal palpation to have 0–1 on the modified Oxford grading scale (unable to contract the PFM) were randomly assigned to an eight-week intervention of learning to contract via palpation, palpation with pelvic tilt, intravaginal ES, or verbal instruction [326]. The results showed that 63.6%, 69.7%, 33.3% and 18.2% in the four groups, respectively, scored 2 after the intervention. Palpation was significantly more effective that ES, but one third of the ES group had learned a correct PFM contraction [326]. The effect on UI measured by ICIQ-UI-SF was significantly better in the palpation group. An RCT [327] compared electrical stimulation with untreated control in 64 women with 0-1 on the modified Oxford grading scale. After the intervention, the ability to contract the PFMs was acquired by 36% of the experimental group and 12% of the control group. The experimental group also improved by a mean of 2 points more than the control group on the ICIQ-UI-SF score.

4.2.4.1.3.3 Long-term efficacy of pelvic floor muscle training

In a SR including nineteen studies, 1,141 women were followed-up for one to fifteen years after PFMT for SUI [328]. Meta-analysis was not performed due to high heterogeneity of outcome measures and training dosage (frequency, intensity, duration, and adherence). Only two studies provided interventions during follow-up. Losses to follow-up ranged between 0% and 39%. Long-term adherence to PFMT varied between 10% and 70%. Five studies reported that the initial success rate on SUI and MUI was maintained in the long term. Long-term success based on responders in the original trial varied between 41% and 85%. Surgery rates in the long term varied between 4.9% and 58%. It was concluded that short-term outcome of PFMT can be maintained at long-term follow-up without incentives for continued training, but there is a high heterogeneity in both interventional and methodological quality in short- and long-term PFMT studies [328].

4.2.4.1.3.4 Efficacy of pelvic floor muscle training in childbearing women

Pelvic floor muscle training to prevent SUI has been studied during pregnancy and in the postpartum period and the results are not reported separately for SUI and other subgroups of UI. A Cochrane review concluded that PFMT in women with and without UI (combined primary and secondary prevention) during pregnancy, produced a 26% reduced risk of UI during pregnancy and the mid-postnatal period [329]. Furthermore, pregnant continent women (primary prevention) who exercised the PFM during pregnancy were 62% less likely to experience UI in late pregnancy and had 29% lower risk of UI three to six months after giving birth. There is insufficient evidence for a long-term effect of antenatal PFMT beyond six to twelve months postpartum. Compared with usual care, there is no evidence that antenatal PFMT in incontinent women decreases incontinence in late pregnancy (very low-quality evidence), or in the mid- (low-quality evidence) or late postnatal periods (very low-quality evidence).

There have been fewer RCTs in the postpartum period than during pregnancy [329]. No primary prevention studies were found in women after birth. For PFMT started after delivery, in a mixed group of continent and incontinent women, there was uncertainty about the effect on UI risk in the late postnatal period (three trials, 826 women; moderate-quality evidence), and in postnatal women with persistent UI, there is no evidence that PFMT results in a difference in UI at more than six to twelve months postpartum (three trials; 696 women; low-quality evidence). However, another RCT found that UI was less frequent in the intervention group, with 57% of patients still symptomatic, compared to 82% of controls, as was bladder-related problems with a prevalence of 27% in the intervention vs. 60% in the control group [330]. Randomised controlled trials of high interventional and methodological quality are needed in the postpartum period.

4.2.4.1.3.5 Efficacy of Pelvic floor muscle training in elderly women

There have been few RCTs on conservative treatment of SUI in elderly women (> 65 years) and many of the studies combined different modalities, such as BT, lifestyle modifications and PFMT [331]. Some of the studies on PFMT and SUI in the general population have included women > 65 years and PFMT seems to be equally effective in elderly women. A SR on conservative management included 23 trials, with nine of moderate-to-high methodological quality and concluded that PFMT in combination with physical training was effective in reducing UI and improving QoL [332]. Prompted voiding and toileting assistance with functional exercise reduced UI. Other behavioural interventions such as night-time prompted voiding and waking routine had no effect on UI reduction. The most recent ICI consensus publication stated that although there are limited studies of PFMT on UI in frail elderly populations, age and frailty alone should not preclude the use of PFMT in appropriate patients with sufficient cognition to participate [331]. More high-quality RCTs, both in frail and healthy older women (> 80 years of age) are needed.

4.2.4.1.3.6 Composite treatments for PFMT

A Cochrane review found insufficient evidence to state whether there were additional effects by adding PFMT to other active treatments (including vaginal cones, electromagnetic stimulation, biofeedback, continence pessary, drugs) when compared with the same active treatment alone for female SUI or mixed UI. However, these results should be interpreted with caution as most of the comparisons were investigated in small, single trials. Also, none of the included trials reported data on adverse events associated with the PFMT regimen, thereby making it very difficult to evaluate the safety of PFMT [333].

A single-blind RCT evaluated whether peri-operative supervised PFMT was superior to standard care (handout) in terms of improvements in SUI symptoms, cure rate, and/or post-operative filling or voiding symptoms among women undergoing synthetic MUS insertion for SUI. The results showed that supervised PFMT improves SUI cure rates associated with synthetic MUS insertion with OR > 3 when considering symptoms of SUI, but does not improve post-operative continence function as measured by a pad test, nor does it lead to fewer post-operative voiding or filling symptoms [334].

4.2.4.1.3.7 Summary of evidence and recommendations for pelvic floor muscle training

Summary of evidence	**LE**
Pelvic floor muscle training is better than no treatment for improving SUI and QoL in women with SUI and MUI across a range of outcomes, including cure rate, improvement rate, QoL, number and volume of urine leaks and treatment satisfaction.	1a
Pelvic floor muscle training exhibits a low rate of adverse events.	1a
Higher-intensity, supervised treatment regimens confer greater benefit in women receiving PFMT.	1a
There is no extra benefit of combining PFMT with biofeedback.	1b
Short-term benefits of intensive PFMT can be maintained in the long term.	2a
Pelvic floor muscle training in the antenatal period is associated with a reduced risk of UI in late pregnancy and in the short term postnatally.	1a
Postpartum PFMT is effective in women with persistent UI.	1b
The benefit of postpartum PFMT in mixed populations (continent and incontinent) of women is uncertain.	1b
Mid-urethral sling surgery is superior to PFMT in women with moderate-to-severe SUI.	1b
Pelvic floor muscle training commencing in the early postpartum period improves UI in women for up to six months.	1b
There is conflicting evidence on whether the addition of ES increases the effectiveness of PFMT alone.	2a
There is low to moderate certainty evidence suggesting benefit of ES in patients with SUI. In addition, ES may be useful for learning a correct PFM contraction.	1b

Recommendations	Strength rating
Offer supervised intensive pelvic floor muscle training (PFMT), lasting at least three months, as first-line therapy to all women with stress urinary incontinence (SUI) or mixed urinary incontinence (including elderly women and pre- and postnatal women).	Strong
Ensure that PFMT programmes are as intensive as possible.	Strong
Balance the efficacy and lack of adverse events from PFMT against the expected effect and complications from invasive surgery for SUI.	Strong
Consider electrical stimulation for treatment of SUI, or as an adjunct for teaching PFM contraction.	Weak

4.2.4.1.4 Electromagnetic stimulation

Electromagnetic stimulation (EMS) has been evaluated for its role in SUI therapy. In a double-blind RCT of EMS including 70 women with SUI, no effect of EMS over sham in any outcome was recorded [335].

4.2.4.1.5 Electroacupuncture

A SR including 15 RCTs and women with SUI treated by electroacupuncture (EA) demonstrated that EA for SUI was effective. The ICIQ-SF scores improved, and 1-hour urine leakage decreased in patients undergoing EA compared with those receiving sham EA, physical exercise or medication [336].

4.2.4.2 Pharmacological management

4.2.4.2.1 Oestrogen

Oestrogenic drugs including conjugated equine oestrogens, oestradiol, tibolone and raloxifene, are used as hormone replacement therapy (HRT) for women with natural or therapeutic menopause.

Oestrogen treatment for SUI have been tested using oral, transdermal, and vaginal routes of administration. Available evidence suggests that vaginal oestrogen treatment with oestradiol and oestriol is not associated with the increased risk of thromboembolism, endometrial hypertrophy, and breast cancer seen with systemic administration [236-238]. Vaginal (local) treatment is primarily used to treat symptoms of vaginal atrophy in postmenopausal women.

A Cochrane SR looked at the use of oestrogen therapy in postmenopausal women given local oestrogen therapy and seventeen studies focused on SUI [236]. There is also a narrative review of oestrogen therapy in urogenital diseases [337]. The Cochrane review found that vaginal oestrogen treatment improved symptoms of SUI in the short term [236]. There were small, low-quality trials comparing vaginal oestrogen treatment with phenylpropanolamine, PFMT, ES and its use as an adjunct to surgery for SUI. Local oestrogen was less likely to improve UI than PFMT but no differences in UI outcomes were observed for the other comparisons. A single trial of local oestrogen therapy comparing a ring device to pessaries found no difference in UI outcomes, although more women preferred the ring device. In one trial, no significant adverse effects following vaginal administration of oestradiol for vulvovaginal atrophy over a two year period were reported [338].

Vaginal oestrogen therapy can be given as conjugated equine oestrogen, oestriol or oestradiol in vaginal pessaries, vaginal rings, or creams. The ideal treatment duration and the long-term effects are uncertain. A review of local oestrogen treatment showed improvement of UI over placebo with vaginal rings, which were favoured subjectively over pessaries [339].

One RCT in postmenopausal women showed a benefit of adding intravaginal oestriol to vaginal ES and PFMT in female SUI [340].

Studies of systemic HRT with non-urogenital primary outcomes have looked for change in urinary continence in secondary analyses. Large trials using conjugated equine oestrogens showed a higher rate of development or worsening of UI compared to placebo and no SUI improvement [341-346]. In a single RCT, use of raloxifene was not associated with development or worsening of UI [347]. Two small RCTs using oral oestriol or oestradiol as HRT for vulvovaginal atrophy suggested that UI symptoms were improved although the evidence was unclear [66, 348].

4.2.4.2.1.1 Summary of evidence and recommendations for oestrogens

Summary of evidence	LE
Vaginal oestrogen therapy improves SUI for postmenopausal women in the short term.	1a
Neoadjuvant or adjuvant use of local oestrogens is ineffective as an adjunct to surgery for SUI.	2b
Systemic HRT using conjugated equine oestrogens does not improve SUI and may worsen pre-existing UI.	1a

Recommendations	Strength rating
Offer vaginal oestrogen therapy to postmenopausal women with stress urinary incontinence (SUI) and symptoms of vulvovaginal atrophy.	Strong
In women taking oral conjugated equine oestrogen as hormone replacement therapy (HRT) who develop or experience worsening SUI, discuss alternative HRT.	Strong

4.2.4.2.2 Duloxetine

Duloxetine inhibits the presynaptic reuptake of neurotransmitters, serotonin (5-hydroxytryptamine; 5-HT) and noradrenaline (NE).

In the sacral spinal cord, an increased concentration of 5-HT and NE in the synaptic cleft increases stimulation of 5-HT and NE receptors on the pudendal motor neurons, which in turn increases the resting tone and contraction strength of the urethral striated sphincter.

Duloxetine was evaluated as a treatment for female SUI or MUI in three SRs [171, 349, 350]. Improvement in UI compared to placebo was observed with no clear differences between SUI and MUI. One study reported cure for UI in 10% of patients. An improvement in the UI QoL questionnaire was not found in the study, which used this as a primary endpoint. In a further study comparing duloxetine, 80 mg daily, with PFMT alone, PFMT + duloxetine, and placebo [351], duloxetine reduced leakage compared to PFMT or no treatment. Global improvement and QoL were better for combined therapy than no treatment. There was no significant difference between PFMT and no treatment in this trial.

Two open-label studies with a follow-up of ≥ 1 year evaluated the long-term effect of duloxetine in controlling SUI [352, 353]. Both studies had a high patient withdrawal rate, due to lack of efficacy and a high incidence of adverse events, including nausea and vomiting (≥ 40% of patients), dry mouth, constipation, dizziness, insomnia, somnolence, and fatigue.

A SR showed significant efficacy for duloxetine compared to placebo in women with SUI, but with increased risk of adverse events [350]. The adverse effects of duloxetine include mental health problems and suicidal ideation. A meta-analysis of four RCTs including 1,910 women with SUI reported no suicidality, violence, or akathisia events, but suggested that discontinuation rate due to adverse events was around one in seven and that the harm may outweigh the benefit of treatment [354]. A meta-analysis of twelve placebo-controlled trials involving almost 3,000 patients showed that in patients with major depressive disorders there were no significant differences in the incidence of suicide-related events with duloxetine vs. placebo [355].

4.2.4.2.2.1 Summary of evidence and recommendations for duloxetine

Summary of evidence	LE
Duloxetine improves SUI in women, but the chances of cure are low.	1a
Duloxetine may cause significant gastrointestinal and central nervous system adverse effects, leading to a high rate of treatment discontinuation, although these symptoms may be limited to the first weeks of treatment.	1a

Recommendations	Strength rating
Offer duloxetine (where licensed) to selected patients with stress urinary incontinence unresponsive to other conservative treatments and who want to avoid invasive treatment, counselling carefully about the risk of adverse events.	Strong

Duloxetine should be initiated and withdrawn using dose titration because of the high risk of adverse events.	Strong

4.2.4.2.3 Adrenergic agonists

A Cochrane SR including 22 RCTs involving 673 women and seven different adrenergic drugs (phenylpropanolamine in eleven trials, midodrine in two, norepinephrine in three, clenbuterol in another three, terbutaline in one, eskornade in one and Ro 115-1240 in one) found weak evidence that adrenergic agonists may improve SUI. Moreover, side effects did occur but were usually minor. More evidence is needed to compare adrenergic drugs with other drugs for SUI and, also with PFMT [356].

4.2.4.3 Surgical management

4.2.4.3.1 General considerations

The use of polypropylene mesh as synthetic MUS for the treatment of SUI has recently come under scrutiny following concerns about long-term complications. In some European countries such as the UK, the use of synthetic MUS has been paused and pelvic mesh was the subject of a parliamentary review published in July 2020 [357]. This review concluded that *"For many women mesh surgery is trouble free and leads to improvements in their condition. However, this is not the case for all. There is no reliable information on the true number of women who have suffered complications. While they may be in the minority, that does not diminish the catastrophic nature of their suffering or the importance of providing support to them and learning from what has happened to them"*.

The range of complications highlighted during the process of this parliamentary review included [357]:

- pain;
- recurrent infections;
- mobility issues;
- recurring or new incontinence/urinary frequency;
- recurring or new prolapse;
- haemorrhage;
- bowel issues;
- erosion of mesh; this can be into the vagina and/or other organs;
- sexual difficulties; including pain on intercourse and a loss of sex life;
- autoimmune issues;
- psychological impacts.

When considering the choice of surgical treatments for SUI the Panel advises individual clinicians to abide by any national or local rules that may be in place regarding mesh surgery. It is essential for clinicians to point out the deficiencies in the long-term evidence regarding mesh use in SUI with specific reference to the complications highlighted above.

In line with the recommendations from NICE [66] and the Scientific Committee on Emerging and Newly Identified Health Risks (SCENIHR) paper [358], the Panel agrees that surgeons and centres performing surgery should:

- be trained in the field of incontinence and for each surgical procedure they perform/offer;
- perform sufficient numbers of a procedure to maintain expertise of him/herself and the surgical team;
- be able to offer alternative surgical treatments;
- be able to deal with the complications of surgery;
- provide suitable arrangements for long-term follow-up.

The establishment of accurate and complete databases registering the interventions, patient profiles and surgical complications or all surgical treatments for SUI is recommended to allow the generation of robust long-term data.

Many surgical procedures are available for uncomplicated SUI patients and the Panel analysed the results of the different procedures in terms of clinical effectiveness, safety and cost-effectiveness based on the recent ESTER SR and economic evaluation [359] and previous SRs including those from the Cochrane Collaboration [360-364].

The outcome parameters used to evaluate surgery for SUI have been limited to:

- continence rate;
- patient-reported outcome measures;
- general and procedure-specific complications;
- generic, specific (UI) and associated (sexual and bowel) QoL.

In this context, it has to be taken into account that a number of products may no longer be available and therefore the recommendations may not be transferable to current devices. The Panel makes a strong recommendation that new devices are only used as part of a structured research programme and their outcomes monitored in a registry, until there is adequate evidence of safety and efficacy.

4.2.4.3.1.1 Shared decision making

The Panel recognises that a shared decision-making approach is paramount when any treatments are proposed but felt particular emphasis should be made for the topic area of surgical treatment for SUI. There are a number of different options available for patients which vary in both efficacy and safety profile. Consequently, the amount of information given to patients considering surgery for SUI is substantial. The Panel would unequivocally advise adherence to the fundamental principles of the shared decision-making process which include:

- full participation from the patient;
- delivery of factual information regarding benefits and risks of any particular treatment, if possible adapted to the specific situation of the patient;
- delivery of information about the experience and expertise of the HCP/institution delivering the treatment, especially for highly specialised procedures such as complex SUI and mesh removal surgery;
- confirmation that the patient understands the information given;
- clinician understanding and documenting individual patient preferences;
- facilitation of deliberation and initial decision-making;
- patient opportunity to consider and confirm any decisions made;
- clinician assistance with implementation of the final decision.

4.2.4.3.1.2 Recommendations for surgical treatment

Recommendations	**Strength rating**
Offer patients who have explored/failed conservative treatment options a choice of different surgical procedures, where appropriate, and discuss the advantages and disadvantages of each approach.	Strong
Use new devices for the treatment of stress urinary incontinence (SUI) only as part of a structured research programme. Their outcomes must be monitored in a registry or as part of a well-regulated research trial.	Strong
Employ a shared decision-making approach when deciding on appropriate treatment for SUI.	Strong

4.2.4.3.2 Surgery for women with uncomplicated stress urinary incontinence

The principal procedures evaluated are:

- open and laparoscopic colposuspension;
- autologous “traditional” slings;
- bulking agents;
- synthetic MUS.

4.2.4.3.2.1 Open- and laparoscopic colposuspension surgery

Open Burch colposuspension was previously considered the most appropriate surgical intervention for SUI, and was used as the comparator in RCTs of newer, less-invasive surgical techniques. These include laparoscopic techniques, which have enabled colposuspension to be performed with a minimally-invasive approach.

Open colposuspension

A number of SRs have covered open surgery for SUI, with a large number of RCTs [359, 361-364]. The Cochrane review on open colposuspension [364] included 55 trials comprising 5,417 women. In most of these trials, open Burch colposuspension was used as the comparator to an experimental procedure. Within the first year, complete continence rates of 85–90% were achieved for open colposuspension, while failure rates in terms of recurrent UI were 17% up to five years and 21% at > 5 years. The risk of reoperation after Burch colposuspension is estimated at 6% within five years [77] and 10.8% within nine years [365]. The reoperation rate specifically for UI was only 2%. Burch colposuspension was associated with a higher rate of development of enterocoele/vault/cervical prolapse (42%) and rectocele (49%) at five years compared to TVT (23% and 32%, respectively). The rate of cystocoele was similar after Burch colposuspension (37%) and after TVT (41%). The Cochrane review concluded that open colposuspension is an effective treatment for SUI and around 70% of women can expect to be dry at five years after surgery.

Laparoscopic colposuspension

A Cochrane review reported on twelve trials comparing laparoscopic to open Burch colposuspension [362]. Although these procedures had a similar subjective cure rate, there was limited evidence suggesting the objective outcomes were poorer for laparoscopic colposuspension. The ESTER SR [359], based on a network meta-analysis, showed that at twelve months open colposuspension was more effective than laparoscopic colposuspension (nine trials) but these findings were based on low-quality evidence. The Surface Under the Cumulative Ranking (SUCRA) score, which is a numerical representation of the overall performance of the treatment, and represents a single number associated with each intervention, was 76.7% after open colposuspension and 48.9% after laparoscopic colposuspension. Laparoscopic colposuspension had a shorter duration and subsequent hospital stay and may be slightly more cost-effective when compared with open colposuspension after 24 months' follow-up.

Single-port laparoscopic Burch can be an alternative treatment, although data confirming efficacy are limited [366].

Complications

Voiding difficulties are more common after laparoscopic colposuspension than after retropubic MUS (7.5% vs. 5.1%) [359]. There was no difference between open colposuspension and retropubic MUS (7.8% vs. 7.5%; OR: 0.87) [359]. The results for the comparisons of *de novo* symptoms of urgency or UUI between open colposuspension and retropubic MUS (11% vs. 8%, OR: 1.49) did not favour either treatment and showed wide confidence intervals [359]. The rate of bladder or urethral perforation was higher for laparoscopic colposuspension compared with open colposuspension (3.7% vs. 0.7%; OR: 4.65) [359].

4.2.4.3.2.1.1 Summary of evidence and recommendation for open and laparoscopic colposuspension surgery

Summary of evidence	**LE**
High subjective cure rates are associated with both open and laparoscopic colposuspension for treatment of SUI.	1a
Objective cure rates are higher for open compared to laparoscopic colposuspension.	1a
Colposuspension is associated with a higher long-term risk of POP than MUS.	1a
Laparoscopic colposuspension has a shorter hospital stay and may be more cost-effective than open colposuspension.	1a
Laparoscopic colposuspension is associated with higher rates of intraoperative bladder perforation and postoperative voiding dysfunction compared to open colposuspension.	1a
The rates of *de novo* urinary urgency following colposuspension are similar to other surgical treatments for SUI.	1a

Recommendation	**Strength rating**
Offer colposuspension (open or laparoscopic) to women seeking surgical treatment for SUI following a thorough discussion of the risks and benefits relative to other surgical modalities.	Strong

4.2.4.3.2.2 Autologous sling

In the past, autologous, cadaveric, xenograft, and synthetic materials have been used for bladder neck pubovaginal sling. Nowadays, use of autologous tissue, either rectus sheath or fascia lata, is the most studied material with the strongest evidence base to support its use [367]. The ESTER SR included three trials of autologous sling vs. open colposuspension, six trials of autologous sling vs. retropubic MUS and one trial of autologous sling vs. transobturator MUS. The quality of evidence was overall very low. The pooled estimate showed that fascial sling had a higher cure rate at one year than open colposuspension (OR: 1.24), retropubic MUS (OR: 1.06) and transobturator MUS (OR: 1.44) but without significance. The SUCRA score was 89.4% for women cured after autologous fascial sling. A sub-analysis from a Cochrane review showed autologous slings had better effectiveness compared to colposuspension at one to five years' follow-up [364]. In an RCT of Burch colposuspension vs. autologous slings, complete continence rates decreased substantially over time in both arms. At five years, the continence rate of colposuspension was 24.1% compared to 30.8% for fascial slings. Satisfaction remained higher in the sling group (83% vs. 73%) and was directly related to continence status [368].

Complications
Adverse events rates were similar for the two treatment groups (Burch 10% and sling 9%) although postoperative obstruction was found exclusively in the sling group. Voiding difficulties appear to be more common after autologous sling (15.4% vs. 10.2%; OR: 1.46) than after retropubic MUS. Compared with open colposuspension, the rate of bladder or urethral perforation was lower for traditional sling (0.6% vs. 3.0%; OR:0.20) [359].

4.2.4.3.2.2.1 Summary of evidence and recommendation for autologous sling

Summary of evidence	**LE**
High cure rates are associated with autologous sling placement for treatment of SUI.	1a
Autologous sling is more effective in terms of cure rate than colposuspension.	1a
Autologous sling has a similar rate of adverse events compared to open colposuspension, with higher rates of voiding dysfunction and postoperative UTI, but lower rates of POP and bladder or urethral perforation.	1a

Recommendation	**Strength rating**
Offer autologous sling placement to women seeking surgical treatment for stress urinary incontinence following a thorough discussion of the risks and benefits relative to other surgical modalities.	Strong

4.2.4.3.2.3 Urethral bulking agents
The concept of this procedure originates from the idea that intra- or peri-urethral injection of an agent able to form artificial cushions under/around the urethra increases resistance at the bladder outlet and facilitates continence.

In a Cochrane SR [369], 2,004 patients were included from fourteen trials of seven different types of intraurethral injection: Ethylene vinyl alcohol copolymer (Uryx™), glutaraldehyde cross-linked collagen (Contigent©), a porcine dermal implant (Permacol©), solid silicone elastomer (Macroplastique©), autologous fat, pyrolytic carbon (Durasphere©), calcium hydroxylapatite (Coaptite©), Polytetrafluoroethylene (Polytef™) and hyaluronic with dextran polymer (Zuidex©). The conclusions state that the available evidence base remains insufficient to guide practice [369].

A recent SR of 56 studies conclude that available data support the use of Bulkamid® and Macroplastique®, which have shown a short-term efficacy of 30%–90% and 40%–85%, respectively, and long-term efficacy of 42%–70%, and 21%–80%, respectively. Bulkamid® appears to have a more favourable safety profile, with no cases of erosion or migration of product associated with its use. Direct comparisons of urethral bulking agents were not performed [370].

A SR of 23 studies using Macroplastique© including 958 patients showed a 75% improvement with 43% dry rate at < 6 months and a 64% improvement and 36% cure rate at > 18 months [371]. A review of 514 elderly women with SUI treated with various agents showed a reduced pad weight in 73% at one-year follow-up, independent of the material injected [372]. The heterogeneity of the populations, the variety of materials used and the lack of long-term follow-up limit guidance for practice. Most of the studies showed a tendency for short-term improvement in UI, with the exception of one RCT, which did not find a difference between saline and fat injection [373].

One trial of 30 women showed a weak, non-significant advantage in terms of patient satisfaction after mid-urethral injection in comparison to bladder neck injection but with no demonstrable difference in continence levels [369]. One small trial found 30% (six out of 20) of patients developed retention of urine following peri-urethral injection compared with 5% (one out of 20) with transurethral injection [374]. A small RCT found no difference in efficacy between mid-urethral and bladder neck injection of collagen [375]. One study treated patients who had received radiotherapy with injection of Bulkamid® and reported ~25% cure at short-term follow-up [376].

Bulking agent injection is generally safe, and the most frequent adverse event is UTI. However, autologous fat or hyaluronic acid should not be used due to the risk of fatal embolism and local abscess formation, respectively [373, 377].

A study reported that women treated by a high-volume surgeon (defined > 75 urethral bulking injections performed over surgical career) had an increased chance of cure and a lower risk of hospital contact postoperatively, compared with women treated by a low-volume surgeon. The risk of 30-day hospital contact was also lower for women treated in a high-volume department (defined > 15 procedures performed per year) [378].

Comparison with other surgical procedures
Two RCTs compared collagen injection to conventional surgery for SUI (silicon particles vs. autologous sling and collagen vs. other surgical procedures). The studies reported greater efficacy but higher complication rates for open surgery [379, 380].

In a recent non-inferiority clinical trial, women with primary SUI were randomised to TVT or polyacrylamide hydrogel urethral bulking agent injection (Bulkamid®) [381]. Mid-urethral TVT slings were associated with better satisfaction and cure rates than Bulkamid® in primary SUI. For objective cure rate, the cough stress test was negative in 95.0% of patients who underwent TVT vs. 66.4% who underwent Bulkamid®.

Another SR examining the relative efficacy of urethral bulking agents [382] included six studies in the quantitative synthesis for a total of 710 patients. The authors found that bulking agents are less effective than other surgical procedures according to subjective improvement after treatment (relative risk [RR] = 0.70; 95% CI: 0.53-0.92). However, the main limitation of this SR and meta-analysis was the absence of a common objective outcome measure to evaluate effectiveness.

4.2.4.3.2.3.1 Summary of evidence and recommendations for urethral bulking agents

Summary of evidence	**LE**
Urethral bulking agents may provide short-term improvement and cure in women with SUI.	1b
Bulking agents are less effective than MUS, Burch colposuspension or autologous sling for cure of SUI and repeat injections may be required in order to achieve sustained benefits.	1b
Autologous fat and hyaluronic acid as bulking agents have a higher risk of adverse events.	1a
Adverse event rates for urethral bulking agents are lower compared to open surgery.	2a
There is no evidence that one type of bulking agent is better than another.	1b
The peri-urethral route of injection of bulking agents may be associated with a higher risk of urinary retention compared to the transurethral route.	2b

Recommendations	**Strength rating**
Offer urethral bulking agents to women seeking surgical treatment for stress urinary incontinence (SUI) following a thorough discussion of the risks and benefits relative to other surgical modalities.	Strong
Offer urethral bulking agents to women with SUI who request a low-risk procedure with the understanding that efficacy is lower than other surgical procedures, repeat injections are likely, and long-term durability and safety are not established.	Strong
Do not offer autologous fat and hyaluronic acid as urethral bulking agents due to the higher risk of adverse events.	Strong

4.2.4.3.2.4 Laser treatment
A SR including sixteen published studies, involving 899 patients with SUI, evaluated effects of laser treatment. The change in the ICIQ-SF score at one, two, and six months was -5.49, -4.97, and -5.48, respectively. The improvement in a 1-hour pad weight test results at one, three-, and twelve-months post treatment was -5.59, -4.96, and -5.82, respectively. The Pelvic organ prolapse/UI sexual questionnaire (PISQ-12) score increased by 5.39 (95% CI: 1.20-9.58) following treatment. Subgroup analysis identified the type and severity of UI as the potential source of heterogeneity. Adverse effects were reported in six of the sixteen trials and affected only a small number of patients. Most adverse events were mild or moderate and required no medical intervention or

resolved in a few days. According to this SR, vaginal laser therapy appears to be a safe, effective, and minimally-invasive treatment option for SUI that can be well tolerated by patients [383].

Another SR including 31 studies and 1,530 women confirmed that laser therapy seems to have a beneficial effect on prolapse and UI, but the level of evidence remains low without any suggestion on the laser type to be used, furthermore no studies are available on cost-effectiveness, in particular looking at a longer-term perspective, because surgical results may have more longevity than laser treatment, which may require re-application [384].

Another SR including a total of 27 studies, evaluated the effects of Er:YAG and Fractional CO_2 lasers. The overall quality of studies was poor, and 23/27 studies were case series (LE:4). Er:YAG laser showed a modest reduction in mild SUI cases, with benefits lasting a maximum of thirteen to sixteen months. Fractional CO_2 laser showed an improvement of mild SUI in few studies; however, no long-term data are available. When reported, adverse events were insignificant, however, they were not reported systematically [260]. A randomised double-blinded sham-controlled study in women with SUI [385] showed a significant reduction in the ICIQ-UI-SF after Er:YAG laser therapy vs. sham manipulated. However, only 21% were subjectively dry (ICIQ-SF = 0) vs. 4% of sham-operated women.

Overall, several limitations have been noted in the current literature regarding vaginal lasers, including variation in laser settings and protocols, short term follow-up, lack of urodynamic evaluation, and poor reporting of appropriate objective measures and adverse events. Based on the available literature, lasers cannot currently be recommended as a treatment option for SUI.

4.2.4.3.2.4.1 Summary of evidence and recommendations for laser treatment

Summary of evidence	**LE**
Several limitations have been noted in the current literature regarding vaginal laser treatment for SUI. These include variation in laser settings and protocols, short term follow-up, lack of urodynamic evaluation, and poor reporting of appropriate objective measures and adverse events.	1b

Recommendations	**Strength rating**
Do not offer vaginal laser therapy to treat stress urinary incontinence symptoms outside of a well-regulated clinical research trial.	Strong

4.2.4.3.2.5 Mid-urethral slings

Early clinical studies identified that non-autologous synthetic slings should be made from monofilament, nonabsorbable material, typically polypropylene, constructed as a 1–2 cm-wide mesh with a large pore size (macroporous) and coloured to facilitate removal [386]. Mid-urethral slings are now the most frequently used surgical intervention in Europe for women with SUI.

Transobturator route versus retropubic route

A Cochrane meta-analysis of MUS procedures for SUI in women was performed in 2017, spanning January 1947 to June 2014 [387]. Moderate-quality evidence from 55 studies showed variable, but comparable, subjective cure rates between retropubic (71–97%) and transobturator (62–98%) slings in the short term (up to one year). No difference in the objective cure rate in the short term was found. However, the ESTER SR [359], based on a network meta-analysis including 36 trials of overall moderate quality, showed that at twelve months retropubic MUS was more effective than transobturator MUS (OR: 0.74). The SUCRA scores for women cured after retropubic MUS were 89.1% vs. 64.1% after transobturator MUS. However, there was no significant difference in these cure rates between the two approaches. Similarly, based on 40 moderate-quality trials, retropubic MUS performed better than the transobturator approach in terms of symptom improvement (RR: 0.76) but the difference was, again, not significant.

Analysis of a randomised equivalence trial of retropubic vs. transobturator MUS for the treatment of SUI in women shows similar findings. This trial confirms equivalence of objective cure rates at twelve but not at 24 months (77.3% and 72.3% objective cure rate for retropubic and transobturator surgery). For both types of MUS, subjective and objective treatment success decreased over time and equivalence of the retropubic and the transobturator routes could not be confirmed at 24 and 60 months, with retropubic MUS demonstrating an increased benefit, despite satisfaction remaining high in both arms [388]. Five years after surgical treatment,

objective success was 7.9% greater in women assigned to retropubic sling compared to transobturator sling (51.3% vs. 43.4%), not meeting prespecified criteria for equivalence. Patient satisfaction decreased over five years but remained high and similar between treatment arms (retropubic sling 79% vs. transobturator sling 85%) [389].

In terms of long-term complications, data are scant but in one study de novo OAB developed in 14% of patients at ten years post transobturator tension-free vaginal tape (TVT-O) [390]. In a multicentre prospective study of women undergoing TOT, failure of previous anti-incontinence procedures was the only predictor of recurrence of SUI [390].

A long-term cohort study of retropubic TVT showed an 89.9% objective cure rate and a 76.1% subjective cure rate at ten years. Overall, 82.6% of patients reported high satisfaction with surgery [391]. A long-term prospective study on transobturator sling showed that, at 145 months, the objective and subjective cure rates were 78.9% and 62.6%, respectively; with no significant deterioration in SUI cure rates over time [392]. Another long-term follow-up study of patients treated with TVT showed a sustained response with 95.3%, 97.6%, 97.0% and 87.2% of patients being cured or improved at five, seven, eleven and seventeen years, respectively [393]. The ESTER network meta-analysis based on cure and improvement suggested that, when comparing surgical treatments for SUI, retropubic MUS, transobturator MUS and traditional sling had the highest efficacy, but this ranking does not consider the complication profile of these techniques. The short- to medium-term adverse event data are sparse [359].

Several health economic analyses of MUS procedures have been published with conflicting results. In a review of 26 economic evaluations and on the basis of a cost–utility and value of information analysis over a ten-year period, the authors concluded that MUS remains among the most cost-effective approaches [360]. A primary economic evaluation of retropubic vs. transobturator tapes over a five-year time period suggested that the latter may be cost-effective and cost-saving compared to the standard TVT approach [394]. Conversely, the findings from the ESTER network meta-analysis stated that over a lifetime, retropubic MUS was, on average, the least costly and most effective surgery but the level of uncertainty in these analyses was high.

Insertion using a skin-to-vagina direction versus a vagina-to-skin direction

The Cochrane review on MUS for female SUI showed no difference in the short- and medium-term subjective cure rates in vagina-to-skin (inside-out) vs. skin-to-vagina (outside-in) approaches, based on moderate-quality evidence [395]. Voiding dysfunction seems to be more frequent in the vagina-to-skin (inside-out) transobturator tape (TOT) group, but this approach is associated with a lower frequency of vaginal perforations (RR: 0.25). Due to the low quality of the evidence, it is unclear whether the lower frequency of vaginal perforations with this approach is responsible for the lower rate of vaginal tape erosions. Likewise, a meta-analysis of RCTs demonstrated no significant difference in efficacy between outside-in and inside-out approaches, but vaginal perforations were, again, less frequent in the latter group (2.6% vs. 11.8%, OR: 0.21) [396]. The five-year data of a prospective, non-RCT of the two techniques showed a high objective success rate (82.6 vs. 82.5%, respectively) with no difference between the two approaches [397]. In a secondary analysis of the E-TOT study (a study of transobturator MUS in the treatment of women with urodynamic MUI), no difference in the patient-reported success rates was found between the vagina-to-skin (inside-out) and the skin-to-vagina (outside-in) groups (63.2% and 65.5%, respectively; OR: 1.11) at nine years follow-up [398].

Complications of synthetic mid-urethral slings

The ESTER network meta-analysis noted that comparative assessment of adverse events between different procedures was not always possible due to the lack of available data [359]. Direct comparisons using head-to-head meta-analyses were mainly carried out for retropubic MUS, transobturator MUS or single-incision slings. The authors did, however, comment that "For other intervention comparisons, the number of studies was generally small and the CIs wide. However, there was some evidence to suggest that bladder perforation was more likely to occur after retropubic MUS than after transobturator MUS, open colposuspension or traditional sling". In particular, the retropubic approach for MUS was associated with a significantly higher rate of bladder perforation than transobturator MUS was (5% vs. 0.2%). Regarding *de novo* voiding dysfunction, 36 studies compared transobturator MUS with retropubic MUS, favouring the former (OR: 0.51). For pain, it is worth noting that it was defined and measured in many different ways across individual trials and across Cochrane reviews. Some pain outcomes were categorised by location (e.g., suprapubic) or time (e.g., short, or long term). These discrepancies made it difficult to combine data from different studies. Data were available mainly for the comparison between retropubic and transobturator MUS and other surgical procedures. However, groin pain was more frequent after transobturator MUS than retropubic MUS (6.3% vs. 1.3%; OR: 3.80). Converse findings were reported for suprapubic pain, which was higher following TVT (1.2% vs. 4.0%; OR: 0.37). Visceral injury

(0.5% vs. 2.4% OR: 0.36), mean operating time, intraoperative blood loss and hospital stay were lower in the transobturator than retropubic MUS groups. The overall vaginal erosion risk was low and comparable in both groups [359].

The rate of tape/mesh exposure or extrusion between retropubic and transobturator MUS was similar (2.1% vs. 2.4%; OR: 1.10). The exact time points at which measurements occurred could not be derived from the Cochrane reviews but most studies were reported to have a short follow-up period (≤ 12 months), with only a few studies having ≥ 2 years' follow-up [359]. Repeat surgery for UI was more common in the transobturator group (RR = 8.79); however, the data are limited and of low quality.

A population-based study performed in Scotland in > 16,000 women with SUI showed a similar rate of complications between mesh and non-mesh surgery [399]. However, a recent study of > 92,000 patients followed in the UK National Health Service showed a significant (9.8%) rate of complications using a broader definition and following patients for a longer period [400]. The level of detail regarding the precise nature of complications in this paper was poor. These findings suggest that, as with any SUI surgery, MUS can be associated with complications and fully informed consent is mandatory.

In general, the available published evidence would suggest that MUS does not seem to be associated with significantly higher rates of morbidity and complications compared to other surgeries for SUI, such as open retropubic Burch colposuspension. Pelvic organ prolapse is more common after colposuspension while voiding dysfunction occurs more often after MUS [364]. The ESTER review has commented that the level of detail regarding short-to-medium adverse event data is poor for all SUI surgeries [359] and the Panel is aware of the recent findings from the Independent Medicines and Medical Devices Safety Review in the UK that has raised the possibility that the level of complications from synthetic MUS may be higher than the medical literature would suggest [357].

The ESTER SR included seven studies comparing reintervention after transobturator and retropubic MUS [359]. Pooled analysis of these studies showed wide CIs and considerable uncertainty around the estimated OR (twelve-month post-surgery: 1.37). At one to five years after the procedure, rates of repeat continence surgery were higher in women undergoing transobturator MUS (18.3%) compared with retropubic MUS (0.5%), although only two studies were available for the analysis. A similar trend was observed in studies with a longer follow-up period (> 5 years) but the pooled analysis of these studies showed wide CIs. For retropubic MUS surgery, the bottom-to-top route was 10% more efficacious than top-to-bottom in terms of subjective cure and it was associated with less voiding dysfunction, bladder perforations and vaginal erosion [359].

Single-incision mid-urethral slings

Although there have been many studies published on single-incision devices, it should be noted that there are significant differences in technical design between devices and it may be misleading to make general statements about them as a class of operation. It should also be noted that some devices have been withdrawn from the market (e.g., TVT Secur®, Minitape, MiniArc®), and yet evidence relating to these devices may still be included in current meta-analyses. There is evidence to suggest that single-incision slings are quicker to perform and cause less postoperative thigh pain, but there is no difference in the rate of chronic pain. There is insufficient evidence for direct comparisons between single-incision slings, and no conclusions have been reached about differences between devices.

The ESTER SR showed, based on low-quality evidence, that at twelve months, retropubic and transobturator MUS were more effective than single-incision sling (TVT, OR: 0.50; TOT, OR: 0.68). The SUCRA score was 39.8% for women cured after single-incision slings. However, since not all single-incision devices have been assessed in a comparative RCT, it may be unsafe to assume that they are collectively technically similar or exhibit the same levels of efficacy.

A recent multicentre noninferiority RCT compared single-incision slings (Ajust® and Altis®) with conventional MUS during 36 months of follow-up, defining patient-reported success as a response of very much or much improved in the Patient Global Impression of Improvement questionnaire. After 36 months of follow-up success was reported by 177 of 246 patients (72.0%) and by 157 of 235 patients (66.8%) in the single-incision and MUS group, respectively. The authors conclude that single-incision slings were noninferior to standard MUS with respect to patient-reported success at fifteen months, and the percentage of patients reporting success remained similar in the two groups at 36-month follow-up [401].

Complications of single-incision slings
Meta-analysis of comparison between single-incision sling and transobturator MUS showed similar rates of mesh erosion or extrusion between interventions (4.8% vs. 3.7%; OR: 1.23). Rates of postoperative pain were higher after retropubic MUS than after single-incision slings (19.2% vs. 6.8%; OR: 0.21).

A noninferior RCT showed at 36 months a percentage of patients with groin or thigh pain of 14.1% with single-incision slings and 14.9% with MUS. Over the 36-month follow-up period, the percentage of patients with tape or mesh exposure was 3.3% with single-incision slings and 1.9% with MUS, and the percentage who underwent further surgery for SUI was 2.5% and 1.1%, respectively [401]. A multicentre single blind RCT compared postoperative pain scores and efficacy of a single-incision sling (Ajust®, n = 100) and a standard TOT (n = 56). Immediate postoperative pain was significantly lower for single-incision sling group, but *de novo* dyspareunia was higher (38.5% vs. 25%, with no statistical difference). No differences were reported in the objective cure at twelve months (90% vs. 88%) [402].

The rate of unspecified pain was higher after transobturator MUS than after single-incision sling at twelve months (1.0% vs. 5.2%; OR: 0.24) and 24 months (1.4% vs. 10.4%; OR: 0.16). Single-incision sling was associated with more repeat surgery compared with transobturator MUS (5.1% vs. 2.9%; OR: 1.57). At > 3 years after the procedure, the repeat surgery rate was 10.3% for single-incision slings vs. 7.6% for transobturator MUS (OR: 1.42) [359].

Sexual function after synthetic mid-urethral sling surgery
A SR examining the effect of synthetic MUS on female sexual function suggested different and contradictory results between studies. More studies have shown an improvement, or no change, in sexual function because of a reduction in coital incontinence, anxiety and avoidance of sex. Dyspareunia was the most common cause of worsening of sexual function and the precise incidence is difficult to estimate as many studies did not report it [403]. A meta-analysis of outcome measures in trials of sling procedures suggests that single-incision slings are associated with a significantly higher improvement in sexual function, however conflicting evidence was seen, compared to standard MUS procedures [404]. A recent RCT comparing single-incision slings with MUS showed similar outcomes with respect to QoL and sexual function in the two groups, with the exception of dyspareunia. Among the 290 women responding to a validated questionnaire, dyspareunia was reported by 11.7% in the single-incision group and 4.8% in the MUS group [401].

4.2.4.3.2.5.1 Summary of evidence and recommendations for mid-urethral slings

Summary of evidence	**LE**
The retropubic MUS appears to provide better patient-reported subjective and objective cure of SUI, compared with colposuspension.	1a
Synthetic MUSs inserted by the transobturator or retropubic route provide equivalent patient-reported outcomes at one year.	1a
Synthetic MUSs inserted by the retropubic route have higher patient-reported cure rates in the longer term.	1b
Long-term analyses of MUS cohorts showed a sustained response beyond 10 years.	2b
The retropubic route of insertion, compared with the transobturator route, is associated with a higher intraoperative risk of bladder perforation and a higher rate of voiding dysfunction.	1a
The transobturator route of insertion is associated with a higher risk of groin pain than the retropubic route.	1a
Long-term analysis of MUS showed no difference in terms of efficacy for the skin-to-vagina (outside-in) compared to vagina-to-skin (inside-out) directions up to nine years.	2a
The top-to-bottom (inside-out) direction in the retropubic approach is associated with a higher risk of postoperative voiding dysfunction.	1b
The comparative efficacy of Ajust® and Altis® single-incision slings against conventional MUS at fifteen and 36 months is non-inferior.	1b
Operating times for insertion of single-incision MUSs are shorter than for standard retropubic slings.	1b
Blood loss and immediate postoperative pain are lower for insertion of single-incision slings compared with conventional MUS.	1b

The rate of mesh exposure, repeat SUI surgery and dyspareunia at 3 years is higher for single-incision slings (Ajust® and Alits®) compared to conventional MUS.	1b
There is no evidence that other adverse outcomes from surgery are more or less likely with single-incision slings than with conventional MUS.	1b
In women undergoing surgery for SUI, coital incontinence is likely to improve.	3
Overall, there is conflicting evidence regarding sexual function following SUI surgery.	1a

NB: Most evidence on single-incision slings is from studies using the tension-free vaginal tape secure device, and although this device is no longer available, it is, however, still included in many systematic reviews and meta-analyses.

Recommendations	**Strength rating**
Offer a mid-urethral sling (MUS) to women seeking surgical treatment for stress urinary incontinence following a thorough discussion of the risks and benefits relative to other surgical modalities.	Strong
Inform women that long-term outcomes from MUS inserted by the retropubic route are superior to those inserted via the transobturator route.	Strong
Inform women of the complications associated with MUS procedures and discuss all alternative treatments in the light of recent publicity surrounding surgical mesh.	Strong
Inform women who are being offered single-incision slings (Ajust® and Altis®), that short term efficacy appears equivalent compared to conventional MUS.	Strong
Inform women who are being offered a single-incision sling that long-term efficacy remains uncertain.	Strong

4.2.4.3.2.6 Other treatments for uncomplicated stress urinary incontinence

Intravesical balloon treatment has been explored for women with SUI. The Vesair® gas-filled intravesical balloon differs from other treatment methods in that it is not intended to increase outlet resistance or minimise urethral hypermobility but to attenuate the fluctuation of intravesical pressure when the abdominal pressure increases [405, 406]. Two sham controlled RCTs have evaluated the Vesair® intravesical balloon [405, 407]. Both reported significant reductions in incontinence symptoms and pad weight, but QoL was not significantly different between study arms. High levels of adverse events were reported in both trials as well as significant numbers of withdrawals/device removals. The most common adverse events were dysuria, urgency, gross haematuria and UTIs.

Mechanical devices have been used to treat SUI for centuries. There are several devices available which act either by supporting the bladder neck or urethra to address urethral hypermobility, or by occluding the urethral lumen. A Cochrane review of eight RCTs that included three small trials comparing mechanical devices to no treatment found inconclusive evidence of benefit [408]. Another SR of mechanical devices concluded that there was insufficient evidence to support their use in women [409]. The place of mechanical devices in the management of SUI remains in question. Currently, there is little evidence from controlled trials on which to judge whether their use is better than no treatment, and large well-conducted trials are required for clarification. There is also insufficient evidence in favour of one particular device and few comparisons of mechanical devices with other forms of treatment [408].

Systematic reviews support the use of compression devices such as the adjustable compression therapy and artificial urinary sphincter (AUS) devices [410, 411]. Although these procedures are largely reserved for those with recurrent or complicated SUI (see Section 4.2.4.3.3.3 External compression devices), these recent additions to the literature include the use of some compression devices for uncomplicated SUI.

4.2.4.3.2.6.1 Summary of evidence and recommendations for other treatments for uncomplicated stress urinary incontinence

Summary of evidence	**LE**
Implantation of an artificial sphincter can improve or cure incontinence in women with uncomplicated SUI.	3
Implantation of the adjustable compression therapy (ACT®) device may improve uncomplicated SUI.	3
Complications, mechanical failure and device explantation often occur with both the artificial sphincter and ACT©.	3

Recommendations	Strength rating
Offer mechanical devices to women with mild-to-moderate SUI who fail conservative treatment only as part of a well-conducted research trial.	Strong
Inform women receiving artificial urinary sphincter or adjustable compression device (ACT®) that, although cure is possible, even in expert centres there is a high risk of complications, mechanical failure, or a need for explantation.	Strong

4.2.4.3.3 Surgery for women with complicated stress urinary incontinence

This section addresses surgical treatment for women with complicated SUI as defined in Section 4.2.2.

Women with associated genitourinary prolapse are included in Section 4.7.

The principal procedures included are:

- Colposuspension or MUS (synthetic or autologous) following failed primary SUI surgery;
- External compression devices: adjustable compression therapy (ACT®) and AUS;
- Adjustable slings.

4.2.4.3.3.1 Colposuspension or mid-urethral sling (synthetic or autologous) following failed primary stress urinary incontinence surgery

Urinary incontinence following SUI surgery may indicate persistent or recurrent SUI, or the development of *de novo* UUI, or both. Careful evaluation including urodynamics is an essential part of the work-up of these patients.

Most of the data on surgery for SUI refer to primary operations. Even when secondary procedures have been included, it is unusual for the outcomes in this subgroup to be separately reported. When they are, the numbers of patients are usually too small to allow meaningful comparisons. This means that no firm recommendations can be made regarding which modality is best for the treatment of recurrent SUI, and previous SRs have commented that in view of the absence of any evidence, clinicians must rely largely on expert opinion or personal experience when advising patients about treatment options [412].

The ESTER network meta-analysis revealed that women with transobturator MUS were more likely to undergo repeat surgery than those who had retropubic MUS, and fewer repeat operations were observed after retropubic MUS compared with other interventions [359]. A recent update of two Urinary Incontinence Treatment Network trials [413] compared the retreatment-free survival rates by initial surgical procedure. Five-year retreatment-free survival rates were 87%, 96%, 97%, and 99% for Burch colposuspension, autologous fascial sling, transobturator, and retropubic MUS, respectively. Types of surgical retreatment included autologous fascial sling (19), bulking agent (18), and synthetic sling (1). This suggests that MUS may not be preferred in cases of recurrent SUI [413].

In these cohorts, 6% of women after standard anti-incontinence procedures were retreated within five years, mostly with injection therapy or autologous fascial sling. Not all women with recurrent SUI chose surgical retreatment.

A Cochrane review attempted to summarise the data regarding different types of MUS procedures for recurrent SUI after failure of primary surgical therapy [414]. The literature search identified 58 records, but all were excluded from quantitative analysis because they did not meet eligibility criteria. Overall, there were no data to recommend or refute any of the different management strategies for recurrent or persistent SUI after failed MUS surgery. Another SR looking at the effectiveness of MUS in recurrent SUI included twelve studies and reported an overall subjective cure rate following MUS for recurrent SUI after any previous surgery of 78.5% at an average 29 months' follow-up [415]. The subjective cure rate following MUS after previous failed MUS was 73.3% at follow-up of sixteen months. The authors commented that there was a lower cure rate with transobturator compared to the retropubic tape for recurrent SUI after previous surgery. Conflicting evidence comes from a SR assessing the effectiveness and complications of various surgical procedures for female recurrent SUI and reported on data from 350 women in ten RCTs with a mean follow-up of 18.1 months [416]. The authors found no difference in patient-reported and objective cure/improvement rates between retropubic and transobturator MUS in the setting of recurrent SUI. There was also no significant difference between Burch colposuspension and retropubic MUS in terms of patient-reported improvement or objective cure/improvement.

A SR of older trials of open surgery for SUI suggested that the longer-term outcomes of repeat open Burch colposuspension may be poor compared to autologous fascial slings [417]. Similarly, one large non-randomised comparative series suggested that cure rates after more than two previous operations were 0% for open Burch colposuspension and 38% for autologous fascial sling [418].

4.2.4.3.3.1.1 Summary of evidence for surgery in those with recurrent stress urinary incontinence following failed primary surgery

Summary of evidence	LE
Failure rates of single-incision slings appear higher than with other types of MUS.	1a
The incidence of repeat surgery is higher in those women who underwent primary transobturator compared to retropubic MUS.	1a
The five-year failure rate of Burch colposuspension appears higher than for synthetic or traditional sling procedures.	2b
Some studies suggest that retropubic synthetic MUS procedures appear to be more effective than transobturator MUS for the treatment of recurrent SUI, but this is not a consistent finding in the literature.	1a
Most procedures are less effective when used as second-line procedures.	2a
Burch colposuspension has similar short-term patient-reported or objective cure rates when compared to TVT for treatment of recurrent SUI.	1b
Autologous sling appears superior to Burch colposuspension for treatment of recurrent SUI.	2b

4.2.4.3.3.2 Adjustable slings

Although adjustable slings are most commonly used for treatment of complicated SUI, they may also be considered for uncomplicated SUI. There are no RCTs investigating outcome of adjustable sling insertion for women with SUI. There are limited data from cohort studies on adjustable tension slings with variable selection criteria and outcome definitions. Few studies have included sufficient numbers of patients or have long enough follow-up to provide useful evidence.

One adjustable sling is the Remeex system (Neomedic International®, Terrassa, Spain), which was investigated in a prospective study of 230 women with SUI [419]. After a mean follow-up of 89 months, 165 patients were cured of SUI (71.7% in the intention-to-treat [ITT] analysis, 80.5% in per protocol [PP] analysis). Forty patients remained incontinent (17.4% in ITT, 19.5% in PP) and 88 patients required readjustment of the sling during follow-up.

The tension was increased in 82 cases due to recurrence of SUI and reduced in six due to outlet obstruction. The currently available adjustable sling devices have differing designs, making it difficult to draw general conclusions about them as a class of procedure.

4.2.4.3.3.2.1 Summary of evidence for adjustable slings

Summary of evidence	LE
There is only low-level evidence to suggest that adjustable MUS devices may be effective for cure or improvement of SUI in women.	3
There is no evidence that adjustable slings are superior to standard MUS.	4

4.2.4.3.3.3 External compression devices

External compression devices are usually used for treatment of recurrent SUI after failure of previous surgery but can be considered for primary treatment. Studies have largely included patients with profound intrinsic failure of the sphincter mechanism, characterised by low VLPP or urethral closure pressure [410, 411]. The two intracorporeal external urethral compression devices available are the adjustable compression therapy (ACT®) device and AUS.

ACT®: Using US or fluoroscopic guidance, the ACT® device is inserted by placement of two inflatable spherical balloons; one on either side of the bladder neck. The volume of each balloon can be adjusted through a subcutaneous port placed within the labia majora. A SR including eight studies published between 2007 and 2013 with follow-up of one to six years revealed 15–44% of patients considered that their SUI had been cured and 66–78.4% were satisfied [410]. The explantation rate was 19–31%. In these studies, a significant reduction in the number of pads used daily was consistently observed after ACT® balloon placement and QoL was significantly improved. The authors concluded that ACT® balloons constitute a reasonable, minimally-invasive alternative for treatment of female SUI due to intrinsic sphincter deficiency, especially in patients who have already experienced failure of standard surgical treatment.

AUS: The major advantage of AUS over other anti-incontinence procedures is the perceived ability to be able to void normally [408]. There have been a few case series of AUS in women, with populations of 45–215 patients and follow-up of one month to 25 years [420-423]. Case series have been confounded by varying selection criteria, especially the proportion of women who have neurological dysfunction or who have had previous surgery. Most patients achieved an improvement in SUI, with reported subjective cure in 59–88%. Common adverse effects included mechanical failure requiring revision (≤ 42% at ten years) and explantation (5.9–15%). In a retrospective series of 215 women followed-up for a mean six years, the risk factors for failure were older age, previous Burch colposuspension and pelvic radiotherapy [423].

Early reports of laparoscopically implanted AUS do not have sufficient patient populations or sufficient follow-up to be able to draw any conclusions [424, 425].

A more recent SR included seventeen studies, but all were retrospective or prospective non-comparative case series [411]. Most patients had undergone at least one anti-incontinence surgical procedure prior to AUS implantation (69.1–100%). Outcomes revealed that complete continence rates were 61–100%. The rates of explantation were 0–45%, erosion rates were 0–22% and mechanical failure rates were 0–44%. The authors concluded that AUS can provide excellent functional outcomes in women with SUI resulting from intrinsic urethral sphincter deficiency but at the cost of high morbidity.

4.2.4.3.3.3.1 Summary of evidence for external compression devices

Summary of evidence	LE
Implantation of an artificial sphincter improves or cures incontinence in women with SUI caused by sphincter insufficiency.	3
Implantation of the AUS device may improve complicated SUI.	3
Implantation of the ACT® device may improve complicated SUI.	3
Complications, mechanical failure, and device explantation often occur with both the artificial sphincter and ACT®.	3
Explantation of AUS is more frequent in older women and among those who have had previous Burch colposuspension or pelvic radiotherapy.	3

4.2.4.3.3.4 Recommendations for complicated stress urinary incontinence

Recommendations	Strength rating
Management of complicated stress urinary incontinence (SUI) should only be offered in centres with appropriate experience (see Section: 4.2.4.3.1).	Strong
Base the choice of surgery for recurrent SUI on careful evaluation, including individual patient factors and considering further investigations such as cystoscopy, multichannel urodynamics, as appropriate.	Strong
Inform women with recurrent SUI that the outcome of a surgical procedure, when used as second-line treatment, is generally inferior to its use as first-line treatment, both in terms of reduced efficacy and increased risk of complications.	Weak
Only offer adjustable mid-urethral sling as primary surgical treatment for SUI as part of a structured research programme.	Strong
Consider secondary synthetic sling, bulking agents, Burch colposuspension, autologous sling or artificial urinary sphincter (AUS) as options for women with complicated SUI.	Weak
Inform women receiving AUS or ACT® device that, although cure is possible, even in expert centres, there is a high risk of complications, mechanical failure, or a need for explantation.	Strong

4.2.4.3.4 Surgery for stress urinary incontinence in special patient groups

4.2.4.3.4.1 Stress urinary incontinence surgery in obese women

There is no agreement about the outcome of incontinence surgery in obese women. Secondary analysis of an RCT on retropubic and transobturator tapes for treatment of women with SUI suggests that obese women experience inferior outcome compared to non-obese women. Stratification of patients according to BMI (< 30 and > 30) shows a significant difference in objective dry rates (negative pad test) at one year (85.6% vs. 67.8%) and five years (87.4% vs. 65.9%) and subjective cure (absence of SUI symptoms) at one year (85.8% vs. 70.7%) and five years

(76.7% vs. 53.6%). At one and five years, 6.7% and 16.3% of patients who were initially dry (negative pad test) after surgery developed a positive pad test [426, 427].

Conversely, short-term outcome of single-incision MiniArc® sling showed comparable objective cure rates (negative cough stress test) at two years (86% and 81% in non-obese and obese women, respectively); similar improvement of the Urinary Distress Inventory six and Incontinence Impact Questionnaire seven was observed in non-obese and obese women [428]. Objective cure rate was also similar with Altis® (88% and 87% in non-obese and obese women) at two years follow-up [429].

4.2.4.3.4.2 Stress urinary incontinence surgery in elderly women

Age appears to be a significant factor in outcome from SUI surgery but there is conflicting evidence. An RCT of 537 women comparing retropubic to transobturator tape, showed that increasing age was an independent risk factor for failure of surgery over the age of 50 years [430]. An RCT assessing risk factors for the failure of TVT vs. TVT-O in 162 women also found that age was a specific risk factor for recurrence at one year [431]. In addition, based on a sub-analysis of a trial cohort of 655 women at two years' follow-up, it was shown that elderly women were more likely to have a positive stress test at follow-up, were less likely to report objective or subjective improvement in stress and UUI, and were more likely to undergo retreatment for SUI. There was no difference in time to postoperative normal voiding [432].

Another RCT comparing immediate TVT vs. no surgery (or delayed TVT) in older women, confirmed efficacy of surgery in terms of QoL and satisfaction, but with more complications in the surgical arm [433].

Furthermore, a SR of the efficacy of treatments of UI in older patients suggests that MUS is successful in older patients (≥ 65 years) with 5.2–17.6% reporting persistent SUI after surgery. No difference in the frequency of *de novo* UUI, persistent UUI or persistent SUI was found in older patients [361].

4.2.4.3.4.3 Summary of evidence and recommendations for stress urinary incontinence surgery in special patient groups

Summary of evidence	LE
Incontinence surgery may be safely performed in obese women; however, outcomes may be inferior.	1
The risk of failure from surgical repair of SUI, and the risk of adverse events, appears to increase with age.	2b
There is no evidence that any surgical procedure has greater efficacy or safety in older women than another procedure.	4

Recommendations	Strength rating
Inform obese women with stress urinary incontinence (SUI) about the increased risks associated with surgery, together with the lower probability of benefit.	Weak
Inform older women with SUI about the increased risks associated with surgery, together with the likelihood of lower probability of benefit.	Weak

4.2.5 Follow-up

The follow-up of patients with SUI is dependent on the treatment given. For conservative and physical therapies, sufficient time should be allowed for the demonstration of a therapeutic effect. For pharmacological treatment, early follow-up is recommended. For most surgical interventions, short-term follow-up should be arranged to assess efficacy and identify any early postoperative complications.

The Panel is supportive of long-term outcome assessment via registries and recognises the paucity of high-quality long-term data, specifically regarding complications from surgery.

4.3 Mixed urinary incontinence

The term MUI is broad because it may refer to equal stress and urgency symptoms, stress-predominant symptoms, urgency-predominant symptoms, urodynamic stress urinary incontinence (USUI or USI) with DO or USUI with clinical urgency symptoms, but no DO [434]. The challenge of this broad definition is that it leads to inconsistencies when evaluating treatment options and outcomes.

4.3.1 Epidemiology, aetiology and pathophysiology

The prevalence rates of MUI vary widely in the literature. Most epidemiological studies have either not considered subtypes of UI, or only reported on SUI, UUI and MUI. The current literature is unclear regarding the population prevalence and risks for the different UI subtypes [435]. There are many urinary symptom questionnaires used in epidemiological research, with varying evidence of validity. Caution is needed when comparing epidemiological studies that do or do not report a separate MUI subgroup, and when generalising from population level data to clinical practice. The problems arise from significant heterogeneity in terms of types of questionnaires/surveys used, population parameters, variable response rates, varying definitions of MUI, and outcome measures.

It seems apparent, however, that MUI is the second most common form of UI, after SUI, with most studies reporting a 7.5–25% prevalence [435]. One can extrapolate that among women with UI, approximately one-third have MUI [436]. In a secondary analysis of a large clinical trial, 655 women were evaluated for UI and their response to treatment [437]. It was found that 50–90% of women fell into the category of MUI based on patient-reported answers to the Medical Epidemiologic and Social Aspects of Aging and Urinary Distress Inventory (UDI) questionnaires. However, when objective criteria such as urodynamic findings were used, only 8% of women were categorised as having MUI.

Mixed urinary incontinence is usually caused by a combination of the same factors that cause SUI and UUI. Several factors may be responsible for its development, including oestrogen deficiency, abnormalities in histomorphology, and microstructural changes [438]. One report postulates that an incompetent sphincter and bladder neck allow urine to enter the proximal urethra during stress, causing a urethro-detrusor reflex that triggers involuntary detrusor contraction, which then causes urgency and UUI [439]. Another study has shown that urine flow across the urethral mucosa increases the excitability of the micturition reflex [440]. Ultimately, it is unlikely that one theory or risk factor can explain the development of MUI and its symptoms; it is more probable that disturbances in several elements and the lack of bladder compensation results in the development of MUI [438].

4.3.2 Diagnostic evaluation

Assessment of patients with MUI begins with a thorough history of the patient's urinary symptoms and follows the recommendations set out in the general evaluation and diagnosis of LUTS in Chapter 3. It is conventional to try and categorise MUI as either stress or urge predominant.

Mixed urinary incontinence is difficult to diagnose, as the condition comprises many phenotypes. Some women exhibit detrusor contractions provoked by physical stressors, some have unprovoked detrusor contractions, and many have no abnormal detrusor contractions, but still report urine leakage with the sensation of urgency. Some women with urgency symptoms do not manifest UUI because their urethral sphincter is strong and often able to prevent urine leakage [441].

The role of urodynamics in MUI is unclear but establishing objective degrees of SUI and DO incontinence may help in counselling patients about the most appropriate initial treatment option.

4.3.2.1 Summary of evidence and recommendations for the diagnosis of mixed urinary incontinence

Summary of evidence	**LE**
There is no evidence that urodynamics affects outcomes of treatment for MUI.	3

Recommendations	**Strength rating**
Complete a thorough history and examination as part of the assessment of mixed urinary incontinence (MUI).	Strong
Characterise MUI as either stress-predominant or urgency-predominant where possible.	Weak
Use bladder diaries and urodynamics as part of the multimodal assessment of MUI to help inform the most appropriate management strategy.	Strong

*4.3.3 **Disease management***

4.3.3.1 Conservative management

Women with MUI generally have more severe symptoms and respond less well to treatment than women with only SUI or UUI [442]. Clinicians are encouraged to begin treatment for MUI with conservative management directed toward the most bothersome component of the symptom spectrum and to reserve surgery as a last resort [441].

4.3.3.1.1 Pelvic floor muscle training

An RCT comparing PFMT with and without an audiotape for 71 women with UI did not find any difference between the two treatment arms [443]. Mean number of incontinent episodes per day decreased from 3.9 overall to 3.2 for participants with MUI. Six months after completing the course of exercises, approximately one third of all enrolees reported that they continued to note good or excellent improvement and desired no further treatment.

A small RCT including 34 women with SUI and MUI compared eight weeks of PFMT with no treatment and found that PFMT significantly increased PFM strength, improving QoL, and reduced the frequency of UI episodes compared to no treatment [444]. Another RCT including SUI and MUI confirmed these results [445].

A multicentre randomised controlled non-inferiority trial on 467 women with MUI was conducted in ten hospitals. Participants were randomised 1:1 to receive EA (36 sessions over twelve weeks with 24 weeks of follow-up) or PFMT–solifenacin (5 mg/day) over 36 weeks. In women with moderate-to-severe MUI, EA was not inferior to PFMT–solifenacin in decreasing the 72-hour incontinence episodes (between-group difference, –1.34%) [446].

In a comparative study of the effectiveness of behavioural therapy and PFMT (combined with MUS vs. sling alone in women with MUI), 416 (86.7%) had post-baseline outcome data and were included in the primary twelve-month analyses [447]. The UDI score in both groups significantly decreased (178.0 to 30.7 points in the combined group, 176.8 to 34.5 points in the sling-only group). The model estimated between-group difference, did not meet the minimal clinically important difference threshold. Adherence to the behavioural therapy and PFMT regimes, which is a prerequisite for achieving a satisfactory outcome, was not reported in the study.

A Cochrane review comparing PFMT with no or sham treatment included 31 RCTs from fourteen countries, but there was only one study including women with MUI and one with UUI and none of them reported data on cure, improvement, or number of episodes of these subgroups [316].

The effect of combining biofeedback with PFMT has already been fully addressed in Section 4.2.4.1.3, and there was no evidence of any additional benefit in a population with predominantly MUI.

4.3.3.1.2 Bladder training

Details on BT programmes are given in Section 4.2.4. The ICI 2017 [322] concluded that for women with UUI or MUI, PFMT and BT are effective first-line conservative therapies. One RCT assigned 108 women with diagnoses of SUI (n = 50), UUI (n = 16), or MUI (n = 42) to six weeks of BT and PFMT or BT alone [448]. Overall, and in the SUI and MUI subgroups, significantly more patients in the BT and PFMT group reported cure and improved symptoms.

4.3.3.1.3 Electrical stimulation

A Cochrane review on ES for SUI included participants with SUI or stress-predominant MUI. Twenty-five percent of the included trials were deemed to have a high risk of bias due to a variety of factors, including baseline differences between groups and industry funding. For subjective cure or improvement of SUI, low-quality evidence indicated that ES was better than no active treatment or sham treatment. Electrical stimulation for OAB and SUI is covered in Sections 4.1.4.1.5.4 and 4.2.4.1.3.2.

4.3.3.2 Summary of evidence and recommendations for conservative management in mixed urinary incontinence

Summary of evidence	**LE**
Pelvic floor muscle training appears less effective for MUI than for SUI alone.	2
Pelvic floor muscle training is better than no treatment for improving UI and QoL in women with MUI.	1a
Bladder training combined with PFMT may be beneficial in the treatment of MUI.	1b

Recommendations	Strength rating
Treat the most bothersome symptom first in patients with mixed urinary incontinence (MUI).	Weak
Offer bladder training as a first-line therapy to adults with MUI.	Strong
Offer supervised intensive pelvic floor muscle training, lasting at least three months, as a first-line therapy to all women with MUI (including elderly and postnatal women).	Strong

4.3.3.3 Pharmacological management

Many RCTs include patients with MUI with predominant symptoms of either SUI or UUI but few report outcomes separately for those with MUI compared to pure SUI or UUI groups.

4.3.3.3.1 Anticholinergics

In an RCT of 854 women with MUI, tolterodine ER was effective for improvement of UUI but not SUI, suggesting that the efficacy of tolterodine for UUI was not altered by the presence of SUI [449]. In another study (n = 1,380) tolterodine was equally effective in reducing urgency and UUI symptoms, regardless of whether there was associated SUI [450]. Similar results were found for solifenacin [451, 452].

4.3.3.3.2 Duloxetine

In one RCT of duloxetine vs. placebo, 588 women were stratified into either stress-predominant, urgency-predominant or balanced MUI groups. Duloxetine was effective for improvement of incontinence and QoL in all subgroups, although results in the stress-predominant groups were better [453]. Treatment-emergent adverse event rate in the duloxetine group was 61.3% with discontinuation rates of 15.7%. Adverse event rates were higher in those participants taking other concomitant antidepressant agents.

Duloxetine was found to have equal efficacy for SUI and MUI in an RCT (n = 553) following secondary analysis of respective subpopulations, but no adverse events data were reported [454].

4.3.3.3.3 Summary of evidence and recommendations for pharmacological management of mixed urinary incontinence

Summary of evidence	LE
Limited evidence suggests that anticholinergic drugs are effective for improvement of the UUI component in patients with MUI.	2
Duloxetine is effective for improvement of both SUI and MUI symptoms, but adverse event rates are high.	1b

Recommendations	Strength rating
Treat the most bothersome symptom first in patients with mixed urinary incontinence (MUI).	Weak
Offer anticholinergic drugs or beta-3 agonists to patients with urgency-predominant MUI.	Strong
Offer duloxetine (where licensed) to selected patients with stress-predominant MUI unresponsive to other conservative treatments and who want to avoid invasive treatment, counselling carefully about the risk of adverse events.	Weak

4.3.3.4 Surgical management

The surgical treatment options for MUI, include all the anti-incontinence procedures as outlined in the SUI Section 4.2.4.3.

Many RCTs include patients with pure SUI or pure UUI as well as patients with MUI. However, few RCTs report separate outcomes for MUI subgroups.

Post hoc analysis of a large RCT showed that in women undergoing either autologous fascial sling or Burch colposuspension, the outcomes were poorer for women with a concomitant complaint of preoperative urgency [432]. A similar post hoc review of another RCT comparing transobturator and retropubic MUS showed that the greater the severity of preoperative urgency, the more likely that treatment would fail [98]. However, an earlier study had found that surgery provided similar outcomes, whether or not urgency was present prior to surgery (this study included only a few patients with urodynamic DO). Another RCT including 93 patients with MUI showed a significant improvement in continence and QoL in the group that had TVT and botulinum toxin A (Botox®) rather than with either treatment alone [455].

In a secondary analysis of a study of transobturator TVTs in the treatment of women with urodynamic MUI, no difference in patient-reported success rates was found between the vagina-to-skin (inside-out) and the skin-to vagina (outside-in) groups (63.2% and 65.5%, respectively) at nine years' follow-up [398].

Analysis of the trial populations included in the meta-analysis on single-incision slings suggests that the evidence can be generalised to women who have predominantly SUI, and no other clinically severe LUT dysfunction. The evidence is not adequate to guide choice of surgical treatment for those women with MUI, severe POP, or a history of previous surgery for SUI.

Research trials should define accurately what is meant by MUI. There is a need for well-designed trials comparing treatments in populations with MUI, and in which the type of MUI has been accurately defined.

4.3.3.4.1 Summary of evidence and recommendations for surgery in patients with mixed urinary incontinence

Summary of evidence	**LE**
Women with MUI are less likely to be cured of their UI by SUI surgery than women with SUI alone.	2
The response of pre-existing urgency symptoms to SUI surgery is unpredictable.	1b

Recommendations	**Strength rating**
Treat the most bothersome symptom first in patients with mixed urinary incontinence (MUI).	Weak
Warn women that surgery for MUI is less likely to be successful than surgery for stress urinary incontinence alone.	Strong
Inform women with MUI that one single treatment may not cure urinary incontinence; it may be necessary to treat other components of the incontinence problem as well as the most bothersome symptom.	Weak

4.4 Underactive bladder

Underactive bladder is a common clinical entity, defined by the ICS as "a symptom complex characterised by a slow urinary stream, hesitancy, and straining to void, with or without a feeling of incomplete bladder emptying sometimes with storage symptoms" [456]. Diagnosis of UAB is based on clinical symptoms and the presentation and aetiology can be variable.

This differs from DU, which is a diagnosis based on urodynamic studies. Detrusor underactivity is defined by the ICS as "*a detrusor contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or failure to achieve complete bladder emptying within a normal time span*" [1]. Acontractile detrusor is specified when there is no measurable detrusor contraction.

Female voiding dysfunction is defined by the ICS as "*a diagnosis based on symptoms and urodynamic investigations characterised by abnormally slow and/or incomplete micturition, based on abnormally slow urine flow rates and/or abnormally high PVR volume*" [113]; ideally on repeated measurement to confirm abnormality. Pressure–flow studies may be required to determine the precise cause of the voiding dysfunction [31].

*4.4.1 **Epidemiology, aetiology, pathophysiology***

4.4.1.1 Epidemiology

Underactive bladder as an entity remains difficult to characterise, partly because its corresponding urodynamic correlate, DU, remains loosely defined, leading to significant variability in diagnostic criteria across research studies and significant overlap of symptoms with other conditions. As a consequence of the variable definition, reported prevalence also varies and ranges from 12-45% in women, with increased prevalence seen with age [75] and in institutionalised elderly women [457].

Several studies have demonstrated similar prevalence rates for DU in the ambulatory setting of around 12–19% [458-460]. As would be expected, voiding symptoms consistent with UAB are higher. In a large cross-sectional, population-based internet survey conducted in the USA, UK and Sweden including 15,861 women aged ≥ 40 years, 20.1% had weak flow, 27.4% had incomplete bladder emptying and 38.3% had terminal dribbling [5].

Both DO during filling and DU in the voiding phase of urodynamic studies can co-exist (formerly known as detrusor hyperactivity with impaired contractility [DHIC]) and one study showed the prevalence of this finding was over 30% in elderly women [457].

4.4.1.2 Aetiology

The presence of DU in diverse clinical groups suggests multifactorial aetiology [461]. Idiopathic DU is probably partly an age-dependent decrease in detrusor contractility with no other identifiable causes, but young women can also have DU. There are many secondary causes of DU, including neurogenic (e.g., multiple sclerosis, multiple systemic atrophy, spinal cord injury, spina bifida, Parkinson's disease, hydrocephalus, transverse myelitis, stroke, Guillain–Barré syndrome, diabetes mellitus, and pelvic nerve injury), myogenic (prolonged bladder overdistension, diabetes mellitus, and BOO) and iatrogenic (pelvic surgery) causes [462].

4.4.1.3 Pathophysiology

Many pathways are involved in normal detrusor contraction, and there are different possible sites of dysfunction [75] with a variety of mechanisms involved in UAB (see Figure 1):

- Central circuits and centres (prefrontal cortex, periaqueductal gray, pontine micturition centre and hypothalamus): failure of integration or processing.
- Efferent pathways (sacral cord, sacral nerves, pelvic nerves, and postganglionic neurons): impaired detrusor activation.
- Afferent pathways (peripheral afferent nerves, anterolateral white column, and posterior column): early termination of voiding reflex.
- Muscle (detrusor myocytes and extracellular matrix): loss of intrinsic contractility.

Different aetiologies can share common pathophysiological mechanisms: for example, diabetes mellitus affects mainly afferent pathways and the detrusor muscle; and neurogenic diseases affect central circuits and efferent/ afferent pathways.

Figure 1: Management and treatment of women presenting with urinary incontinence, site of dysfunction, major aetiological factors, mechanisms

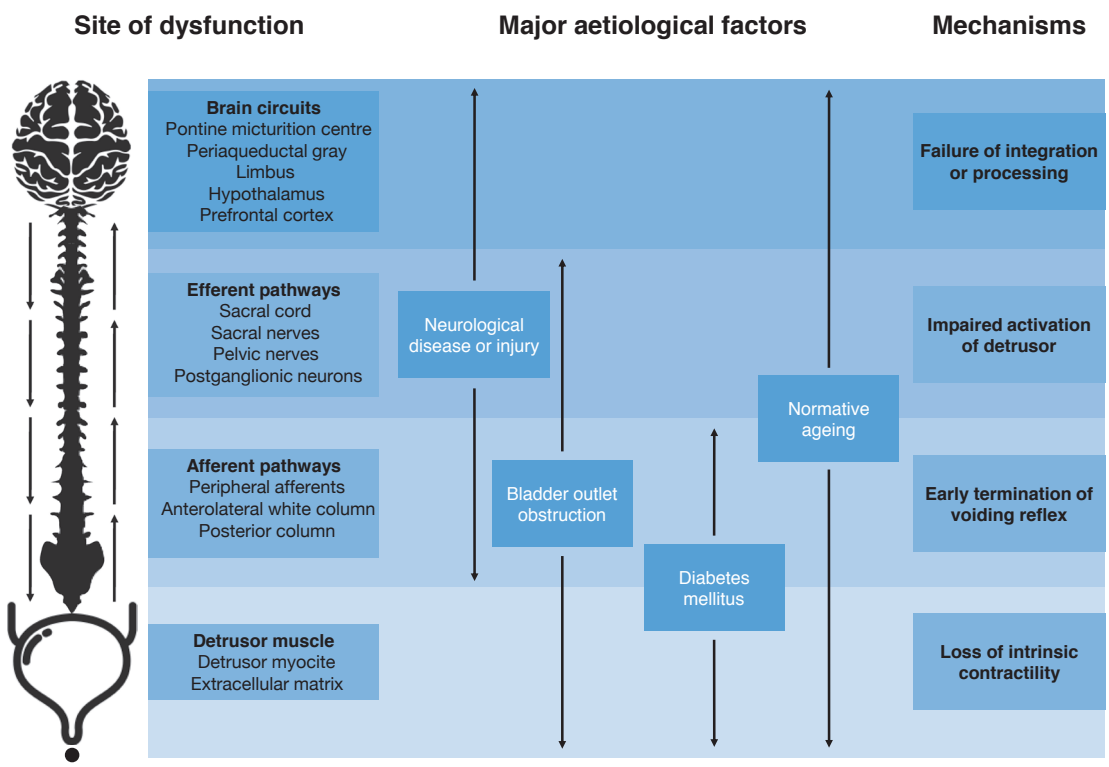

**Figure reproduced with permission from the publisher, from Osman N. et al. [785].*

*4.4.2 **Classification***

There is no current classification system of UAB. Patients can be classified according to presumed aetiology or pathogenic mechanism, but without sufficient longitudinal data or high-level evidence to establish prognostic factors, the classification of UAB patients in terms of relevant clinical characteristics or risk of complications is not possible.

*4.4.3 **Diagnostic evaluation***

4.4.3.1 Symptoms associated with detrusor underactivity

A retrospective study correlated LUTS with urodynamic findings in 1,788 patients (1,281 women). Women with DU, defined as detrusor pressure at maximum flow rate (PdetQmax) < 20 cm H2O, maximum flow rate (Qmax) < 15 mL/s, BVE < 90% and no sign of obstruction on video-urodynamic studies, had a significantly higher occurrence of reduced and/or interrupted stream, hesitancy, feeling of incomplete bladder emptying, palpable bladder, and absent and/or decreased sensation compared with women with normal pressure and flow [463]. A qualitative study on a small sample of male and female patients diagnosed with DU reported a variety of LUTS and associated impact on QoL. Storage symptoms of nocturia, increased daytime frequency, and urgency, and the voiding symptoms of slow stream, hesitancy, and straining were reported by over half of the patients. A sensation of incomplete emptying and post-micturition dribble were also frequently described. The impact of their symptoms on QoL was variable, but in general, storage symptoms were more bothersome [464].

Based on current data, it is not possible to find a pivotal symptom or collection of symptoms to identify DU patients. The ICI Questionnaire-Underactive Bladder (ICIQ-UAB) has been developed as a research PROM tool [465].

4.4.3.2 Urodynamic studies

Non-invasive studies like uroflowmetry, PVR volume measurement and BVE determination are potentially useful to identify women who might have DU. There is considerable symptomatic overlap with BOO, and uroflowmetry and PVR volume findings may also be similar. Only invasive urodynamics with pressure–flow studies can reliably distinguish DU from BOO and these urodynamic diagnoses can coexist. Diagnosis in women is particularly difficult as they can void by relaxing the pelvic floor, that is, without detectable detrusor contraction during pressure–flow study and without increased abdominal pressure [466]. The simplest methods to define and diagnose DU are based on the use of cut-off values of Q_{max} and $P_{det}Q_{max}$, possibly combined with cut-off values of PVR volume and BVE. However, there is no consensus on which cut-off values should be used [467]. It is obvious that the prevalence of DU depends on the criteria used. In a retrospective study of 1,015 women, DU was found in 14.9% when using Q_{max} < 12 mL/s or PVR volume > 150 mL; in 9.6% when using $P_{det}Q_{max}$ < 30 cm H_2O and Q_{max} < 10 mL/s; and in 6.4% when using $P_{det}Q_{max}$ < 20 cm H_2O, Q_{max} < 15 mL/s and BVE < 90% [468].

More elaborate methods combine urodynamic data into an index or a physical quantity that reflects bladder contraction strength. A value below a certain threshold would thus diagnose DU. Again, there is no consensus regarding what is normal/abnormal. Table 4 provides an overview of the best-known parameters, their background, and typical values. Watt's factor (WF) estimates the power generated by the detrusor per unit area of bladder surface [469] and it varies during voiding. Usually, WF_{max} is considered. Alternatively, its value at Q_{max} can be used. Projected isovolumetric pressure (PIP) is a gross simplification of the bladder output relation and estimates the maximum detrusor pressure that can be generated by the bladder when the outlet is closed; the isovolumetric detrusor pressure. The bladder contractility index (BCI) is a reduction of PIP to an index [470]. The population in which PIP and BCI were developed mainly consisted of men. Projected isovolumetric pressure 1, is similar to PIP and also estimates the isovolumetric detrusor pressure, but was developed in an entirely female population via an experimental method [471].

A third method of quantifying bladder contraction strength involves stop tests. One study compared three types of direct measurement of isovolumetric pressure: (1) the voluntary stop test, in which the patient voluntarily interrupted flow; (2) the mechanical stop test, in which flow was interrupted by a balloon catheter; and (3) the continuous occlusion test, in which the subject tried to void against a blocked outlet. The latter had the best reliability and best detected drug-induced changes, though the results of the mechanical stop tests were similar [472].

All parameters discussed above give some information about the strength of detrusor contraction in a given void. They do not necessarily reflect what the detrusor might potentially achieve under optimum conditions [473]. Also, they give no information on voiding duration. No parameters for this are available. Finally, abnormally low bladder contraction strength does not necessarily imply insufficient bladder contraction strength to achieve optimal voiding. Table 4 summarises different parameters to measure detrusor contraction in female patients.

Table 4: Most used parameters to measure detrusor contraction in female patients

Parameter	Basis	Population	Values
Watt's factor [469]	Hill equation of muscle contraction in a spherical organ, with fixed constants obtained from experimental and clinical studies	Eight asymptomatic female volunteers aged 28–45 years (median 34 years)	Ideal voiding (bell-shaped flow curves): WF_{max} 11-24 W/m^2 Non-ideal voiding: WF_{max} 5–10 W/m^2 Normally WF_{max} > 7 W/m^2 (expert opinion, unspecified population) [474]
Projected isovolumetric pressure (cm H_2O) and BCI, using PIP as an index [470, 475]	Bladder output relation, simplified to a straight line with fixed slope of 5 cm H_2O/mL/s (formula: $P_{det}Q_{max} + 5xQ_{max}$)	Unspecified population, mainly men with BPO	Classification based on expert opinion: > 150: strong contraction 100–150: normal contraction 50–100: weak contraction < 50: very weak contraction
Projected isovolumetric pressure 1 (cm H_2O) [471]	Comparison of Q_{max} and $P_{det}Q_{max}$ values with stop test results (Formula: $p_{det}Q_{max} + Q_{max}$)	100 women with UUI aged 53–89 (mean 70) years	5^{th}-95^{th} percentile: 29–78 cm H_2O Mean: 49 cm H_2O Median: 48 cm H_2O Proposed typical values: 30-75 cm H_2O
Continuous occlusion test [472]	Direct measurement of isovolumetric voiding contraction	70 women with UUI aged 53–89 (mean: 70) years	Mean ± SD: 48.7 ± 24.4 cm H_2O

BCI = Bladder contractility index; PIP = Projected isovolumetric pressure; UUI = urgency urinary incontinence; WF = Watt's factor.

*4.4.4 **Disease management***

As there are different possible causes and pathogenic mechanisms involved in female UAB, preventive and therapeutic strategies are difficult to define. Among preventive strategies, early recognition after major surgery or labour might prevent long-term problems associated with prolonged bladder over-distension. Nerve-sparing techniques for radical pelvic surgery are more favourable in terms of early recovery of bladder function [476, 477].

Treatment of female DU includes strategies to ensure bladder drainage, increase bladder contraction, decrease urethral resistance, or a combination of the two [474]. The management goals for UAB are to improve symptoms and QoL, to reduce the risk of complications, and to identify situations where interventions may not be appropriate.

4.4.4.1 Conservative management

4.4.4.1.1 Behavioural interventions

Regular or timed voiding in women with impaired bladder sensations have been done to avoid bladder over-distention. Assisted voiding by abdominal straining with adequate relaxation of the PFM, double or triple voiding are potential strategies to improve bladder emptying. However, none of these manoeuvres has proven efficacy in an RCT. Furthermore, there is a possible association between voiding by excessive abdominal straining and the risk of POP [478]. A small retrospective study in women with neurogenic acontractile detrusor secondary to spina bifida showed that Valsalva voiding may increase the risk of rectal prolapse compared with CISC [479].

4.4.4.1.2 Pelvic floor muscle relaxation training with biofeedback

There are no RCTs on PFM relaxation training in adult women with UAB. Contrary to common beliefs, one study found significant relaxation of the PFMs after contraction [480] and another study found that PFM relaxation training over time increased the speed of relaxation after a single contraction [481]. There is some evidence from the paediatric literature, including one RCT that compared efficacy of PFM relaxation with biofeedback plus combined therapy (including hydration, scheduled voiding, toilet training and diet) vs. combined therapy alone in children with non-neuropathic UAB and voiding dysfunction. Mean number of voiding episodes was significantly increased in the relaxation training group compared with the group with only combined treatment. Post-void residual volume and voiding time decreased considerably, whereas maximum urine flow increased significantly in the relaxation group compared with the combined treatment group [482].

4.4.4.1.3 Clean intermittent self-catheterisation

Clean intermittent self-catheterisation is the most commonly used therapy to manage high PVR volume and urinary retention [117]. It reduces the risk of complications such as UTI, UUT deterioration, bladder stones and overflow UI, etc. It has not yet been established whether the incidence of UTI, other complications and user satisfaction, are affected by either sterile or clean intermittent catheterisation (IC), coated or uncoated catheters or by any other strategy [483]. The use of hydrophilic catheters may be associated with a lower rate of UTI, but further evidence is needed, as current data comes from neurogenic patients [484]. The average frequency of catheterisation is four to six times per day [485] and the catheter sizes most often used are 12–16 Fr. In aseptic IC, an optimum frequency of five times showed a reduction of UTI [485]. Frequency of catheterisation needs to be based on individual need and capability, to prevent chronic and repeated over-filling of the bladder [486]. Thorough counselling regarding techniques, frequency, equipment, and adverse effects of CISC should be given to all potential patients in line with good medical practice.

For people using CISC, a Cochrane review found no evidence that one type of catheter or regimen of catheterisation was better than another [487]. However, a recent narrative review suggests that, in certain populations, single-use catheters may reduce urethral trauma and UTI [488].

4.4.4.1.4 Indwelling catheter

Indwelling urinary catheter may be an option for some women who have failed all other treatments and are unable to perform CISC. Complications include UTI, stone formation, and urethral damage. Suprapubic catheterisation may be preferable over urethral catheterisation to minimise the risk of urethral trauma and pain [489].

4.4.4.1.5 Intravesical electrical stimulation

Intravesical electrical stimulation (IVES) can be used to improve bladder dysfunction by stimulating A-delta mechanoreceptor afferents but requires intact afferent circuits and healthy detrusor muscle. One retrospective study in sixteen patients (eleven females) found that two-thirds of patients with a weak detrusor after prolonged bladder over-distension regained balanced voiding after IVES due to detrusor reinforcement [490].

4.4.4.2 Pharmacological management

4.4.4.2.1 Parasympathomimetics

Theoretical approaches to UAB pharmacological treatment include direct stimulation of detrusor cell muscarinic receptors using parasympathomimetic agents such as carbachol or bethanechol or acetylcholinesterase inhibitors such as distigmine, pyridostigmine or neostigmine.

A SR on the use of parasympathomimetics in patients with UAB included ten RCTs (controls typically received placebo or no treatment). Three studies reported significant improvements relative to the control group, but six did not and one even reported significant worsening of symptoms. There was no evidence for differences between individual drugs, specific uses of such drugs, or in outcome measures [491]. The review concluded that the available studies do not support the use of parasympathomimetic for treating UAB, especially when frequent and/or serious adverse effects (gastrointestinal upset, blurred vision, bronchospasm, and bradycardia) are taken into account.

4.4.4.2.2 Alpha-adrenergic blockers

In order to improve bladder emptying, decreasing outlet resistance through sympathetic blockade at the bladder neck/urethra has been investigated. One prospective study with tamsulosin showed similar improvement in terms of uroflowmetry parameters (specifically in the percentage of patients who had a good therapeutic response) in women with BOO (39.4%) or DU (32.7%) [492]. Another longitudinal study including fourteen women with DU showed clinical and urodynamic improvements after tamsulosin [493]. A prospective single-blind RCT in female patients with DU compared the efficacy of alpha-blocker, cholinergic drugs, or combination therapy, with the latter exhibiting the best results [494].

4.4.4.2.3 Prostaglandins

Prostaglandins are prokinetic agents that promote smooth muscle contraction. Prostaglandins E2 and F2 have been used intravesically to treat urinary retention after surgery. A Cochrane review showed a significant association between intravesical prostaglandin and successful voiding among postoperative patients with urinary retention. However, the success rate was low (32%) with wide 95% CI, compared to placebo. The RCTs included in the pooled analysis were underpowered with methodological limitations and the event rate was very low, indicating a very low certainty of the evidence [495]. Intravesical prostaglandin treatment is rarely used, and further research is necessary before it can be taken up more widely.

4.4.4.3 Surgical management

4.4.4.3.1 Sacral nerve stimulation

Sacral nerve stimulation is often used for therapy of non-obstructive urinary retention. The mechanism of action has not been fully elucidated, but activation of afferent sensory pathways, modulation–activation of the central nervous system, and inhibition of inappropriate activation of the guarding reflex are some of the mechanisms proposed.

An RCT included 37 patients in the implantation arm and 31 in the standard medical therapy arm, showing a mean decrease in PVR volume and a mean increase in voided PVR volume compared to standard treatment [496]. A meta-analysis of seven studies also showed a mean difference in PVR volume reduction of 236 mL and a mean voided volume increase of 299 mL [497]. The response rate during the trial phase ranged from 33-90% (mean 54.2%) and the success rate of permanent implantation ranged from 55-100% (mean 73.9%), highlighting that patient selection is crucial [498].

The importance of careful patient selection has been emphasised with one study suggesting women with evidence of anatomical BOO, suspected loss of intrinsic detrusor contractility or neurogenic bladder dysfunction show lower response rates [499].

4.4.4.3.2 Onabotulinumtoxin A

OnabotulinumtoxinA intersphincteric injections in external striated urethral sphincter may improve voiding in patients with DU by reducing outlet resistance and reducing the guarding reflex. Some retrospective case studies have shown improvement in voiding symptoms, recovery of spontaneous voiding, and improvement in urodynamic parameters (reduction of voiding pressure and/or urethral closure pressures, reduced PVR volume) [500, 501]. The duration of symptomatic relief is short; typically, three months but the reported incidence of *de novo* SUI is low.

4.4.4.3.3 Transurethral incision of the bladder neck

Transurethral incision of the bladder neck has been described in a small series of women with refractory DU. In a retrospective case study, 40/82 (48.8%) women achieved satisfactory outcomes (spontaneous voiding with voiding efficiency ≥ 50%), but five (6.1%) patients developed SUI and two (2.4%) developed a vesico-vaginal fistula [502].

4.4.4.3.4 Myoplasty

One retrospective multicentre study reported the long-term results of latissimus dorsi detrusor myoplasty in patients with bladder acontractility, with 71% recovering complete spontaneous voiding, with a mean PVR volume of 25 mL [503]. No other groups have published their experience to reproduce these findings.

4.4.4.4 Summary of therapeutic evidence on detrusor underactivity

The level of evidence for most therapeutic interventions for DU is low. Only CISC remains as a gold standard to reduce the adverse consequences of a high PVR volume and incomplete voiding, in spite of the low level of evidence that supports this statement.

4.4.4.4.1 Summary of evidence and recommendations for underactive bladder

Summary of evidence	**LE**
Abdominal straining with relaxation of the PFM may improve bladder emptying but increases the risk of POP.	3
Pelvic floor muscle relaxation training may increase voiding episodes, decrease post-void residual volume and voiding time.	3
Clean intermittent self-catheterisation has proven efficacy in terms of effecting bladder emptying in patients who are unable to do so.	3
Indwelling transurethral catheterisation and suprapubic cystostomy are associated with a range of complications as well as an increased risk of UTI.	3
Intravesical electrical stimulation may be useful in some patients after prolonged bladder over-distension, but long-term efficacy remains unproven.	3
Parasympathomimetics do not improve clinical or urodynamic parameters of UAB and frequent and/or serious adverse effects may arise.	1b
Alpha-adrenergic blockers in women with UAB may be effective in improving voided volume and reducing PVR volume.	2b

Very low certainty evidence indicates that intravesical prostaglandins may promote successful voiding in patients with urinary retention after surgery.	1a
Sacral nerve stimulation improves voided volume and decreases PVR volume in women with DU.	1b
There is limited evidence for the effectiveness of onabotulinumtoxinA external urethral sphincter injections to improve voiding in women with UAB.	3
Transurethral bladder neck incision may improve voiding in women with DU, but complications (SUI, vesico-vaginal fistulae) may occur.	3
There is very limited evidence for the effectiveness of detrusor myoplasty for bladder acontractility.	3

Recommendations	Strength rating
Encourage double voiding in those women who are unable to completely empty their bladder.	Weak
Warn women with underactive bladder (UAB) who use abdominal straining to improve emptying about pelvic organ prolapse risk.	Weak
Use clean intermittent self-catheterisation (CISC) as a standard treatment in patients who are unable to empty their bladder.	Strong
Thoroughly instruct patients in the technique and risks of CISC.	Strong
Offer indwelling transurethral catheterisation and suprapubic cystostomy only when other modalities for urinary drainage have failed or are unsuitable.	Weak
Do not routinely recommend intravesical electrical stimulation in women with UAB.	Weak
Do not routinely recommend parasympathomimetics for treatment of women with UAB.	Strong
Offer alpha-adrenergic blockers before more-invasive techniques.	Weak
Offer intravesical prostaglandins to women with urinary retention after surgery only in the context of well-regulated clinical trials.	Weak
Offer onabotulinumtoxinA external sphincter injections before more-invasive techniques as long as patients are informed that the evidence to support this treatment is of low quality.	Weak
Offer sacral nerve stimulation to women with UAB refractory to conservative treatment.	Strong
Do not routinely offer detrusor myoplasty as a treatment for DU.	Weak

*4.4.5 **Follow-up***

Natural history and clinical evolution at long-term follow-up of women with DU is not well known. No longitudinal cohort studies are described in the literature. The interval between follow-up visits depends on patient characteristics, treatments given and the frequency of urinary complications.

4.5 Bladder outlet obstruction

*4.5.1 **Introduction***

Bladder outlet obstruction is defined by the ICS as *"obstruction during voiding, characterised by increased detrusor pressure and reduced urine flow rate"* [1]. Its precise diagnosis requires urodynamic evaluation including an assessment of pressure and flow.

Voiding dysfunction has previously been defined in Section 4.4. In women, voiding dysfunction can be caused by BOO or DU [1]. There are also non-obstructive causes and therefore voiding dysfunction, and BOO should not be used interchangeably. Another term that must be differentiated from BOO and voiding dysfunction is dysfunctional voiding, which is a specific and discrete form of voiding dysfunction characterised by an intermittent and/or fluctuating flow rate due to involuntary intermittent contractions of the peri-urethral striated muscle during voiding in neurologically normal individuals [113].

*4.5.2 **Epidemiology, aetiology, pathophysiology***

4.5.2.1 Epidemiology

Estimates of prevalence of BOO among women vary from 2.7-29% [504]. One large series of women undergoing urodynamic evaluation for LUTS found that ~20% are diagnosed with BOO. The wide variance is due to several factors, including differences in definitions and diagnostic criteria for female BOO, differences in study populations, and variation in study methods. The estimated prevalence rates of LUTS due to BOO in women are lower than those reported in men (18.7–18.9% vs. 24.3–24.7%) [505].

Prevalence of voiding LUTS is associated with age [54, 506, 507], parity [54, 508], prolapse [54, 508] and prior continence surgery [54, 508]. Bladder outlet obstruction has long been postulated to cause mainly voiding symptoms [509] but recent data from a series of 1,142 women referred for evaluation of LUTS suggest that storage symptoms may be predominant in women diagnosed with BOO, and excess daytime urinary frequency was the most common symptom reported by 69% [504].

4.5.2.2 Pathophysiology

Bladder outlet obstruction can be either anatomical (mechanical) or functional. In anatomical BOO, there is a physical or mechanical obstruction to the outflow of urine, whereas in functional BOO there is a non-anatomical, non-neurogenic obstruction of the outlet usually resulting from non-relaxation of the bladder neck, sphincter or PFM, or increased urethral sphincter tone or PFM contraction during voiding, as observed in patients with dysfunctional voiding.

Mechanisms for anatomical (mechanical) obstruction include external compression, fibrosis, stricture or injury to the urethra and kinking of the urethra due to POP. Progressive fibroblastic reaction around the urethra induced by mesh tapes or slings used in incontinence surgery may also cause anatomical (mechanical) obstruction [462]. In a retrospective review of 192 women diagnosed with BOO, 64% had mechanical obstruction [504].

Functional obstruction may be caused by contraction, or failure of relaxation, of the bladder neck and/or urethral sphincter complex or the PFMs during sustained detrusor contraction [509]. The exact causes of this lack of relaxation, or contraction, are often elusive but might be due to sympathetic hyperactivity or hypertrophy of the bladder neck smooth muscle for primary bladder neck obstruction [510], or may be mostly behavioural for dysfunctional voiding [511].

4.5.2.3 Aetiology

Conditions associated with anatomical BOO include POP, incontinence surgery, urethral stricture, urethral stenosis, urethral diverticulum, urethral caruncle, urethral malignancies and paraurethral masses.

Conditions associated with functional BOO include primary bladder neck obstruction, dysfunctional voiding, and idiopathic urinary retention (Fowler's syndrome).

In primary bladder neck obstruction, the bladder neck fails to open adequately during voiding, in the absence of an anatomical obstruction [512]. It is estimated that 4.6–16% of women presenting with voiding symptoms have primary bladder neck obstruction [510].

Dysfunctional voiding is due to involuntary intermittent contractions of the peri-urethral striated or levator muscles during voiding in neurologically normal women, and is thought to be caused by faulty learned toileting behaviour [462]. There is also some evidence of a link between dysfunctional voiding and a history of sexual abuse [513].

Idiopathic urinary retention, also known as Fowler's syndrome, is a primary disorder of the external urethral sphincter with hypertrophy of the muscle fibres, which fail to relax during micturition. It is associated with decreased detrusor contractility via enhancement of the guarding reflex. It is seen most often, but not exclusively, in young women with urinary retention and is characterised by increased urinary sphincter volume and activity/tone, which may be hormonally triggered [514].

Alpha-adrenergic agonists, such as pseudoephedrine commonly contained in decongestants, can lead to some form of functional obstruction due to their stimulatory effects, which may contract the bladder neck and lead to urinary retention [515].

Neurological conditions can also bring about functional BOO in women. These conditions are not considered in these guidelines and are covered elsewhere [9].

*4.5.3 **Classification***

4.5.3.1 Anatomic bladder outlet obstruction

Anatomical BOO involves a physical or mechanical obstruction of the outflow of urine not related to urethral or pelvic muscle tone.

4.5.3.2 Functional bladder outlet obstruction

Functional BOO involves a non-anatomical, non-neurogenic obstruction of the outflow of urine resulting from non-relaxation or increased tone in the bladder neck and/or urethral sphincter complex or the PFMs (Table

5). Neurological causes of functional BOO are not considered in these guidelines and are covered in the EAU Guidelines on Neuro-urology [9].

Table 5: Main causes of female bladder outlet obstruction

Functional BOO	Anatomical BOO
• Primary bladder neck obstruction • Dysfunctional voiding • Idiopathic urinary retention (Fowler's) syndrome	• Urethral stricture • Anti-incontinence surgery • Pelvic organ prolapse • Urethral diverticulum • Urethral caruncle • Urethral malignancies • Paraurethral masses

4.5.3.3 Recommendation for classification of bladder outlet obstruction

Recommendation	Strength rating
Use standardised classification of bladder outlet obstruction in women (anatomical or functional), and research populations should be fully characterised using such classification.	Strong

4.5.4 Diagnostic evaluation

Diagnosis of BOO in women, although dependent on formal pressure–flow studies, may be suggested by several clinical and other non-invasive assessments.

4.5.4.1 Clinical history

In terms of clinical history, a range of LUTS may be elicited and these may not be confined to voiding LUTS. Women may not present until they have the possible complications of BOO, such as recurrent UTI, chronic urinary retention or acute/chronic kidney disease [504]. The evidence regarding clinical utility of symptoms for the diagnosis of BOO is inconclusive and limited to small retrospective studies [516, 517]. Perhaps some of the difficulty in evaluating the diagnostic accuracy of urinary symptoms comes from the observation that a significant proportion of women presenting with obstruction also have concomitant storage symptoms, making urodynamic evaluation essential. In a large study of > 5,000 women with urinary symptoms including 163 with BOO, additional urodynamic diagnoses were noted in 54% [518].

4.5.4.2 Clinical examination

There are no studies evaluating the clinical utility of physical examination in women with suspected BOO; nevertheless, it is widely considered as a key part of the medical assessment. It allows for visual inspection of the urethra and vagina for possible causes of mechanical obstruction as well as an assessment of the pelvic floor, which may be the cause of functional obstruction.

4.5.4.3 Uroflowmetry and post-void residual volume

Reduced Q_{max} and incomplete bladder emptying can result from weakness in the contractile strength of the detrusor muscle, or increased outlet resistance due to functional or anatomical/mechanical BOO. The use of uroflowmetry to differentiate between anatomical and functional BOO was explored in a retrospective study of 157 women [511], which concluded that Q_{max} was significantly lower in patients with anatomical obstruction, but a large degree of overlap was noted. The largest evaluation of the diagnostic utility of urine flow studies and PVR volume estimation was a retrospective analysis of > 1,900 patients with symptoms of voiding dysfunction, of whom > 800 were diagnosed with BOO based on urodynamic assessment [519]. Functional BOO was > 6 times more common than anatomical/mechanical obstruction, which does not agree with most of the other epidemiological literature for female BOO. The authors found that although urine flow rate alone was not accurate enough to diagnose BOO, PVR of ≥ 200 mL could differentiate bladder neck dysfunction from the other causes of BOO, with a receiver-operator characteristics (ROC) area under the curve (AUC) of 0.69. Conversely, in a retrospective study involving 101 women primarily presenting with SUI, a good correlation between abnormal uroflowmetry and urodynamic obstruction (phi = 0.718) was found [520].

4.5.4.4 Ultrasound

The major utility of US scanning in women with BOO is to detect possible complications such as BWT/DWT upper tract dilatation/hydronephrosis. However, the diagnostic capabilities of US have been investigated in

a 2021 SR of 16 non-randomised studies and reported a moderate pooled sensitivity and high specificity for DWT, while 6 studies evaluating US-estimated bladder weight (UEBW) reported a high sensitivity and specificity [521]. A prospective case–control study of 27 patients with cystoscopically confirmed bladder neck obstruction [522] reported the diagnostic value of shear wave elastography (SWE) and acoustic radiation force impulse imaging (ARFI) for female BOO was compared and the authors concluded that ARFI was more accurate than SWE, but a combination of the techniques was superior to either one alone.

4.5.4.5 Magnetic resonance imaging

Magnetic resonance imaging in patients with pathological urethral stricture can determine the degree of peri-urethral fibrosis, although the prognostic and clinical significance of such a finding has not been established [523].

4.5.4.6 Electromyography

Electromyography (EMG) has been most extensively studied in the subgroup of women with BOO due to idiopathic urinary retention caused by a high-tone non-relaxing sphincter (Fowler's syndrome). Abnormal urethral EMG activity may be associated with non-relaxation of the striated sphincter, abnormally high urethral pressure, and, through an exaggerated guarding reflex, poor bladder sensation and reduced detrusor contractile strength [513, 524]. Complex repetitive discharges and decelerating bursts are specific urethral EMG abnormalities that have been described in patients with high-tone non-relaxing sphincter, although these abnormalities have also been noted in asymptomatic volunteers [525, 526]. A review of voiding dysfunction in women included 65 studies with only a small number addressing the diagnostic utility of PFM EMG [462]. The authors commented that increased EMG activity of the PFM can be seen during voiding or non-relaxation, and when this is coupled with pressure–flow information from urodynamics, it may be useful to differentiate between functional and anatomical obstruction. Further evidence for this comes from a retrospective study of 157 women with roughly equal numbers of women with functional and anatomical obstruction, which concluded that a low level of PFM EMG activity is characteristic of anatomical obstruction [511]. Additional neurophysiological tests, such as anal sphincter EMG, bulbocavernosus reflex, and pudendal sensory evoked potentials can assess the integrity of the somatic S2–4 nerve roots; however, their clinical utility in the context of non-neurogenic female BOO needs to be better defined [513].

4.5.4.7 Cystourethroscopy

Cystourethroscopy can be useful to visualise any anatomical/mechanical obstruction and provide information regarding its nature, location and calibre. Given that pelvic malignancy may cause anatomical BOO, cystourethroscopy is considered an essential part of the diagnostic pathway. Formal urethral calibration may be useful for women with BOO secondary to pathological urethral stricture and various different urethral calibre thresholds have been used, from 14-20 Fr [527].

4.5.4.8 Urodynamics and video-urodynamics

Pressure–flow studies are the mainstay of BOO diagnosis and the characteristic abnormalities are a combination of low flow and concomitant high detrusor pressure [512]. However, while the general definition of BOO is well established, with some data supporting its clinical validity in male patients [528], the urodynamic definition of female BOO remains controversial [509]. Several urodynamic criteria have been introduced but none has been established as a standard due to lack of clinical validation [509, 529]. The Blaivas-Groutz nomogram, which plots free Q_{max} and maximum detrusor pressure ($P_{det \cdot max}$) measured during urodynamic studies, is one of the most popular [530] but has been suggested to overestimate obstruction [531]. The addition of fluoroscopic imaging suggested by Nitti and colleagues introduces a video-urodynamic criterion for obstruction [76]. However, both methods lack data supporting their clinical validity, especially regarding their predictive value for therapeutic intervention outcomes [74].

In a large retrospective study of 1,914 patients, 810 of whom were diagnosed with BOO, several urodynamic cut-off values were determined by ROC curve analysis to optimise the diagnostic accuracy of video-urodynamic studies [519]:

- $P_{det}Q_{max} \geq 30$ cm H_2O for differentiating BOO from bladder dysfunction and normal studies (ROC AUC = 0.78);
- the Abrams-Griffiths number > 30 for differentiating anatomical from functional BOO (ROC AUC = 0.66);
- $P_{det}Q_{max} \geq 30$ cm H_2O for differentiating dysfunctional voiding from poor relaxation of the external sphincter (ROC AUC = 0.93).

More recently, Solomon and Greenwell devised a female BOO nomogram that parallels the ICS nomogram used for male BOO [532]. It allows the calculation of an alternative BOO female index (BOOIf), using a formula closely aligned to its male counterpart: $BOOIf = P_{det}Q_{max} - 2.2Q_{max}$.

It is interpreted with a different algorithm however:
- BOOIf < 0: < 10% probability of obstruction;
- 5 < BOOIf < 18: equivocal, ≥ 50% likelihood of obstruction;
- BOOIf > 18: 90% likelihood of obstruction.

The Solomon–Greenwell nomogram was the first to be tested for clinical validity. In a recent series of 21 unselected consecutive women treated for BOO, the authors observed significant improvement of all urodynamic parameters (Q_{max}, $P_{det}Q_{max}$ and BOOIf) in female patients who became asymptomatic postoperatively [533].

An alternative urodynamic parameter of area under the detrusor pressure curve during voiding (corrected for voided volume) has been proposed following a prospective study of 103 women [534]. The authors concluded that this variable appears to be the most discriminating urodynamic parameter for the diagnosis of female BOO. This suggested diagnostic method has not been independently validated.

Voiding cystourethrography (VCUG) alone or in conjunction with concomitant pressure–flow studies may be useful in delineating the site of obstruction. Characteristic features include:
- radiographic evidence of obstruction between the bladder neck and distal urethra in the presence of sustained detrusor contraction [76];
- lack of funnelling appearance of the bladder neck/tight bladder neck in primary bladder neck obstruction;
- proximal dilatation of the urethra with distal narrowing in women with urethral stricture disease or pelvic-floor hypertonicity.

IIt is not uncommon for women with voiding dysfunction, specifically functional BOO, to be unable to provide a flow during (video)urodynamic testing. Failure to relax the PFM can enhance the guarding reflex, limiting detrusor contractility.

4.5.4.9 Summary of evidence and recommendations for diagnosis of bladder outlet obstruction

Summary of evidence	**LE**
Evaluation of LUTS by history and examination alone is insufficient to accurately diagnose female BOO.	3
Urine flow studies cannot accurately diagnose BOO in women.	3
Ultrasound scanning is unable to accurately diagnose BOO in women.	2b
Electromyography alone is unable to accurately diagnose BOO in women, although it may be of use in combination with pressure–flow studies and in differentiation of anatomical vs. functional BOO.	3
Cystourethroscopy can be useful to visualise any anatomical/mechanical obstruction and provide information regarding its nature, location, and calibre.	4
Urodynamics (often combined with video-fluoroscopy) is the standard test for evaluating female BOO.	3

Recommendations	**Strength rating**
Take a full clinical history and perform a thorough clinical examination in women with suspected bladder outlet obstruction (BOO).	Strong
Do not rely on measurements from urine flow studies alone to diagnose female BOO.	Strong
Perform cysto-urethroscopy in women with suspected anatomical BOO.	Strong
Perform urodynamic evaluation in women with suspected BOO.	Strong

*4.5.5 **Disease management***

Therapeutic interventions for BOO aim to decrease outlet resistance in order to increase urinary flow, improve bladder emptying and thus reduce voiding and storage LUTS [74, 509, 529]. Treatment choice is commonly dictated by the underlying cause of the obstruction.

4.5.5.1 Conservative management

4.5.5.1.1 Behavioural modification

Behavioural modification interventions are often tailored to individual patients' needs, symptoms and circumstances and can include elements such as education regarding normal voiding function, self-monitoring of symptoms, changes in lifestyle factors that may affect symptoms, avoidance of constipation, and alteration of voiding technique. Ultimately, techniques aim to improve the coordination between the detrusor and sphincter, resulting in their synergistic action [74, 509, 529].

These individual components of self-management have not been evaluated separately and most recommendations are derived from consensus methodology. They may help reduce symptoms resulting from BOO but no quantification of their effect is possible.

4.5.5.1.2 Pelvic floor muscle training +/- biofeedback

In the context of BOO, physiotherapy aims to teach patients to relax their PFMs and striated urethral sphincter during voiding. Pelvic floor muscle contraction, particularly in women with pelvic floor dysfunction, has been shown to significantly reduce vaginal resting pressure and surface EMG activity [480].

As mentioned in the section discussing UAB (Section 4.4.4.1.2), most of the evidence supporting PFMT in dysfunctional voiding is from paediatric studies.

4.5.5.1.3 Electrical stimulation

Application of electrodes that allow for controlled contraction and relaxation of the PFMs may theoretically facilitate the relaxation of the external sphincter and pelvic floor but no critical evaluation of this intervention in women with BOO has been published.

4.5.5.1.4 Use of vaginal pessary

Intravaginal devices such as pessaries aim to relieve voiding symptoms and improve bladder emptying by physical correction of the obstruction caused by a POP. In a prospective study of eighteen women with grade three or four cystocoeles and diagnosed with BOO by urodynamics (defined as $P_{det}Q_{max}$ > 25 cm H_2O, Q_{max} < 15 mL/s), normal voiding was noted in seventeen (94%) immediately after placement of a vaginal pessary. No other outcomes were available in this series [535]. No long-term data are available on the use of vaginal pessary for BOO.

4.5.5.1.5 Urinary containment

The use of containment devices in BOO is to achieve social continence in patients with urinary retention and associated overflow UI and is often only a temporary measure. There are no published studies on the outcomes or adverse events associated with the use of urinary containment devices for the management of female BOO, though there are many involving women with UI who may have BOO as an underlying cause.

4.5.5.1.6 Urinary catheterisation

Significant urinary retention from BOO may be addressed by actively bypassing the obstruction and draining the residual urine. Catheterisation may be used as a treatment itself or as an adjunct to an initial treatment of urethral dilatation or urethrotomy or bladder neck incision. There are two ways of using a catheter: CISC or indwelling catheterisation [117].

After UI surgery, BOO may be managed by short-term catheterisation in most patients who have transient postoperative voiding difficulty. For a few women who develop chronic urinary retention, CISC or indwelling catheterisation may be offered [462].

A small RCT investigated the effectiveness of CISC to prevent recurrence after internal optical urethrotomy for urethral stricture disease. In the treatment group, CISC was done twice a day for one week, and once a day for four weeks, then once weekly for seven weeks post-urethrotomy. Freedom from stricture recurrence, determined by urethrography and uroflowmetry performed twelve weeks postoperatively, was higher in the catheterisation group compared to the group with no catheterisation (78.5% vs. 55.4%) [536]. This finding mirrors the Cochrane review on self-dilatation for urethral stricture among men that showed less recurrence with the performance of self-dilatation [537].

In a series of 20 patients with voiding dysfunction after TVT who were put on a CISC programme, overall cure rate was 59%, with cure defined as consistent residual volume < 100 mL. Half of these patients were voiding normally within twelve weeks [538].

See Section 4.4.4.1.3 for further evidence related to CISC.

4.5.5.1.7 Intraurethral inserts

An intraurethral insert is a short silicone catheter containing an internal valve and pump mechanism positioned in the female urethra. The valve-pump mechanism is operated by an external control unit, which activates to open the valve and the pump to draw urine from the bladder and allow voiding. At the end of urination, the pump ceases and the valve closes to regain continence. The insert is routinely replaced once a month.

One study reported the use of this device in 92 women with voiding dysfunction of various aetiologies including multiple sclerosis, prior pelvic surgery, pelvic radiation, diabetes mellitus, spinal stenosis and injury. The device was removed within seven days of insertion in 60% of the cases due to discomfort, peri-catheter leakage or technical difficulty. An additional 20% of patients had late discontinuation. All those who continued to use the device were satisfied, with PVR volumes remaining < 100 mL. Adverse events included migration into the bladder in six cases and symptomatic UTI in four cases [539, 540]. Extended, long-term data on the use of urethral inserts are not available.

4.5.5.1.8 Extracorporeal magnetic stimulation

Extracorporeal magnetic stimulation involves the patient sitting on a device that induces consistent PFM contraction and relaxation at a set frequency and interval by repeated magnetic stimulation of motor nerve fibres. It is postulated that patients therefore learn to spontaneously contract or relax the PFM, which may enhance their ability to relax their pelvic floor while voiding [541].

In a small (n = 60) prospective non-randomised trial, alfuzosin was compared to EMS and to the combination of alfuzosin + EMS in women with functional BOO. They observed significant increase of Q_{max} and significant decrease of International Prostate Symptom Score (IPSS) in all groups and significantly greater improvement in the QoL question of the IPSS in the combination therapy group [541].

4.5.5.1.9 Summary of evidence and recommendations for conservative treatment of bladder outlet obstruction

Summary of evidence	**LE**
Pelvic floor muscle relaxation training with biofeedback may result in relaxation of the pelvic muscles and external urethra in women with dysfunctional voiding.	3
There is no available evidence in the published literature on the clinical effect of ES for management of female BOO.	NA
In women with large (grade three or four) cystocoeles causing BOO, placement of a vaginal pessary may improve voiding efficiency.	3
Regular CISC after urethrotomy is better than no catheterisation to prevent recurrence of urethral strictures.	1b
A CISC programme in women with voiding dysfunction after TVT has a cure rate of 59%.	3
Women who use an intraurethral device have lower PVR volume, but most require its removal due to complications.	3
Extracorporeal magnetic stimulation combined with alfuzosin may be more effective than either of these therapies alone in women with functional BOO.	2a

Recommendations	**Strength rating**
Offer pelvic floor muscle training (PFMT) aimed at pelvic floor muscle relaxation to women with functional bladder outlet obstruction (BOO).	Weak
Prioritise research that investigates and advances understanding of the mechanisms and impact of PFMT on the coordinated relaxation of the pelvic floor during voiding.	Strong
Offer the use of a vaginal pessary to women with grade three or four cystocoeles and BOO who are not eligible/inclined towards other treatment options.	Weak
Offer urinary containment devices to women with BOO to address urinary leakage as a result of BOO, but not as a treatment to correct the condition.	Weak
Offer clean intermittent self-dilatation to women with urethral strictures or post-urinary incontinence surgery for BOO.	Weak
Do not offer an intraurethral device to women with BOO.	Strong

*4.5.6 **Pharmacological management***

4.5.6.1 Alpha-adrenergic blockers

Alpha-adrenergic blockers are postulated to relieve LUTS caused by BOO in women via smooth muscle relaxation in the bladder neck, thus decreasing bladder outlet resistance [542].

Systematic reviews on the use of alpha-blockers in women generally involve studies with a population that includes women complaining of LUTS and voiding dysfunction. Confirmation of BOO is often not required in the trials included [543, 544]. These reviews showed significant improvements in symptoms and urodynamic parameters associated with their use [543-545]. A meta-analysis of fourteen RCTs comparing alpha-blockers and placebo in women with LUTS showed significant symptom relief after alpha-blocker treatment relative to placebo, but no significant difference in Q_{max}, PVR volume and adverse event rates [543]. This is in contrast to prospective non-comparative trials that consistently showed improvements in voiding and storage symptoms, bother scores, and urodynamic parameters (Q_{max}, PVR, $P_{det}Q_{max}$, MUCP after alpha-blocker use compared to baseline) [492, 493, 546-548].

A SR performed by the Panel of studies on alpha-blockers used specifically for women with BOO included one placebo-controlled RCT, one RCT comparing two types of alpha-blockers, and six prospective non-comparative studies [150]. In the only placebo-controlled RCT reporting subgroup analyses in women with urodynamically proven BOO (based on the Blaivas-Groutz nomogram) no significant difference was observed in the changes of IPSS, IPSS sub scores, Q_{max}, PVR volume and bladder diary after eight weeks of alfuzosin (n = 58) vs. placebo (n = 59). Of note, no EMG and/or voiding cysto-urethrography was used to distinguish between dysfunctional voiding and primary bladder neck obstruction [549].

Information on the comparative effectiveness of the different types of alpha-blockers was limited to one RCT. A small trial of 37 women with IPSS > 8, Q_{max} < 12 mL/s and PVR volume > 50 mL, compared tamsulosin and prazosin over a three-month treatment period. More patients treated with tamsulosin were completely satisfied with their treatment (16/20 vs. 9/20). Both treatment groups showed significant improvement in symptom scores from baseline but no further statistical comparison between the groups was done. However, a larger decrease in AUA symptom score was seen in the tamsulosin group compared with the prazosin group. More adverse events were reported with prazosin (thirteen vs. one case) [550].

4.5.6.2 Striated muscle relaxants

Baclofen is a gamma-aminobutyric acid (GABA) agonist that exerts its effect on the GABAergic interneurons in the sacral inter-mediolateral cell column responsible for the relaxation of the striated urinary sphincter during voiding.

A randomised placebo-controlled crossover trial investigated the efficacy and safety of a four-week course of oral baclofen 10 mg three times/day in 60 women diagnosed with BOO, based on increased EMG activity with sustained detrusor contraction during voiding. It showed a lower number of voids, significant improvements in Q_{max} and $P_{det}Q_{max}$ with baclofen compared with placebo. PVR volume, maximum cystometric capacity and MUCP were not significantly different between the groups. Adverse event rates were also similar, with the most common being somnolence, dizziness, and nausea. An important limitation of this study was the lack of patient-reported outcomes to assess symptoms and QoL [551].

4.5.6.3 Oestrogens

The relative reduction in urethral wall compliance seen in atrophic urethritis due to oestrogen deprivation may be responsible for urethral obstruction in postmenopausal women. Oestrogen therapy is thus theoretically expected to improve the condition. There are no published studies on the use of oestrogens specifically for the management of female BOO.

4.5.6.4 Sildenafil

Sildenafil, by inhibiting phosphodiesterase five, increases the levels of nitric oxide in the female urethral sphincter, thereby promoting urethral relaxation.

A placebo-controlled, randomised crossover trial that included twenty women with partial or complete retention or obstructive voiding, with high MUCP and elevated US-estimated sphincter volume (> 1.6 cm) showed that while there was significant improvement in symptom scores and urodynamic parameters from baseline with sildenafil treatment, this difference was not significant when compared with placebo [552].

4.5.6.5 *Thyrotropin-releasing hormone*

Intravenous thyrotropin-releasing hormone (TRH) has been postulated as a neurotransmitter that induces urethral relaxation [553]. The exact mechanism is unclear.

In a small RCT of sixteen women with voiding difficulty, eight (three with BOO) were randomised to receive 200 µg intravenous bolus of TRH, and eight (three with BOO) received saline. No difference in the decline in functional profile lengths and maximum urethral closure pressures were noted between treatment groups, despite a significant decline noted from baseline in the treatment group. No subgroup analysis of women with BOO was reported [553].

4.5.6.6 *Summary of evidence and recommendations for pharmacological management*

Summary of evidence	**LE**
Alpha-adrenergic blockers may be associated with improvement in symptom scores from baseline, but not urodynamic parameters compared with placebo.	1a
Tamsulosin is associated with greater improvement in symptom score compared with prazosin.	1b
Oral baclofen is better than placebo in improving Q_{max} and $P_{det}Q_{max}$, but not other urodynamic parameters. Its effects on symptoms are not well reported.	1b
Current evidence does not show that sildenafil is superior to placebo in improving symptoms or urodynamic parameters of female patients with BOO.	1b
Trials including women with voiding problems of mixed aetiologies showed no difference in urodynamic outcomes between intravenous TRH and placebo.	1b

Recommendations	**Strength rating**
Offer uroselective alpha-blockers, as an off-label option, to women with functional bladder outlet obstruction (BOO) following discussion of the potential benefits and adverse events.	Weak
Offer oral baclofen to women with BOO, particularly those with increased electromyography activity and sustained detrusor contraction during voiding.	Weak
Only offer sildenafil to women with BOO as part of a well-regulated clinical trial.	Strong
Do not offer thyrotropin-releasing hormone to women with BOO.	Strong

4.5.7 ***Surgical management***

4.5.7.1 *Intra-sphincteric botulinum toxin injection*

Botulinum toxin inhibits the presynaptic release of acetylcholine, which reduces urethral sphincter tone. It is also believed to decrease the release of noradrenaline in the urethra to counteract external urethral sphincter overactivity [554].

Evidence on the use of botulinum toxin for female BOO is limited to small case series. Most studies included mixed populations without subgroup analyses, or the diagnosis of voiding dysfunction could not be ascertained as solely resulting from BOO. No comparative trial exclusively involving female BOO patients using botulinum toxin has been identified in the literature.

A SR including several reports of small case series using variable doses of onabotulinumtoxinA injected periurethrally in women with dysfunctional voiding showed improvements in symptoms, and reductions in residual volume and voiding detrusor pressure. Larger series in adults (both sexes) showed success rates of 86–100% [554].

A double-blind, placebo-controlled RCT (n = 73) resulted in significantly lower IPSS score and larger voided volume after 100 U onabotulinumtoxinA compared with saline in 31 men and women with dysfunctional voiding. Dysfunctional voiding was defined by a spinning top appearance on real-time fluoroscopy, poorly relaxed urethral sphincter on EMG, and a normal-to-high voiding pressure with a low and/or intermittent urinary flow rate, a PVR volume > 300 mL, and a low voiding efficiency. Other urodynamic parameters were comparable between the groups [555]. A subgroup analysis on the female population of this study was not available.

Two small case series in women with BOO reported the effects of intrasphincter 100 U onabotulinumtoxinA. Both showed improvement in symptom and bother scores and significant reduction in PVR volume [513, 556]. One study reported increased Q_{max} and improved static urethral pressure profile (UPP) [513]. The average symptom-free duration was 16.8 weeks in another study [556]. Adverse events included UTI and temporary need for CISC. No SUI was reported.

4.5.7.2 Sacral nerve stimulation

Sacral nerve stimulation is postulated to decrease urethral tone and to work by blockade of the inhibitory urethral afferent impulses, which cause inhibition of normal bladder contraction.

No comparative trial has been identified in the literature on the use of neuromodulation for female BOO.

Most publications on neuromodulation for voiding dysfunction are retrospective reviews of cases, involving a mix of patient populations who underwent the procedure for different indications. In studies that indicated a subgroup of patients with urinary retention, there was either no urodynamic confirmation of the nature of the retention or separate outcomes were not reported for participants with retention.

A review of 60 women who underwent SNS for urinary retention associated with outlet obstruction (defined as UPP > 100 cm H_2O, increased urethral sphincter volume > 1.8 mL, and abnormal EMG with repetitive discharges and decelerating bursts) showed an overall spontaneous voiding rate of 72% over a mean follow-up of four years. Of those who continued to require CISC up to twice daily postoperatively, the frequency was less than prior to surgery (degree not specified). There were 99 adverse events and 63 surgical revisions. In this series, half of the patients underwent a one-stage SNS procedure and the other half a two-stage procedure. The proportion of patients who required CISC-assisted voiding was higher in the two-stage group (27% vs. 17%). More serious adverse events (defined as events requiring admission or surgical revision to resolve issues such as loss of response, lead migration and surgical revisions) were associated with the one-stage procedure [557].

4.5.7.3 Pelvic organ prolapse surgery

Pelvic organ prolapse surgery may relieve BOO by correcting the urethral kinking caused by the prolapse or by relieving the urethral compression brought about by the prolapsing organ [74, 509, 529].

Bladder outlet obstruction due to POP may be addressed by corrective surgery. Based on reviews, the majority of patients who had BOO caused by POP who had repair of their cystocoele demonstrated improvement of their voiding difficulties [462, 558].

A multicentre prospective study involving 277 women with at least grade two symptomatic POP who underwent surgery demonstrated a significant reduction in voiding symptoms and PVR volume one year postoperatively [559].

A retrospective study of 50 women who underwent laparoscopic sacrocolpopexy for POP showed a significant increase in mean postoperative Q_{max} and decrease in $P_{det}Q_{max}$ and PVR in those aged ≥ 65 years. The OAB symptom score improved but there was no significant difference in the ICIQ-SF score postoperatively [560].

4.5.7.4 Urethral dilatation

Urethral dilation involves the passage of sequentially greater diameter dilators into the urethra, causing the obstructing fibrotic tissue to break open, thereby widening the lumen. It is considered the primary procedure of choice for women suspected of urethral stricture disease [527]. Dilation of up to 30–40 Fr has been done. There is no standard dilatation technique; dilatation of up to 43 Fr has been described, although other authors suggest dilating to 30 or 35 Fr.

A systematic review of female urethral stricture management included three trials involving urethral dilatation. Pooled analysis of data from 93 women showed a mean success rate of 49% after urethral dilation to 41 Fr with a mean follow-up of 46 months. Mean time to failure was 12 months. In treatment-naïve patients, success rate (as defined by trialists) was 58%, compared with 27.2% in patients who had undergone previous dilatation [561].

An RCT of 50 women with OAB syndrome and associated urodynamically confirmed BOO (defined as a Q_{max} < 15 mL/s with a voided volume of ≥ 100 mL and/or PVR volume > 200 mL, not due to urethral stricture) compared the effect of cystoscopy and bladder distension with urethral dilatation (n = 22) and cystoscopy only (n = 28) after six weeks' follow-up. Significantly more patients who had cystoscopy only had persistent urgency at six weeks and six months postoperatively. Urodynamic parameters did not significantly change

pre- and postoperatively in both groups. The greater improvement in QoL scores based on the King's Health Questionnaire domain scores seen in the non-urethral dilatation group in this trial should be interpreted cautiously because of the higher baseline scores. There were no significant changes in Q_{max}, PVR volume, voided volume or $P_{det}Q_{max}$ in any of the two groups at six weeks' questioning the role of any of these two options for therapeutic management of BOO. Also, six patients (12%) developed postoperative SUI [562].

A prospective trial of 86 women with primary urethral stricture compared on-demand vs. intermittent urethral dilatation to 24 Fr every two months. It showed an overall increase in Q_{max} and decrease in PVR volume post-dilatation. Significantly greater improvements were seen in the intermittent urethral dilatation group [563].

Worsening or new-onset SUI is a concern with urethral dilatation, but it is less of a concern than after urethrotomy or surgical reconstruction. Patients have also reported frequency and urgency post-dilatation [564].

4.5.7.5 Urethrotomy

Urethrotomy involves incision of the urethra endoscopically or using a urethrotome. It addresses the urethral narrowing by cutting open the scar tissue which is causing the obstruction [74, 509, 529, 564].

A prospective study of ten women with urethral strictures investigated the effect of Otis urethrotomy to 40 Fr followed by six weekly dilatations. There was significant improvement in IPSS, QoL, voided volume, Q_{max} and PVR volume at six months. Only the improvements in PVR volume and QoL were maintained on long-term follow-up (mean 82 months) [565].

4.5.7.6 Bladder neck incision/resection

Transurethral bladder neck incision decreases resistance at the bladder neck by cutting open the hypertrophic bladder neck smooth muscle in patients with primary bladder neck obstruction. Transurethral incision of the bladder neck may be performed with a unilateral incision at the twelve o'clock position or with bilateral incisions at the five and seven o'clock, two and ten o'clock or three and nine o'clock positions, or four incisions at the three, six, nine and twelve o'clock positions. This may be done using a resectoscope with a Collin's knife, cold knife, or using laser energy. Some authors report additional resection of the bladder neck between the five and seven o'clock positions.

A review of non-comparative studies on bladder neck incision for the treatment of bladder neck obstruction in women reports success rates of 76–100% [512].

Bladder neck incision was compared with V-Y-reconstruction using Nesbit's technique in a retrospective study of seventeen women with BOO, diagnosed by various uroradiological, endoscopic and urodynamic investigations. The results showed similar symptomatic improvement rates and postoperative PVR volume between the two groups. V-Y plasty had a longer operating and catheter time, lower uroradiological improvement rate, higher transfusion rate, and higher adverse event rate [566].

Several prospective case series consistently reported significant improvements in IPSS, QoL, Q_{max}, $P_{det}Q_{max}$ and PVR volume after treatment compared to baseline, regardless of the site of the incision, type of energy used or the length of follow-up [567-570].

The largest case series with 84 patients diagnosed with primary bladder neck obstruction (based on lack of funnel shape of the bladder neck during voiding-on-voiding cysto-urethrography, P_{det} > 20 cm H_2O and Q_{max} < 12 mL/s) showed success in 84.5% of patients with improvement in IPSS, QoL, Q_{max} and $P_{det}Q_{max}$ after mean follow-up of 27.4 months (6–78 months). Complications included vesico-vaginal fistula (VVF) (3.6%), SUI (4.7%) and urethral stricture (3.6%) [567].

No comparisons have been made between the different incision techniques (location, length, and depth of incision, implement used – cold knife vs. hot knife vs. laser, with or without resection). However, in a case series of 84 patients, complications of VVF and SUI were noted in the cohort of patients who had their incisions at five and seven o'clock positions, and not in those who had their incisions at two and ten o'clock [567].

Adverse events include SUI, requirement for reoperation, and recurrence. Postoperative SUI was reported in 3– 33% [512].

4.5.7.7 Urethroplasty/urethral reconstruction

Surgical reconstruction of the female urethra has been used in the management of extensive urethral stricture. Several urethroplasty techniques include the use of vaginal or labial flaps, as well as vaginal and buccal grafts after cutting open the fibrotic tissue causing the urethral obstruction [571]. The use of bladder flaps has also been reported [572], and laboratory-engineered tissue grafts have also been used [572].

The surgical approaches have been described based on the position relative to the urethra; dorsal, ventral, or circumferential. The dorsal approach is believed to provide better mechanical support and a more vascularised bed for a graft or flap. However, there is greater risk of damage to the sphincter and clitoral bodies with this approach. The ventral approach is more familiar to most surgeons and requires less urethral mobilisation. However, it is reported as being more prone to urethrovaginal fistulae, although it is not clear to what extent [527].

Reviews of studies reporting outcomes of urethroplasty state success rates of 57–100% [573]. Pooled analysis from six studies using vaginal or labial flaps showed a mean success rate of 91% with a mean follow-up of 32 months. Vaginal or labial graft urethroplasty was reported to have an 80% success rate with a mean follow-up of 22 months.

Oral mucosal grafts, reported in seven studies, had a mean success of 94% after a mean follow-up of fifteen months [527]. A later review of studies on dorsal buccal mucosal graft reported success rates of 62–100%, with a pooled success rate of 86% [574]. A long-term study with a mean follow-up of 32 months showed a stricture recurrence rate of 23.1% [573].

4.5.7.8 Urethrolysis

Bladder outlet obstruction in women occurring as a complication of surgery for SUI may be managed surgically by urethrolysis, to regain urethral mobility. Urethrolysis may involve removal of peri-urethral anti-incontinence sutures, scar tissue and fibrosis.

Case series showed success rates measured as improved voiding and lower residual volumes, improvement, or resolution of symptoms and QoL, and improvement of urodynamic parameters after treatment [575-577]. *De novo* SUI was reported in 39% in one study [577]. Another study reported an association of persistent postoperative bladder symptoms with greater delay to performing urethrolysis [578].

4.5.7.9 Removal/excision/section/loosening of mid-urethral sling

In women who develop BOO after placement of a mid-urethral sling, surgical management may include tape loosening, incision or division, and excision and/or removal of the tape [462].

Several small retrospective reviews of cases using different techniques of sling revision (incision, partial excision, or excision) showed good success rates in terms of symptom reduction, resumption of voiding with significant reduction in PVR volume and improvement of urodynamic parameters. Stress urinary incontinence recurs in a small proportion of patients and often to a lesser degree than prior to the sling procedure. Studies have shown long-term efficacy, including preservation of continence.

In a series of 63 women who presented with voiding dysfunction and persistent PVR volume > 100 mL after tape surgery for UI, different techniques were compared. Comparisons involved sling revision: sling division (n = 46) vs. partial sling excision (n = 13) vs. sling revision (division or excision) with an additional anti-SUI procedure (n = 4). The authors reported an overall success rate of 87% (PVR volume < 150 mL). No significant difference in success rates was demonstrated among the different revision techniques. There was a greater need for surgery for recurrent SUI in the partial sling excision group without an anti-SUI procedure (23% vs. 2.2 and 0) [579].

One study showed that patients who underwent surgical release > 180 days after initial anti-UI surgery had significantly less recurrent SUI compared with patients who underwent the release sooner (15% vs. 46%) [580].

4.5.7.10 Summary of evidence and recommendations for surgical management of bladder outlet obstruction

Summary of evidence	**LE**
Intrasphincteric injection of botulinum toxin results in the improvement of symptoms and urodynamic parameters.	2
Sacral nerve stimulation results in spontaneous voiding and a reduction in CISC rate in the majority of female BOO patients in idiopathic urinary retention.	3

More serious adverse events and surgical revisions were associated with the one-stage neuromodulator implantation procedure.	3
Repair of POP improved PVR and voiding symptoms.	3
Urethral dilatation in women with BOO results in significant improvement in OAB symptoms, but improvements in urodynamic parameters of voiding are inconsistent.	1b
Programmed intermittent urethral dilatation results in better outcomes compared with on-demand dilatation.	3
Effects of urethral dilation are poorly sustained, requiring repeat intervention in the long term.	3
Internal urethrotomy followed by regular dilatations resulted in significant improvement in symptoms and urodynamic parameters in women with BOO.	3
Bladder neck incision in females with BOO results in improvements in symptoms and urodynamic parameters.	3
Complications of bladder neck incision are not common, but include VVF, SUI, and urethral stricture.	3
Urethroplasty using grafts or flaps in women with BOO due to urethral stricture have good success rates with significant improvements of symptoms, QoL scores and urodynamic parameters compared to baseline.	3
Urethroplasty results in better QoL and Q_{max} compared to urethral dilatation.	2
Long-term results showed significant stricture recurrence rate after urethroplasty.	3
Urethrolysis performed on women with voiding problems after anti-UI surgery resulted in improvements in symptoms, QoL and urodynamic parameters post-operatively.	3
Delayed urethrolysis was associated with persistent post-operative bladder symptoms.	3
Sling revision in women who presented with urinary retention or voiding problems and significant PVRs after sling surgery for UI resulted in improvements in symptoms and urodynamic parameters, resumption of voiding and reductions in PVRs.	3
Sling revision is associated with the risk of recurrent SUI.	3

Recommendations	**Strength rating**
Offer intra-sphincteric injection of botulinum toxin to women with functional bladder outlet obstruction (BOO).	Weak
Offer sacral neuromodulation to women with functional BOO.	Weak
Advise women with voiding symptoms associated with pelvic organ prolapse that symptoms may improve after surgery.	Weak
Offer urethral dilatation to women with urethral stenosis causing BOO but advise on the likely need for repeated intervention.	Weak
Offer internal urethrotomy with postoperative urethral self-dilatation to women with BOO due to urethral stricture disease but advise on its limited long-term improvement and the risk of postoperative urinary incontinence (UI).	Weak
Do not offer urethral dilatation or urethrotomy as a treatment for BOO to women who have previously undergone mid-urethral synthetic tape insertion due to the theoretical risk of causing urethral mesh extrusion.	Weak
Inform women of limited long-term improvement (only in terms of post-void residual volume and quality of life) after internal urethrotomy.	Weak
Offer bladder neck incision to women with BOO secondary to primary bladder neck obstruction.	Weak
Advise women who undergo bladder neck incision on the small risk of developing stress urinary incontinence (SUI), vesico-vaginal fistula or urethral stricture postoperatively.	Strong
Offer urethroplasty to women with BOO due to recurrent urethral stricture after failed primary treatment.	Weak
Caution women on the possible recurrence of strictures on long-term follow-up after urethroplasty.	Weak
Offer urethrolysis to women who have voiding difficulties after anti-UI surgery.	Weak

Offer sling revision (release, incision, partial excision, or excision) to women who develop urinary retention or significant voiding difficulty after tape surgery for UI.	Strong
Caution women about the risk for recurrent SUI and the need for a repeat/concurrent anti-UI surgery after sling revision.	Strong

*4.5.8 **Follow-up***

Women with BOO should be followed up and monitored regularly due to the risk of further deterioration of voiding or renal function in case of persistence and progression of the obstruction. For those who received treatment, monitoring must be done for recurrence of BOO. In particular, women who undergo urethral dilation, urethrotomy or urethroplasty for urethral stricture need to be monitored for stricture recurrence.

4.6 Nocturia

Nocturia was defined by the ICS in 2002 as "*the complaint that the individual has to wake at night one or more times to void*" and quantified in an updated document in 2019 as "*the number of times an individual passes urine during their main sleep period, from the time they have fallen asleep up to the intention to rise from that period*" [581]. The EAU Guidelines Panel on Urinary Incontinence conducted a SR on nocturia in women [582]. The search covered evidence up to 2017 and this review was updated with a scoping search in 2020.

*4.6.1 **Epidemiology, aetiology, pathophysiology***

The prevalence of nocturia varies according to age with 4–18% of women aged 20–40 years experiencing ≥ 2 episodes per night, compared to 28–62% of women aged ≥ 70 years [583]. In a study of 1,000 community-dwelling older adults, female nocturia was associated with older age, African American race, history of UI, lower limb oedema and hypertension [584]. A report on > 5,000 adults aged 30–79 years identified around 28% with nocturia and found additional correlates with increased cardiac disease, type 2 diabetes, and diuretic use [585]. A SR and meta-analysis with moderate certainty evidence based on the GRADE approach, demonstrated that the higher incidence of nocturia among hypertensive patients was more strongly associated (1.2 to 1.3-fold) among Black and Asian women, unrelated to their age or BMI status [586]. Another SR with moderate certainty of evidence based on the GRADE approach showed that nocturia was associated with a 1.2-fold increased risk of falls and possibly an approximately 1.3-fold increased risk of fractures [587]. Another SR and meta-analysis concluded that nocturia is probably associated with an ~1.3-fold increased risk of death [587].

The aetiology of nocturia is multifactorial and can include both urological and non-urological causes. Urological conditions which may exhibit nocturia as a significant symptom include OAB syndrome, BOO, DU, and dysfunctional voiding. Non-urological causes include 24-hour polyuria (which includes nocturnal polyuria), congestive heart failure, sleep apnoea, restless leg syndrome, peripheral vascular disease, sleep disorders, night-time food ingestion, dependent oedema, and excessive fluid intake [588]. Given the varied aetiology of this symptom, there are a range of possible pathophysiological mechanisms, including: (1) 24-hour polyuria (e.g., diabetes mellitus, primary polydipsia, and diabetes insipidus); (2) nocturnal polyuria (e.g., behavioural, peripheral oedema, obstructive sleep apnoea, glycosuria, hormonal abnormalities and cardiac dysfunction); (3) diminished bladder capacity (e.g., OAB syndrome/DO, PFM dysfunction, BOO, pharmaceuticals, LUT calculi or tumours, and neurological bladder dysfunction); and (4) primary or secondary sleep disorders [589].

In postmenopausal women the relative deficiency in endogenous oestrogen production is thought to exacerbate all major pathophysiological mechanisms that may underlie nocturia [590].

*4.6.2 **Classification***

Classification of nocturia is dependent on bladder diary analysis and several parameters have been defined as important [591]:

- nocturnal urine volume – total volume of urine passed during the night (this includes the first morning void but does not include the last void prior to sleep);
- maximum voided volume – largest single voided volume in 24 hours;
- nocturia index – nocturnal urine volume divided by maximum voided volume;
- nocturnal polyuria index – nocturnal urine volume divided by 24-hour urine volume;
- nocturnal urine production – nocturnal urine volume divided by duration of sleep, in hours.

Analysis of these parameters allows clinical classification of nocturia based on physiological abnormalities that can cause nocturia:

- 24-hour polyuria;
- nocturnal polyuria;
- diminished bladder capacity;
- sleep disorders.

*4.6.3 **Diagnostic evaluation***

Evaluation of nocturia should include a thorough medical history and physical examination with particular reference to history of sleep disorders, fluid balance, associated LUTS, cardiovascular and endocrine co-morbidity, renal disease, current medications, and history of urological disease [591, 592]. There are several nocturia-specific symptom scores, such as the ICI Questionnaire-Nocturia, Nocturia Quality of Life Questionnaire (N-QoL), and Nocturia Impact Diary; some of which were developed in men. These questionnaires have shown good content and discriminant validity, reliability, and sensitivity to change as well. A further screening tool that aims to identify causes of nocturia is the Targeting the individual's Aetiology of Nocturia to Guide Outcomes (TANGO) assessment tool [593-595]. The PLANET study (PLanning Appropriate Nocturia Evaluation and Treatment) has suggested a useful tool for initial history taking called the SCREeN tool, with questions focused on evaluating areas of Sleep, Cardiovascular, Renal, Endocrine and Neurological function [596].

A bladder diary is a vital initial investigation tool in patients complaining of nocturia and further supplementary investigations are guided by any abnormalities identified. Bladder diary analysis can allow for calculation of the parameters detailed in Section 4.6.2. A low nocturnal bladder capacity or global bladder capacity will be highlighted by reduced voided volumes during nocturnal hours or both night and day. This suggests an underlying urological condition such as OAB syndrome, BOO or DU. The term 24-hour polyuria is defined as 24-hour urine production > 40 mL/kg [597] and may be present in conditions such as diabetes mellitus or diabetes insipidus. The definition of nocturnal polyuria is age dependent and the thresholds for this diagnosis range from 20% (in younger persons) to 33% (age > 65 years) of the 24-hour urine volume produced during sleep. This may also be observed in patients with loss of circadian rhythm, cardiovascular disease, sleep apnoea, or sleep disorders [591]. A large study conducted across European and American centres involving ~2,000 patients identified nocturnal polyuria as a contributory cause of nocturia in 89% of patients who were being treated for LUT abnormalities such as OAB syndrome or benign prostatic enlargement [598].

As an alternative to the ≥ 3-day bladder diary a nocturnal-only diary has been investigated in men [599]. The results showed acceptable sensitivity and specificity for the nocturnal bladder diary compared with the standard bladder diary for most parameters. The nocturnal-only diary was not able to diagnose 24-hour polyuria and has not yet been validated for use in women.

A 2022 SR and nominal group technique (NGT) consensus exercise based on fourteen observational studies of mixed populations recommended including blood tests for renal function, thyroid function, HbA1c and calcium levels in the initial work-up of patients presenting with nocturia [600-602].

Sleep disorders are potentially highly influential in nocturia, but often overlooked. A 2022 SR and NGT expert consensus based on thirteen mixed studies (nine cohort, three cross-sectional and one case-control) recommended the use of screening questions to reach a clinical diagnosis of sleep disorder (insomnia, restless legs syndrome/periodic limb movements of sleep and parasomnias) to offer conservative treatment within primary care [601].

4.6.3.1 Summary of evidence and recommendations for diagnosis of nocturia

Summary of evidence	**LE**
A thorough medical history is an integral part of the evaluation of women presenting with nocturia, including screening for sleep disorders.	4
Nocturia-specific questionnaires are sensitive to symptom changes.	3
A bladder diary allows for calculation of important indices and can identify potential causes of nocturia.	3
Nocturnal-only bladder diaries have been evaluated in men only.	3
Consider renal function, thyroid function, HbA1c and calcium level blood tests in the initial workup of women presenting with nocturia.	2

Recommendations	**Strength rating**
Take a complete medical history from women with nocturia, including screening for sleep disorders.	Strong
Use a validated questionnaire during assessment of women with nocturia and for re-evaluation during and/or after treatment.	Weak
Use a three-day bladder diary to assess nocturia in women.	Strong

Do not use nocturnal-only bladder diaries to evaluate nocturia in women.	Weak
Consider screening for sleep disorders and performing renal function, thyroid function, HbA1c and calcium level blood tests in the initial workup of women presenting with nocturia as predominant symptom.	Strong

*4.6.4 **Disease management***

When evaluating the results of trials involving treatment strategies for nocturia, it is vital to examine for clinical significance as statistical significance can be achieved with small reductions in nocturia episodes.

4.6.4.1 Conservative management

The individual components of self-management have not been critically evaluated and most recommendations are traditionally derived from consensus methodology. Interventions such as those listed below may help with nocturia but, for the majority, no quantification of their effect is possible:

- reduction of fluid intake at specific times;
- avoidance/moderation of intake of caffeine or alcohol;
- distraction techniques;
- bladder retraining;
- pelvic floor muscle training;
- reviewing medication;
- treatment of constipation.

The available data for conservative treatment of nocturia show significant heterogeneity. In a SR [582], three studies [603-605] were favourable for conservative treatment with PFMT, with another failing to confirm a benefit [606].

The highest level of evidence comes from a study of 131 patients (a secondary analysis from a prospective RCT that had urgency-predominant UI as the primary inclusion criterion). The study found that training in PFM contraction, which included four sessions of biofeedback-assisted PFMT, reduced nocturia by a median 0.50 episodes per night and was significantly more effective than anticholinergic drug treatment or placebo [603]. The certainty of evidence associated with this treatment is moderate.

A smaller RCT of 50 women with urinary complaints, randomised 1:1 to BT and PFMT compared with a control group receiving no treatment, showed a significant decrease in patients' complaints of nocturia [604]. Another RCT in only 24 women compared PFMT only to Interferential Therapy plus [605]. Although the authors did not find significant differences between the groups, the change in nocturia episodes before and after treatment was statistically significant in both groups. This study was underpowered by the authors' own admission. The level of certainty of the evidence from these two trials is low. A large randomised, two-arm, parallel design, superiority trial (n = 647; women), compared the effects of unsupervised behavioural PFMT programmes delivered in a two-hour class format and 20 minutes video format on UI prevention. No significant between-group differences of nocturia were observed at 3 months and 12 months, but at 24 months, women in the 2 hour class group were less likely to have fewer nocturia episodes (OR = 0.5; 95 % CI: 0.3–0.7; p = 0.005) compared with those in the 20 minutes video group, but the authors concluded that the evidence is not sufficient to support one management strategy [605].

A multicentre, open-labelled, RCT evaluated whether cognitive behavioural therapy (CBT) using a self-assessment via a checklist is effective in improving nocturia in a mixed population (30/78 women). The mean rate of achievement of the CBT group was 64.4%. There was no significant difference between the two groups in night-time frequency based on the IPSS Q7 at four weeks but episodes of nocturia on the frequency volume chart (FVC) were significantly smaller in the CBT group (1.9 ± 0.9) than in the control group (2.4 ± 1.3; p = 0.039) [607].

In a secondary analysis from a prospective RCT, 210 women with urgency UI (UUI) were evaluated for change from baseline in the number of episodes of nocturia and nocturnal incontinence between groups allocated to medical treatment (tolterodine ER 4 mg) alone vs. medical treatment plus PFMT [606]. No significant difference between the groups was found and the actual difference in nocturia episodes in either treatment arm was small. The level of certainty of the evidence from this trial is low.

A recent RCT has explored both individual and group PFMT with a specific secondary outcome of number of patients with two or more nocturia episodes per night [319]. The authors reported similar reductions, with > 30% of patients who had ≥ 2 episodes of nocturia at baseline no longer experiencing this level of symptoms at one year after PFMT.

One small, single-centre RCT in which functional magnetic stimulation was compared with no treatment in 39 women reported a significant decrease in nocturia (together with voiding frequency and pad use) in the treatment group compared with the control group [608].

In patients with obstructive sleep apnoea who complain of nocturia, continuous positive airway pressure has been shown to be effective in a SR and meta-analysis of five RCTs involving both sexes [609]. This treatment was associated with an average numerical reduction in nocturia of > 2 episodes per night.

4.6.4.1.1 Summary of evidence and recommendations for conservative management of nocturia

Summary of evidence	**LE**
Individual or group PFMT appears to be equally effective for reduction in nocturia episodes.	1b
Most studies evaluating PFMT for nocturia in women with additional urinary symptoms have shown positive results compared with placebo or anticholinergic drugs.	1b
Treatment of nocturia secondary to obstructive sleep apnoea with continuous positive airway pressure reduces nocturia episodes.	1a

Recommendations	**Strength rating**
Offer women with lower urinary tract symptoms (LUTS) lifestyle advice prior to, or concurrent with, treatment.	Strong
Offer pelvic floor muscle training for nocturia (either individually or in the group setting) to women with urinary incontinence or other storage LUTS.	Strong
Offer women with nocturia and a history suggestive of obstructive sleep apnoea a referral to a sleep clinic for assessment of suitability for continuous positive airway pressure treatment.	Strong

4.6.4.2 Pharmacological management

4.6.4.2.1 Desmopressin

Desmopressin is a synthetic analogue of the hormone vasopressin and is most often used for management of nocturia due to nocturnal polyuria. In a SR [582], three trials specifically conducted in women were found but more additional data could be extracted from studies in mixed populations. The earliest evidence comes from a 1982 single-site crossover trial involving 25 women treated with 20 g desmopressin or placebo and revealed a significant decrease in nocturnal urine output at six weeks [610]. A more recent multicentre, multinational double-blind RCT involving 141 women used desmopressin 0.1, 0.2 or 0.4 mg orally at bedtime after a dose-titration period [611]. This increased the likelihood of a positive outcome because non-responders were excluded at that stage. At three weeks, significant reductions in nocturnal urinary frequency and nocturnal diuresis were reported. In another multicentre double-blind RCT, 58 women were randomised into five groups (twelve receiving placebo, twelve desmopressin 10 µg, eleven desmopressin 25 µg, eleven desmopressin 50 µg and twelve desmopressin 100 µg) for four weeks [612]. A dose–response relationship was observed, and women appeared more sensitive than men to desmopressin. Significant changes in nocturnal urine volumes were reported in favour of the higher desmopressin doses. Differences in the nocturnal polyuria index also tended to favour desmopressin over placebo and the higher desmopressin doses. The level of certainty of the evidence from these trials is low.

Desmopressin can be safely combined with anticholinergics with significant benefit in women with OAB and nocturnal polyuria, as shown by a multicentre RCT of 97 patients [613]. A *post hoc* analysis of data comparing three-month once-daily combination (desmopressin 25 µg/tolterodine 4 mg, n = 49) or monotherapy (tolterodine 4 mg/placebo, n = 57) revealed a significant reduction in nocturnal void volume and time to first nocturnal void in favour of combination therapy. The level of certainty of the evidence from this trial is moderate.

Pooled data from three RCTs were used to examine the adverse event profile of desmopressin, specifically hyponatraemia [614]. The authors reported that the majority tolerate desmopressin treatment without clinically significant hyponatraemia, but risk increased with age and lower baseline serum sodium concentration. They advised that desmopressin treatment in elderly patients should include careful monitoring of the serum sodium concentration and should be avoided in patients with a baseline serum sodium concentration below normal range.

4.6.4.2.2 Anticholinergics

A SR [582] identified three RCTs involving anticholinergics such as oxybutynin 2.5 mg/day [603] and tolterodine 4 mg/day [606, 613]. A secondary analysis from a prospective RCT involving 131 women with nocturia followed up for eight weeks found that women receiving 2.5 mg immediate-release oxybutynin once daily (with the possibility of self-titration and dose escalation to 5 mg three times daily) had fewer nocturia episodes than women receiving placebo [603]. Women receiving oxybutynin plus behavioural therapy also exhibited a significant decrease in nocturia episodes compared with placebo and oxybutynin alone. A multicentre RCT with 305 women followed up for eight weeks examined the efficacy of tolterodine tartrate 4 mg alone or in combination with behavioural training [606]. Significant differences compared with baseline were observed in mean nocturia episodes and nocturnal incontinence episodes in both groups, but no difference was reported between the two treatment groups. The level of certainty of the evidence from this trial is moderate.

In an RCT including 97 women with nocturnal polyuria and OAB syndrome, comparing three months of once daily combination (desmopressin 25 µg/tolterodine 4 mg, n = 49) or monotherapy (tolterodine 4 mg/placebo, n = 57), a significant reduction in mean number of nocturnal voids compared with baseline was reported in both groups [613]. The level of certainty of the evidence from this trial is moderate.

A large comparative study followed 407 women with OAB and nocturia for four weeks [615]. The patients were given tolterodine as monotherapy in one group, and tolterodine combined with estazolam (a benzodiazepine) in the other group. Significant changes from baseline in both groups for the main outcome of number of nocturia episodes were reported. Combination therapy showed a significant benefit for women with OAB and nocturia compared with monotherapy in terms of differences in number of nocturia episodes, urgency episodes in 24 hours, UUI episodes in 24 hours, and voided volume per micturition. The level of certainty of the evidence from this trial is very low.

A small multicentre RCT compared oxybutynin patch vs. mirabegron on nocturia-related QoL in women with OAB. Both treatments showed improvements in N-QoL score at four weeks, but mirabegron showed statistical differences at eight weeks. Additionally, only mirabegron decreased nocturnal frequency and water intake, and prolonged hours of uninterrupted sleep eight weeks after administration with statistical significance, whereas oxybutynin patch did not [616].

4.6.4.2.3 Oestrogens

In a SR [582], only a single RCT investigating the efficacy of oestrogen for nocturia was identified [617]. This trial compared an oestradiol-releasing vaginal ring with an oestriol vaginal pessary in 251 women followed up for six months. There was no difference between the treatment groups in the number of women reporting nocturia, although they reported significant change from baseline in both treatment arms with > 50% of subjects responding in each arm. The certainty of evidence for this outcome was low.

4.6.4.2.4 Diuretic treatment

In a randomised placebo-controlled study an afternoon dose of 40 mg furosemide (taken six hours before bedtime) in an attempt to establish complete diuresis before bedtime was given to elderly men [618]. In the 43 men who completed the study, night-time frequency in the furosemide group fell by 0.5 episodes compared with placebo, and percentage night-time voided volume fell by 18%. No such study has been carried out in female patients.

4.6.4.3 Summary of evidence and recommendations for pharmacological management of nocturia

Summary of evidence	**LE**
Desmopressin treatment for nocturia shows significant reductions in nocturnal urine output, nocturnal urinary frequency, and nocturnal polyuria index.	1b
Most nocturia patients tolerate desmopressin treatment without clinically significant hyponatraemia; however, the risk increases with increasing age and decreasing baseline serum sodium concentration.	1a
Treatment of nocturia in OAB patients with anticholinergic drugs shows reduction in nocturia episodes.	1b
Combination of PFMT and anticholinergics does not appear to confer additional benefit over anticholinergics alone.	1b
Combination of anticholinergic and desmopressin treatment appears to reduce nocturnal voided volume and time to first nocturnal void in women with nocturnal polyuria.	1b
Vaginal oestrogen may be beneficial in the treatment of nocturia in around 50% of women.	1b

Afternoon (timed) diuretic treatment with furosemide reduces nocturia episodes and nocturnal voided volume in men but no similar studies have been conducted in women.	1b
Assessment of clinical significance is important when evaluating trials involving treatment strategies for nocturia, as statistical significance can be achieved with small reductions in nocturia episodes.	3

Recommendations	Strength rating
Offer desmopressin treatment for nocturia secondary to nocturnal polyuria to women, following appropriate counselling regarding the potential benefits and associated risks (including hyponatraemia).	Strong
Carefully monitor serum sodium concentration in elderly patients treated with desmopressin. Avoid prescribing desmopressin to patients with a baseline serum sodium concentration below normal range.	Strong
Offer anticholinergic treatment for nocturia to women with urge urinary incontinence or other LUTS, following appropriate counselling regarding the potential benefits and associated risks.	Strong
Inform women with nocturia that combination of behavioural therapy and anticholinergic drugs is unlikely to provide increased efficacy compared with either modality alone.	Weak
Offer combination of anticholinergics and desmopressin to women with overactive bladder and nocturia secondary to nocturnal polyuria, following appropriate counselling regarding the potential benefits and associated risks.	Weak
Offer vaginal oestrogen treatment to women with nocturia, following appropriate counselling regarding the potential benefits and associated risks.	Weak
Offer timed diuretic treatment to women with nocturia secondary to polyuria, following appropriate counselling regarding the potential benefits and associated risks.	Weak

4.6.4.4 Surgical management

Surgical treatment is generally reserved for those with underlying correctable LUT disorders. The effect of surgical treatments on symptoms of nocturia can be found in the relevant condition-specific sections of this guideline.

*4.6.5 **Follow-up***

Follow-up of patients with nocturia is dependent on the underlying aetiology of this symptom and the treatment given.

4.7 Pelvic organ prolapse and lower urinary tract symptoms

*4.7.1 **Epidemiology, aetiology, pathophysiology***

Pelvic organ prolapse is a common condition in adult women. The prevalence of POP is 3–6% when bothersome symptoms are used to characterise the condition and increases to 50% when a purely anatomical definition is used [619].

The estimated lifetime risk for POP surgery is 12.6% [620]. Parity, vaginal delivery, ageing, and obesity are the most commonly recognised risk factors [621].

Although the aetiology of POP is not fully understood, birth trauma to the levator ani complex is recognised as central to its development. In normal physiology, an intact levator ani complex functionally closes the genital hiatus surrounding the vagina, limiting the pressure gradient between the intra-abdominal and intravaginal areas. During physical activities, this reduces stress on the endopelvic fascia and its condensations (e.g., ligaments), which are crucial in securing the bladder, uterus, and rectum to their surroundings. Current aetiological concepts include widening of the levator hiatus due to birth trauma, which creates a low-pressure area in the vagina and consequently increased stress on the ligaments, fascial elements, and PFMs during physical activity. When the supporting function of the muscles and connective tissues fails, POP may develop [622]. This concept also explains the time lapse between birth trauma and occurrence of POP.

Pelvic organ prolapse and LUTS often occur simultaneously in women. In isolation, both POP and LUTS are prevalent conditions in women, although the prevalence of LUTS in women with POP exceeds that of LUTS in women without POP [619]. In a meta-analysis and SR, consistent results demonstrated a higher prevalence of OAB symptoms and UUI in patients with POP than without POP [619, 623]. The observation that LUTS may improve or worsen after POP treatment suggests a link between these two entities [619]. Clinical examples include the occurrence of BOO symptoms in severe POP, and disappearance of SUI symptoms with progression

of POP (and conversely the occurrence of SUI after treatment of POP) [624]. Pelvic organ prolapse is also associated with symptoms of bowel and/or sexual dysfunction [625].

*4.7.2 **Classification***

Since 1996, POP has been classified according to the Pelvic Organ Prolapse-Quantification (POP-Q) system [626]. For specifics on how to perform the POP-Q measurement and the nine standard points to be measured (Figures 2 and 3), we refer to the original publications [626, 627].

The vagina is divided into anterior (bladder), posterior (rectum) and apical (cervix or vaginal vault) compartments. After scoring the position of the nine POP-Q points, a prolapse of each compartment is graded numerically from stage 0 to 4, with stage 0 being no prolapse and stage 4 being complete eversion of the compartment. A crucial marker in staging POP is the hymenal remnant. Any POP with a maximum descent that is still 1 cm above the hymen (e.g., in the vagina) is considered a stage 1 POP. A maximum descent between 1 cm above and 1 cm below (outside the vagina) the hymen is a stage 2 POP. Any descent beyond 1 cm below the hymen is a stage 3 POP.

The figures below show the POP-Q staging in comparison to the Baden–Walker system (and others) used before the international consensus on the POP-Q staging was introduced as the new standard.

*4.7.3 **Diagnostic evaluation***

Pelvic organ prolapse is a clinical diagnosis and is staged according to the POP-Q system. Pelvic organ prolapse that is above the hymen should only produce mild symptoms at most [628]. In cases where there is a discrepancy between the clinical symptoms and POP-Q staging, it is advised to consider performing the POP-Q measurement in a standing rather than supine position or re-evaluating at a later time in the day. Magnetic resonance imaging assessment demonstrated a marked difference in POP staging between supine and standing position [629]. Additional diagnostic tests for POP are mainly indicated if there are accompanying symptoms like LUTS or bowel dysfunction. Imaging techniques are not advised for the routine diagnostic work-up of patients presenting with POP [66]. The role of urodynamics in the diagnostic work-up of SUI has been discussed in Section 4.2, of this guideline.

The use of techniques to reduce POP during urodynamic evaluation to diagnose occult SUI is common practice. This information may be used to decide if additional anti-UI surgery should be offered at the time of POP surgery or to counsel patients on the possible after-effects of POP treatment.

There are several POP reduction methods that may be used during physical examination or urodynamic evaluation. In a multicentre observational study, five different cough/stress tests were compared for their ability to detect SUI in women with POP [630]. Stress urinary incontinence during at least one of the five tests occurred in 60/205 (29.2%) women without SUI symptoms. Looking at single test performance, the detection rate of occult SUI in women without symptoms increased from 4.4% in case of no reduction to 22% in case of reduction with a pessary.

A large RCT included women with POP without symptoms of SUI, who were randomised to sacro-colpopexy with or without Burch colposuspension [631]. Three hundred and twenty-two stress-continent women with stages 2–4 prolapse underwent standardised urodynamic testing, and the protocol included five prolapse reduction methods. Preoperatively, twelve of 313 (3.7%) women demonstrated urodynamic SUI without prolapse reduction. Preoperative detection of urodynamic SUI with prolapse reduction at 300 mL was by pessary, 6% (5/88); manual, 16% (19/122); forceps, 21% (21/98); swab, 20% (32/158); and speculum, 30% (35/118). Another large trial included women with POP without SUI symptoms randomised to vaginal POP surgery with or without (sham incision) MUS [632]. Before surgery, 33.5% (111/331) of women demonstrated SUI at a prolapse-reduction cough stress test. In an observational study of 172 women with POP without SUI, 19% of women were diagnosed with occult SUI by basic office evaluation (with prolapse reduction with swab on forceps) and 29% on urodynamic evaluation [633].

In summary, SUI can be demonstrated in women with POP without symptoms of SUI after POP reduction in up to 30% of cases. There is no consensus on the best reduction technique.

Although the detection rate of occult SUI increases after reduction of POP in women without SUI symptoms, its clinical value is under debate.

In one trial, preoperative stress-continent women were evaluated during urodynamic testing with prolapse reduction to determine if they were more likely to report postoperative SUI, regardless of concomitant colposuspension (controls 58% vs. 38% and Burch colposuspension 32% vs. 21%) [631]. In another trial, women with SUI during the cough stress test after POP reduction reported UI at three months in 29.6% in the synthetic MUS group, compared with 71.9% in the sham group [632]. Women with a positive prolapse reduction stress test before surgery appeared to receive more benefit from a synthetic MUS at three months, but not at twelve months, than did those with a negative test.

In a large observational study, women did not receive additional anti-UI surgery even if they had SUI after POP reduction preoperatively. In this scenario, 9% (16/172) of women developed postoperative *de novo* SUI and six underwent surgery for *de novo* SUI [633]. Women with demonstrable preoperative SUI were more at risk of postoperative SUI: 28% vs. 5%. Based on urodynamic evaluation only, one more woman was predicted to have postoperative SUI, but all six women who underwent treatment for *de novo* SUI showed SUI during basic office evaluation.

In a model developed to predict the risk of *de novo* SUI in women undergoing POP surgery based on findings from two trials, twelve preoperative predictors were tested [634]. Positive SUI during a preoperative prolapse reduction test was included in this model, but it failed to be a significant predictor as a single item. Preoperative POP stage was not associated with risk of *de novo* SUI.

4.7.3.1 Summary of evidence and recommendation for detection of SUI in women with POP

Summary of evidence	LE
Pelvic organ prolapse reduction during cough stress test, in office or during urodynamics detects SUI in ~30% of continent women.	2a
Women with SUI after POP reduction preoperatively (occult SUI) is likely to be at increased risk of developing SUI symptoms after POP surgery.	2a

Recommendation	Strength rating
Perform pelvic organ prolapse (POP) reduction test in continent women to identify those with occult stress urinary incontinence and counsel them about the pros and cons of additional anti-incontinence surgery at the time of POP surgery.	Strong

4.7.3.2 Urodynamics in women with pelvic organ prolapse and LUTS (without stress urinary incontinence)
The role of urodynamics is less clear in women presenting with POP and concurrent LUTS, other than SUI. Pelvic organ prolapse is a complex condition incorporating different compartments of the vagina and presenting at different stages of severity. Information about detrusor activity, as assessed with urodynamics, may provide information about the risk of developing DO after surgery, but also on the risk of urinary retention due to DU. An observational study assessed predictors for DO following POP surgery for POP-Q stage 3 or higher in 1,503 women and the authors concluded that preoperative maximum urethral closure pressure > 60 cm H2O, Qmax < 15 mL/s, maximum detrusor voiding pressure (D_{max}) ≥ 20 cm H_2O and PVR volume ≥ 200 mL were independent risk factors for postoperative DO [635]. A small observational study (n = 49) evaluated patients with preoperative DU (detrusor pressure at maximum flow was ≤ 10 cm H_2O and Q_{max} ≤ 12 mL/s) after POP surgery. Surgery objectively cured DU in 47% of women and urodynamic findings normalised after surgery [636]. The 2019 NICE Guidelines do not include a recommendation to perform urodynamics as part of the diagnostic work-up of POP, except for combination with symptomatic SUI [66].

4.7.4 ***Disease management***
Pelvic organ prolapse symptoms can be treated with PFMT, vaginal pessary, surgery, or a combination of these treatments. The scope of these guidelines is to focus on LUTS in women; therefore, only data on the effect of treatment of urinary symptoms are presented.

4.7.4.1 Conservative management of pelvic organ prolapse
The 2013 NICE guidelines on Urinary Incontinence and POP in Women had an updated management section in 2019, including a full evidence review [66]. The overall conclusion with respect to conservative treatment for POP was that the evidence is of low quality. Thirteen RCTs were identified. Seven studies presented data on changes in urinary symptoms [637-643]. An additional search identified four RCTs that addressed the addition of PFMT to POP surgery [644-647], and one that compared combined PFMT/Pilates therapy with lifestyle advice by leaflet [648].

Five studies [638, 640-642, 648] compared PFMT to lifestyle advice/leaflet; one study [639] compared PFMT alone to PFMT with pessary; one study [643] compared PFMT to pessary therapy; and five studies compared surgery for POP with or without addition of PFMT [637, 644-647].

4.7.4.1.1 Pelvic floor muscle training versus lifestyle advice
An RCT (n = 109) reported that, at six months' follow-up, the ICIQ-UI-SF scores improved in favour of the PFMT group (2.40 points) compared with a control group receiving lifestyle advice only (0.2 points), but the mean baseline score in the PFMT group was higher than in the control group (7.4 vs. 5.9) [638]. Likewise, it has to be noted that the absolute ICIQ-UI-SF values at six months' follow-up were not significantly different between PFMT (4.8) and controls (5.2).

Two publications from one RCT reported on the three-, six- and twelve-month results of lifestyle advice only vs. lifestyle advice combined with group PFMT [640, 641]. The Urogenital Distress Inventory-6 (UDI-6) and Urinary Impact Questionnaire-7 (UIQ-7) questionnaires were used to assess urinary symptoms. At three months' follow-up, both groups (53 women in the lifestyle group and 56 in the lifestyle + PFMT cohort) reported significantly improved UDI-6 scores, while the lifestyle-only group also reported significantly greater improvement in the UIQ-7 score. Between-group comparison showed no differences in UDI-6 and UIQ-7 scores at six months. At twelve months' follow-up, the majority of women had sought additional treatment (70% in the lifestyle-only group

and 48% in the lifestyle/PFMT group). The number of patients remaining on the original therapy was too small to reach strong conclusions.

One RCT reported on six- and twelve-months follow-up of 225 women with POP-Q stage 1–3 randomised to individualised PFMT and 222 women randomised to lifestyle leaflet information only (control) [642]. At six months, significantly more women in the control group reported UI, the need to strain to empty their bladder, and the feeling of incomplete emptying compared to the PFMT group. ICIQ-SF score was also significantly worse in the control group as compared to the PFMT group. However, at twelve months, there was no significant difference in these items between groups. It has to be noted that 50% in the control group received additional treatment within the twelve-month study period. Twenty-seven percent had additional PFMT, which may have had an effect on the twelve-month data.

Another RCT reported on the 24-month follow-up of 414 women with stage 1–3 POP (207 assigned to PFMT/Pilates and 207 to lifestyle advice) [648]. Urinary symptoms were assessed with the ICIQ-UI-SF and a question about UI and difficulty emptying the bladder. At 24 months, the ICIQ-UI-SF score was significantly better in the intervention group (mean difference −0.83). However, the proportion of women reporting any UI did not differ between the groups, nor did the number of pads used weekly.

One RCT compared PFMT alone to PFMT and pessary for symptomatic POP [639]. Urinary tract symptom changes were assessed using UDI-6 and UIQ at six and twelve months follow-up. At twelve months, there was no difference in the between-group comparison. With respect to the UIQ, women in the pessary/PFMT group showed a significant improvement from baseline, but the PFMT-only group did not. Women in the pessary/PFMT group reported significantly more frequent *de novo* SUI (48% vs. 22%), and more improvement of pre-existing voiding difficulty (62.5% vs. 35.5%).

4.7.4.1.2 Pelvic floor muscle training versus pessary only

One RCT reported on the 24-month follow-up of 82 women with symptomatic POP randomised to pessary therapy and 80 women randomised to PFMT [649]. Both in the ITT and per protocol analyses, the UDI-6 score did not differ significantly between groups at 24 months of follow-up.

4.7.4.1.3 Surgery alone versus surgery with pelvic floor muscle training

An assessor blinded RCT compared surgery for POP with or without additional pre-and postoperative PFMT. At twelve months after surgery, there were no significant differences between the groups on the change in scores of the UDI nor the IIQ scores [637].

Another RCT reported on the six-month follow-up of 57 women (28 surgery/29 surgery with PFMT). There was a significant improvement in the UDI-6 score for both groups, but not between groups [645].

Another RCT reported on the results of a 2x2 factorial design in which women were first randomised between two surgical techniques for POP and between additional PFMT (n = 188) or not (n = 186) [646]. The UDI was used to assess urinary symptoms up to 24 months. No significant differences were found between the addition of PFMT to surgery or not. Another study of the same population reported on SUI in particular [647]. No significant differences were found between women who had additional PFMT and those who had not.

In 2020 an RCT reported on 40- and 90-days follow-up of 48 women randomised to supervised PFMT before and after surgery and 40 women having surgery only [644]. No significant differences in UDI-6 scores were identified at 40 and 90 days.

ICI 2017 [18] concluded that there is level 1a evidence that PFMT reduces pelvic floor symptoms in women with POP, there is some evidence that it reduces POP specific symptoms like bulging. Some RCTs also show an improvement in POP stage with PFMT [650]. The NICE guidelines on the management of POP advocate considering supervised PFMT for ≥ 16 weeks as initial treatment for symptomatic prolapse [66]. The use of pessary is also to be considered, alone or combined with PFMT. It is important to recognise that a benefit is expected on typical POP symptoms, like feeling or seeing a bulge out of the vagina, and not on LUTS, as the reported RCTs showed. From a urological perspective, initiating conservative treatment for asymptomatic POP in order to treat UI or bladder emptying problems is not supported by the data.

4.7.4.1.4 Pessary versus surgery alone

A prospective cohort study showed that surgery in comparison with pessary treatment resulted in statistically significant more women reporting subjective improvement [651].

4.7.4.1.5 Summary of evidence and recommendation for the conservative treatment of pelvic organ prolapse and lower urinary tract symptoms

Summary of evidence	LE
Pelvic floor muscle training improves LUTS for up to 6 months in POP patients who do not have additional pessary or surgical treatment.	2a
If pessary therapy or surgical intervention is used for POP, PFMT does not show an additional benefit.	2a

Recommendations	Strength rating
Inform women with pelvic organ prolapse (POP), who do not need a vaginal pessary or surgical intervention, about the potential relief from lower urinary tract symptoms (LUTS) from pelvic floor muscle training (PFMT).	Strong
Do not offer preoperative PFMT to improve outcome of LUTS if pessary therapy or surgical intervention is indicated for POP.	Strong

4.7.4.2 Pelvic organ prolapse surgery and overactive bladder

Only a few studies have specifically addressed the effect of POP surgery on OAB symptoms. A SR of twelve studies, excluding women with SUI, evaluated OAB symptoms before and after surgery [623]. All but one study reported improvement of OAB symptoms. The same authors performed a prospective analysis of 505 women who had POP surgery with or without mesh [652]. Mean follow-up was 12.7 months. The incidence of bothersome urinary frequency reduced from 36.6% to 14.6%, with *de novo* symptoms occurring in 6.1%. Bothersome urgency symptoms reduced in 36.8% to 12.9% of women, with 5.0% developing *de novo* symptoms. Urge urinary incontinence symptoms reduced from 21.2% to 6.1% of women, with 5.3% developing *de novo* symptoms.

One observational study evaluated frequency and urgency symptoms without consideration of bother in 87 women undergoing POP surgery and showed an improvement in frequency by 75%, and in urgency in 83% [653]. The effect of the POP-Q stage did not seem to influence the effect of surgery on OAB symptoms [652, 653].

Another observational study (n = 43) evaluated the effect of posterior repair on OAB/DO and showed a 70–75% improvement rate in both parameters after surgery [654].

4.7.4.3 Pelvic organ prolapse surgery and bladder outlet obstruction

The criteria for BOO are based on urodynamic assessment. POP can be categorised as anatomical BOO, which is addressed in Sections 4.5.2.2 and 4.5.3.1.

4.7.4.4 Pelvic organ prolapse surgery and stress urinary incontinence

The aim of this section is to address the options available to women who require surgery for POP and who have associated SUI (either before or after reduction of prolapse), and to assess the value of prophylactic anti-UI surgery in women with no evidence of SUI.

A SR and meta-analysis of ten trials on prolapse surgery with or without an anti-incontinence procedure was reported in 2018 [655]. In addition, a Cochrane review including nineteen trials (n = 2,717) evaluating bladder function after surgery for POP presented analyses of women with POP and SUI, women with POP and occult SUI, and women with POP who were continent [656].

4.7.4.4.1 Vaginal pelvic organ prolapse surgery in women with stress urinary incontinence

Two trials addressed postoperative SUI in patients who had been diagnosed with SUI preoperatively and had vaginal POP surgery [657, 658]. Two trials (n = 185 and 134) compared the use of MUS at initial POP surgery to POP surgery alone. The RR for postoperative SUI was 0.30 in favour of the combined POP surgery and MUS group. One of these two trials also compared the use of MUS at initial POP surgery and at three months if SUI persisted [657]. At twelve months' follow-up, there was no difference between the groups regarding postoperative UI (RR 0.41); however, 44% of the women without initial MUS never required surgery and 29% were dry.

4.7.4.4.2 Abdominal pelvic organ prolapse surgery in women with stress urinary incontinence

One RCT randomised 47 women with POP and SUI to an abdominal POP surgical procedure, e.g., sacro-colpopexy with or without Burch colposuspension. Additional SUI surgery did not improve postoperative SUI as compared to sacro-colpopexy alone (RR: 1.38) [659]. This finding remained consistent over five years' follow-up

[660]. Another RCT compared the addition of a MUS or Burch colposuspension to an abdominal sacro-colpopexy in 113 women with POP and SUI [661]. At two years' follow-up, the RR for postoperative SUI was 0.54 in favour of the MUS group.

4.7.4.5 Vaginal pelvic organ prolapse surgery in continent women

One RCT compared vaginal POP surgery alone with concomitant POP surgery and MUS in 220 women. Postoperative SUI occurred in 46/113 (40.7%) women who had POP surgery alone, compared to 30/107 (28.0%) who had additional MUS (RR: 0.69) [656].

4.7.4.5.1 Abdominal pelvic organ prolapse surgery in continent women

Two RCTs compared abdominal sacro-colpopexy with (n = 180) or without (n = 187) Burch colposuspension with an outcome favouring the addition of Burch colposuspension (RR for *de novo* SUI: 0.69) [659, 662]. However, 34% of women in the prophylactic Burch colposuspension group developed *de novo* SUI (as compared to 49% in the control group). An RCT with medium-term follow-up (mean 39.5 months) showed that additional SUI surgery was needed by only 1/31 women (3%) in both groups [660, 663].

4.7.4.5.2 Vaginal pelvic organ prolapse surgery in women with prolapse and occult stress urinary incontinence

Five RCTs including a total of 194 women who had vaginal POP repair alone and 174 women who had an additional MUS at the time of primary surgery were identified [632, 664-667]. The RR of postoperative SUI was 0.38 in favour of the MUS group.

4.7.4.6 Adverse events associated with combined pelvic organ prolapse and stress urinary incontinence surgery

Data from six RCTs on vaginal POP surgery with MUS were pooled to assess adverse events [632, 657, 658, 665-667]. Urgency urinary incontinence was less frequent after combination surgery as compared to POP surgery alone (28% vs. 42%; RR: 0.7), but there was a tendency towards more voiding problems. Adverse events directly related to surgery occurred more often in the combination group (28% vs. 15%; RR: 1.8), as did serious adverse events such as bladder perforation, urethral injuries, and tape exposure (14% vs. 8%; RR: 1.7) [655].

In summary, it is difficult to generalise the results of trials using different procedures to treat both POP and UI. It seems that with a combined procedure, the rate of postoperative SUI is lower but voiding symptoms and complication rates are higher. Studies using MUS have shown more significant differences in UI outcomes with combined procedures than when other types of anti-UI procedure have been used. It must be taken into account that although more women are dry after combined surgery for POP with MUS, there are potential adverse events that should be balanced against potential benefits.

4.7.5 Summary of evidence and recommendations for surgery in women with both pelvic organ prolapse and stress urinary incontinence

Summary of evidence	**LE**
Women with POP and UI	
Surgery for POP and SUI shows a higher rate of cure of UI in the short-term than POP surgery alone.	1a
There is conflicting evidence on the relative long-term benefit of surgery for POP and SUI vs. POP surgery alone.	1a
Combined surgery for POP + SUI carries a higher risk of adverse events than POP surgery alone.	1a
Continent women with POP	
Continent women with POP are at risk of developing SUI postoperatively.	1a
Women with POP and OAB	
There is some low-level inconsistent evidence to suggest that surgical repair of POP can improve symptoms of OAB.	2b

Recommendations for women requiring surgery for bothersome pelvic organ prolapse (POP) who have symptomatic or occult stress urinary incontinence (SUI)	**Strength rating**
Offer simultaneous surgery for POP and SUI only after a full discussion of the potential risks and benefits of combined surgery vs. POP surgery alone.	Strong

Inform women of the increased risk of adverse events with combined prolapse and anti-urinary incontinence surgery compared to prolapse surgery alone.	Strong
Recommendations for women requiring surgery for bothersome POP who do not have symptomatic or occult SUI	
Inform women that there is a risk of developing *de novo* SUI after prolapse surgery.	Strong
Do not offer concomitant anti-incontinence surgery at the time of abdominal prolapse surgery.	Strong

4.8 Urinary fistula

The evidence relating to diagnosis and treatment of urinary fistulae is generally low level and largely composed of case series and other consensus statements. In particular, the epidemiology, aetiology, diagnosis, treatment and prevention of obstetric and non-obstetric fistulae have been described in detail during the 2016 ICI conference [668]. Most non-obstetric fistulae are iatrogenic in origin, caused by pelvic surgery (e.g., hysterectomy for benign or malignant conditions, bowel resection, and urological surgery). The risks during pelvic surgery increase proportionally to the complexity of the resection, the extent of the primary disease, and with a past history of radiotherapy (especially for recurrent disease). When a fistula occurs following radiotherapy for primary treatment, this may be an indication of tumour recurrence.

*4.8.1 **Epidemiology, aetiology and pathophysiology***

4.8.1.1 Obstetric fistula

According to the WHO, fistulae affect > 2 million women, mostly from sub-Saharan African and Asian countries. The pooled prevalence of fistula from population studies is 0.29/1000 pregnancies [669]. Poor quality obstetric care, staff unaccountability, late referral, and poor nursing standards have been identified as health system causes [669]. However, obstructed labour is poorly documented. The main individual risk factors include age at first marriage, short stature, pregnancy with a male child, failure to attend antenatal care, low socio-economic status, low social class, lack of employment, and illiteracy [670-672]. Obstetric fistulae have detrimental consequences on global and individual health and are associated with malnutrition, sexual dysfunction, anxiety, depression, insomnia, social isolation, worsening poverty, and suicide [673, 674].

4.8.1.2 Iatrogenic fistula

Poor obstetric care is usually responsible for VVFs in the developing world. By contrast, in the developed world, gynaecological or pelvic surgery is the main cause of VVF. In a recent French epidemiological study, pelvic surgery accounted for two thirds of VVF causes [675].

4.8.1.2.1 Post-gynaecological surgery

An injury to the urinary tract during hysterectomy for benign conditions (60–75%), hysterectomy for malignant conditions (30%) and caesarean section (6%) are the main causes of postoperative VVF in the developed world [676, 677]. The risk of pelvic organ fistula following hysterectomy ranges from 0.1-4% [678].

Fistulae may also occur as a result of primary or recurrent malignancy, or as a consequence of cancer treatment by surgery, radiotherapy, and/or chemotherapy.

In a study including 536 women undergoing radical hysterectomy for invasive cervical cancer, bladder injury occurred in 1.5% with VVFs forming in 2.6% and uretero-vaginal fistulae (UVFs) in 2.4% of cases [679]. Overall, the rate of urogenital fistula appears to be ~9 times higher following radical hysterectomy for malignant disease as compared to that following simple hysterectomy (abdominal or vaginal for benign conditions) [680]. Bladder-sparing techniques during pelvic exenteration can increase the risk of fistula formation [681].

4.8.1.2.2 Radiation fistula

The risk of fistula seems to be higher for postoperative external beam radiation (1.9%) compared to intravaginal brachytherapy (0.8%) [682], without any predictive factor being identified [683]. This is most likely due to the heterogeneity of data regarding the tumour type and stage, the form of radiation, and the site and dose delivered.

4.8.1.2.3 Rare causes of vesico-vaginal fistula

Foreign bodies such as pessaries, sex toys, cups etc. can be a cause of delayed presentation of VVF [684-686]. Ketamine abuse has also been shown to be responsible for fistula formation [687].

4.8.1.3 Summary of evidence for epidemiology, aetiology, and pathophysiology of urinary fistula

Summary of evidence	LE
The risk of injury to the urinary tract and subsequent fistula formation is higher in women with malignant disease undergoing radical surgery than in women with benign disease undergoing simple surgical procedures.	2
The rate of fistula formation following external beam radiotherapy for gynaecological cancer appears to be of the same order as that following surgical treatment.	4

4.8.2 ***Classification***

Due to the plethora of VVF classification systems, a consensual classification system needs to be adopted. The Waaldijk and Goh classifications are widely used for diagnosis and follow-up [688-690] but were originally designed for obstetric fistulae and their use in iatrogenic fistulae is less relevant [691]. Waaldijk's classification is based on the size and site of the fistulae and divides them into three main categories: type 1 are VVFs with no urethral involvement; type 2 are those that involve the urethra (and are sub-classified into those with circumferential and non-circumferential urethral involvement); and type 3 are fistulae involving other parts of the urinary tract. Goh's classification also uses the presence or absence of urethral involvement to sub-categorise VVFs and considers the degrees of fibrosis present. The WHO classification (Table 6) was originally developed for obstetric fistulae and separates fistulae into simple and complex.

Table 6: Adapted WHO Classification of fistulae [669]*

Simple fistula with good prognosis	Complex fistula with uncertain prognosis
• Single fistula < 4 cm • Vesico-vaginal fistula • Closing mechanism not involved • No circumferential defect • Minimal tissue loss • Ureters not involved • First attempt to repair	• Fistula > 4 cm • Multiple fistula • Recto-vaginal mixed fistula, cervical fistula • Closing mechanism involved • Scarring • Circumferential defect • Extensive tissue loss • Intravaginal ureters • Failed previous repair • Radiation fistula

**Although this classification was developed for obstetric fistula initially, it could be relevant for iatrogenic fistula as well.*

4.8.2.1 Recommendation for the classification of urinary fistula

Recommendation	Strength rating
Use a classification system for urinary tract fistulae to try to standardise terminology in this subject area.	Strong

4.8.3 ***Diagnostic evaluation***

Leakage of urine is the hallmark sign of a urogenital fistula. The leakage is usually painless, may be intermittent if it is position dependent, but more usually is constant. Unfortunately, intraoperative diagnosis of a genito-urinary or gastrointestinal injury is made in only about half of the cases [692]. Diagnosis of VVF usually requires clinical assessment often in combination with appropriate imaging or laboratory studies. As for any LUTS, history taking and focused physical examination with direct visual inspection are essential parts of urinary fistula diagnostic evaluation. Cystoscopy and retrograde bladder filling with a coloured fluid with placement of a tampon into the vagina to identify staining facilitate diagnosis of VVF. A double-dye test to differentiate between UVF and VVF may be useful in some cases [677]. Testing the creatinine level in either the extravasated or collected fluid will confirm fluid leakage as urine. Contrast-enhanced CT with late excretory phase reliably diagnoses urinary fistulae and provides information about ureteric integrity and the possible presence of associated urinoma. Magnetic resonance imaging, in particular with T2 weighting, also provides diagnostic information regarding fistulae [693].

Summary of evidence	LE
As for any LUTS, history taking and focused physical examination with direct visual inspection are essential parts of urinary fistula diagnostic evaluation.	3
Cystoscopy and retrograde bladder filling with a coloured fluid with placement of a tampon into the vagina to identify staining facilitate diagnosis of VVF.	3
Contrast-enhanced CT with late excretory phase reliably diagnoses urinary fistulae and provides information about ureteric integrity.	3
Magnetic resonance imaging, in particular with T2 weighting, also provides diagnostic information regarding fistulae.	3

Recommendations	Strength rating
Take a complete medical history and perform a focused physical examination including direct visual inspection for evaluation of women with suspicion of urinary fistula.	Strong
Use cystoscopy and retrograde bladder filling with a coloured fluid to confirm the diagnosis of urinary fistula.	Weak
Contrast-enhanced CT with late excretory phase and magnetic resonance imaging can be used in cases where the diagnosis of urinary fistula is challenging or to provide additional diagnostic information.	Weak

*4.8.4 **Management of fistula***

4.8.4.1 Management of vesico-vaginal fistula

4.8.4.1.1 Conservative management

4.8.4.1.1.1 Spontaneous closure

The reported spontaneous closure rate is 13 ± 23% [694], although this applies largely to small fistulae (< 1 cm) [668, 695]. Hence, immediate management is usually by urinary catheterisation or diversion; however, within the first two weeks following fistula occurrence, delayed surgical exploration and repair can be planned.

4.8.4.1.1.2 Pharmacotherapy

Several case reports describe a successful fistula closure rate following the induction of amenorrhoea by oestrogen, oestrogen/progesterone combinations or luteinising hormone releasing hormone analogues specifically for small (< 7 mm), uretero- or vesico-uterine fistulae following caesarean section [696-702]. One RCT comparing the efficacy of using fibrin glue compared to Martius flap inter-positioning (n = 14; < 4 cm and n = 5; > 5 cm) did not report significantly different outcomes between the two types of treatment but the closure rates were relatively low in both groups (68.4% vs. 57.9%) [703].

4.8.4.1.1.3 Palliation and skin care

During the intervening period between diagnosis and repair, UI pads with the aim of prevention of skin complications related to chronic urinary leakage can be provided and the use of a barrier cream or local oestrogen can also be considered [704, 705].

4.8.4.1.2 Surgical management

Overall closure rates after surgical repair of vesico-vaginal fistulae range from 58-100% [706].

4.8.4.1.2.1 Timing of surgery

Findings from small uncontrolled case series suggest no difference in success rates for early (within four weeks) or delayed (after three months) closure of VVF [707, 708].

4.8.4.1.2.2 Surgical approaches

Vaginal procedures

There are two main types of closure techniques applied to the repair of urinary fistulae, the classical saucerisation/partial colpocleisis [694] and the more commonly used dissection and repair in layers or flap-splitting technique [709]. There are no data comparing their outcomes.

Abdominal procedures

There are no RCTs comparing abdominal and vaginal approaches. Repair by the abdominal route is indicated when high fistulae are fixed at the vaginal vault and are inaccessible via a vaginal approach. A transvesical repair has the advantage of being entirely extraperitoneal. A simple transperitoneal repair is used less often

although it is favoured by some using the laparoscopic approach. A combined transperitoneal and transvesical procedure may be utilised for fistula repair following caesarean section. Results of secondary and subsequent repairs are not as successful as the initial repair [710].

Laparoscopic and robotic procedures
Small series (single figures) have reported using these techniques, but while laparoscopic repair is feasible with and without robotic assistance, no series to date have compared outcomes with alternative surgical approaches.

Trimming of fistula edge
A single RCT compared trimming of the fistula edge with no trimming. There was no difference in success rates but failed repairs in trimmed cases had larger recurrences than untrimmed cases, which were smaller [711].

Tissue interposition
Tissue flaps are often added as an additional layer of repair during VVF surgery. Most commonly, such flaps are utilised in the setting of recurrence after a prior attempt at repair, for VVF related to previous radiotherapy (described later), ischaemic or obstetric fistulae, large fistulae, and finally those associated with a difficult or tenuous closure due to poor tissue quality. However, there is no high-level evidence that the use of such flaps improves outcomes for either complicated or uncomplicated VVF.

Postoperative management
There is no high-level evidence to support any particular practice in postoperative management, but most reported series used catheter drainage for > 10 days and longer periods in complex or radiation-associated fistulae (up to three weeks). The performance of postoperative cystography prior to catheter removal can theoretically miss a persistent fistula if not done with a micturition phase or if the fistula is located at the bladder neck.

4.8.4.1.3 Management of complications of vesico-vaginal fistulae
The complications of VVF repair are varied and can include:
- Persistence or recurrence of fistula;
- Persistence or recurrence of UI;
- Persistence of LUTS or occurrence of new LUTS, including *de novo* OAB and/or SUI;
- Infections: wound and UTIs/urosepsis;
- Ureteric obstruction (ligation, fibrosis or injury);
- Bladder outlet obstruction (meatal stenosis, urethral stricture or bladder neck obstruction);
- Bladder contracture;
- Vaginal stenosis;
- Sexual dysfunction (vaginismus/dyspareunia);
- Rare complications (granulomas/diverticulum formation);
- Neurological complications (foot drop/neurogenic bladder);
- Psychological trauma (social isolation/divorce/mental illness);
- Infertility.

The literature on the treatment and management of complications of fistula repairs is scarce and is mostly experienced based. It is impossible to provide any specific evidence-based guidance.

4.8.4.2 Management of radiation fistulae
Modified surgical techniques are often required, and indeed, where the same techniques have been applied to both surgical and post-radiation fistulae, the results from the latter have been consistently poorer [712]. Due to the wide field abnormality surrounding many radiotherapy-associated fistulae, approaches include permanent urinary and/or faecal diversion [712, 713] or preliminary urinary and faecal diversion, with later undiversion in selected cases following reconstruction. In cases where life expectancy is deemed to be short, ureteric occlusion and nephrostomy insertion might be more appropriate.

4.8.4.3 Management of ureteric fistulae
Patients at higher risk of ureteric injury require experienced surgeons who can identify and protect the ureter and its blood supply to prevent injury and recognise injury promptly. Immediate repair of any intraoperative injury should be performed by observing the principles of debridement, adequate blood supply and tension-free anastomosis with internal drainage using stents [714]. Delayed presentation of UUT injury should be suspected in patients whose recovery after relevant abdominal or pelvic surgery is slower than expected, if there is any fluid leak, and if there is any unexpected dilatation of the pelvicalyceal system.

While there is no evidence to support the use of one surgical approach over another, there is consensus that repair should adhere to the standard principles of tissue repair and safe anastomosis and be undertaken by an experienced team. Conservative management is possible with internal or external drainage, endoluminal management using nephrostomy and stenting where available, and early (< 2 weeks) or delayed (> 3 months) surgical repair when required [715]. Functional and anatomical imaging should be used to follow-up patients after repair to guard against development of ureteric stricture and deterioration in renal function.

Uretero-vaginal fistula occurring in the early postoperative phase predominantly after hysterectomy is the most frequent presentation of UUT fistulae in urological practice. An RCT in 3,141 women undergoing open or laparoscopic gynaecological surgery found that prophylactic insertion of ureteric stents made no difference to the low risk (1%) of ureteric injury [716].

Endoscopic management is sometimes possible by retrograde stenting, percutaneous nephrostomy and antegrade stenting if there is pelvicalyceal dilatation, or ureteroscopic realignment [717]. However, the long-term success rate is unknown. Antegrade endoluminal distal ureteric occlusion combined with nephrostomy tube diversion often palliates urinary leakage due to malignant fistula in the terminal phase [718]. If endoluminal techniques fail or result in secondary stricture, the abdominal approach to repair is standard and may require end-to-end anastomosis, reimplantation into the bladder using psoas hitch or Boari flap, or replacement with bowel segments with or without reconfiguration. As a last resort, nephrectomy may be considered, particularly in the context of a poorly functioning kidney and an otherwise normal contralateral kidney [719-723].

4.8.4.3.1 Management of urethro-vaginal fistulae

4.8.4.3.1.1 Aetiology

Although urethro-vaginal fistulae are rare, most of them in adults have an iatrogenic aetiology. Causes include surgical treatment of SUI with bulking agents or synthetic slings, surgery for urethral diverticulum and genital reconstruction. Irradiation and even conservative treatment of prolapse with pessaries can lead to formation of fistulae.

4.8.4.3.1.2 Diagnostic evaluation

Clinical vaginal examination, including the three-swab test, is often sufficient to diagnose urethro-vaginal fistulae. Urethroscopy and cystoscopy can be performed to assess the extent and location of the fistulae. In cases of difficult diagnosis, VCUG or US can be useful. An 3D-MRI or CT scan is becoming utilised more widely to clarify anatomy [724, 725].

4.8.4.3.1.3 Surgical management

Choice of surgery will depend on the size, localisation, and aetiology of the fistula and the amount of tissue loss. Principles of reconstruction include identifying the fistula, creation of a plane between the vaginal wall and urethra, watertight closure of the urethral wall, eventual interposition of tissue, and closure of the vaginal wall.

One case series reported that a vaginal approach yielded a success rate of 70% at first attempt and 92% at second attempt, and that an abdominal approach only led to successful closure in 58% of cases [726]. A vaginal approach required less operating time, had less blood loss and shorter hospitalisation.

Most authors have described surgical principles that are identical to those of VVF repair, and primary closure rates of 53–95.4% have been described. A series of 71 women, treated for urethro-vaginal fistulae reported that 90.1% of fistulae were closed at the first vaginal intervention. Additionally, 7.4% were closed during a second vaginal intervention. Despite successful closure, SUI developed in 52% of cases. Stress urinary incontinence patients were treated with synthetic or autologous slings and nearly 60% became dry and an additional 32% improved. Urethral obstruction occurred in 5.6% and was managed by urethral dilation or urethrotomy [727].

4.8.4.3.1.4 Flaps and neo-urethra

The simplest flap is a vaginal advancement flap to cover the urethral suture line. Labial tissue can be harvested as a pedicled skin flap. This labial skin can be used as a patch to cover the urethral defect but can also be used to create a tubular neo-urethra [728, 729]. The construction of a neo-urethra has mostly been described in traumatic aetiologies. In some cases, a transpubic approach has been used [730]. The numbers of patients reported are small and there are no data on the long-term outcome of fistula closure and continence rates. The underlying bulbo-cavernosus tissue can be incorporated in the pedicled flap and probably offers better vascularisation and more bulking to the repair. This could allow a safer placement of a sling afterwards, in those cases where bothersome SUI would occur postoperatively [731, 732].

4.8.4.3.1.5 Martius flap

In obstetrical fistula repair, the Martius labial bulbocavernosus muscle/fat flap was not found to have any benefit. However, the Martius flap is still considered by some to be an important adjunctive measure in the treatment of genitourinary fistulae for which additional bulking with well-vascularised tissue is needed [733]. The series of non-obstetrical aetiology are small and all of them are retrospective. There are no prospective data, nor randomised studies [734]. The indications for Martius flap in the repair of urethra-vaginal fistulae remain unclear.

4.8.4.3.1.6 Rectus muscle flap

Rectus abdominis muscle flaps have been described by some authors [735, 736].

4.8.4.3.1.7 Alternative approaches

An alternative retropubic retro-urethral technique has been described by Koriatim [737]. This approach allows a urethro-vesical flap tube to be fashioned to form a continent neo-urethra.

4.8.4.4 Summary of evidence and recommendations for the management of urinary fistula

Summary of evidence	**LE**
Spontaneous closure of surgical fistulae does occur and appears more likely for small fistulae although it is not possible to establish the rate with any certainty.	3
There is no evidence that the timing of repair makes a difference to the chances of successful closure of a fistula.	3
There is no high-quality evidence of differing success rates for repair of VVFs by vaginal, abdominal, transvesical, and transperitoneal approaches.	3
A variety of interpositional grafts can be used in either abdominal or vaginal procedures, although there is little evidence to support their benefits in any specific setting.	3
Post-radiation fistula	
Success rates are lower for irradiated fistulae than for non-radiated fistulae.	3
Ureteric fistula	
Prophylactic ureteric stent insertion does not reduce risk of ureteric injury during gynaecological surgery.	2
Antegrade endoluminal distal ureteric occlusion combined with nephrostomy tube diversion often palliates urinary leakage due to malignant fistula in the terminal phase.	4
Urethro-vaginal fistula	
Urethro-vaginal fistula repair may be complicated by SUI, urethral stricture, and urethral shortening, which may necessitate long-term follow-up.	3

Recommendations	**Strength rating**
General	
When reporting on outcomes after fistula repair, authors should make a clear distinction between fistula closure rates and postoperative urinary incontinence rates and the time at which the follow-up was organised.	Strong
Do not routinely use ureteric stents as prophylaxis against injury during routine gynaecological surgery.	Strong
Suspect ureteric injury or fistula in patients following pelvic surgery if a fluid leak or pelvicalyceal dilatation occurs postoperatively, or if drainage fluid contains high levels of creatinine.	Strong
Use three-dimensional imaging techniques to diagnose and localise urinary fistulae, particularly in cases with negative direct visual inspection or cystoscopy.	Weak
Manage upper urinary tract fistulae initially by conservative or endoluminal techniques where such expertise and facilities exist.	Weak
Surgical principles	
Surgeons involved in fistula surgery should have appropriate training, skills, and experience to select an appropriate procedure for each patient.	Weak

Attention should be given as appropriate to skin care, nutrition, rehabilitation, counselling, and support prior to, and following, fistula repair.	Weak
Tailor the timing of fistula repair to the individual patient and surgeon requirements once any oedema, inflammation, tissue necrosis, or infection, are resolved.	Weak
Ensure that the bladder is continuously drained following fistula repair until healing is confirmed (expert opinion suggests: ten to fourteen days for simple and/or post-surgical fistulae; fourteen to 21 days for complex and/or post-radiation fistulae).	Weak
Where urinary and/or faecal diversions are required, avoid using irradiated tissue for repair.	Weak
Use interposition graft when repair of radiation associated fistulae is undertaken.	Weak
Repair persistent urogenital fistulas by an abdominal approach using open, laparoscopic, or robotic techniques according to availability and competence.	Weak
Urethro-vaginal fistulae should preferably be repaired by a vaginal approach.	Weak

4.9 Urethral diverticulum

A female urethral diverticulum is a sac-like protrusion composed of the entire urethral wall or only the urethral mucosa, situated between the peri-urethral tissues and the anterior vaginal wall.

*4.9.1 **Epidemiology, aetiology, pathophysiology***

Urethral diverticulum is an uncommon condition with an estimated prevalence of 1–6%. A prevalence of up to 10% was reported among women with LUTS attending a tertiary referral centre [738]. However, as many patients are asymptomatic or misdiagnosed, the true incidence is unknown [739-741]. Given the rarity of the condition, most published series are small and single institutional. Urethral diverticulum is thought to arise from repeated obstruction, infection, and subsequent rupture of peri-urethral glands into the urethral lumen, resulting in an epithelialised cavity that communicates with the urethra [739].

Iatrogenic damage to the urethra may also play a role, as up to 20% of women with urethral diverticula are noted to have a history of urethral surgery, dilation, or traumatic delivery [739, 742]. Iatrogenic urethral diverticula formation associated with synthetic sub-urethral sling has also been reported [743-745].

*4.9.2 **Classification***

Table 7: Classification system for female urethral diverticula based on characteristics*

Localisation	Mid-urethral Distal Proximal Full length
Configuration	Single Multi-loculated Saddle shaped
Communication	Mid-urethral No communication visualised Distal Proximal
Continence	Stress urinary incontinence Continent Post-void dribble Mixed incontinence

**Limited LNS C3 classification of urethral diverticula [742, 746, 747].*

*4.9.3 **Diagnostic evaluation***

The commonly encountered symptoms for urethral diverticulum such as pain, urgency, frequency, recurrent UTIs, vaginal discharge, dyspareunia, voiding difficulties or UI [748], are common to many other LUT dysfunctions. Consequently, there is no pathognomonic cluster of symptoms to identify urethral diverticulum. Many patients with urethral diverticulum are asymptomatic. However, urethral diverticulum often presents with a palpable urethral mass. It may be possible to express a purulent exudate from the urethra. Occasionally a stone may develop within the diverticulum.

Urethral diverticulum can be diagnosed by physical examination, VCUG and MRI. Other investigations include urethrocystoscopy, endocavitary (often transvaginal or sometimes transurethral) pelvic floor US and double balloon urethrography.

No robust diagnostic accuracy studies have addressed the question of the best test to confirm the diagnosis in women with clinical suspicion of urethral diverticulum. A case series of 27 patients concluded that endoluminal (vaginal or rectal) MRI has better diagnostic accuracy than VCUG [749] and determines the size and extent of urethral diverticulum more accurately. A case series of 60 patients reported that the sensitivity, specificity, positive predictive value and negative predictive value of MRI was 100%, 83%, 92% and 100%, respectively [750]. Another case series reported 100% specificity and sensitivity of MRI in 60 patients [751]. However, a case series of 41 patients reported a 25% discrepancy between MRI and surgical findings [752]. Endoluminal MRI with either a vaginal or rectal coil may provide even better image quality than simple MRI [753].

Magnetic resonance imaging is the gold standard for the diagnosis and planning of surgical repair and is also useful in diagnosing diverticular inflammation or tumour [754, 755].

Urethrocystoscopy can be used to visualise the ostia of the diverticula. Knowledge of the ostias' location and number can assist with surgical planning since they need to be closed after diverticulectomy. However, given the challenges of urethroscopy in women, the ostia are only seen in 42% of cases [748].

If VCUG is performed, antero-posterior and lateral images are required to optimally characterise the configuration of the diverticulum. There is a high risk of false negatives since the ostia of the diverticula must be patent and the patients must be able to void during the study. In more complex diverticula where there is septation, the entire diverticulum may not be visualised underestimating its complexity or size [756]. The sensitivity of VCUG is 73.5% which is significantly worse than MRI [748].

Ultrasound can be performed transabdominally, trans-vaginally or trans-perineally to identify the diverticulum. In particular, the transvaginal approach allows imaging of the urethra from the meatus to the bladder neck in several planes and can identify the number, size, location, and contents of the diverticulum. This technique is challenging and requires a skilled ultrasonographer. Additionally, the probe can compress the urethra, causing distortion [756]. A meta-analysis reported that US of any kind had a sensitivity of 82.0%, which was inferior to that of MRI [756]. However, a recent publication on trans-labial US reported a sensitivity of 95% [757]; therefore, this approach may be explored further by researchers in the future.

For patients who cannot undergo MRI and those in whom the ostia cannot be seen on cystoscopy, double balloon urethrography is an option. Sensitivity of 94.7% has been reported, which is comparable to that of MRI, but it is technically difficult, requires an experienced radiologist/radiographer and specialised equipment, can be painful for the patient and carries a risk of UTI. Given the current popularity of other imaging modalities, many units may not have access to this technique [756].

4.9.3.1 Associated voiding dysfunction

Although the presentation of urethral diverticulum is often non-specific and variable, urethral diverticulum can be associated with voiding dysfunction and SUI or UUI.

One recent series reported SUI in 60% of patients with urethral diverticulum [758]. Urethral diverticulum is most often located at the level of the mid-urethra. This location often overlaps with the external sphincter. However, urethral diverticulum may also extend proximally toward the bladder neck in the vicinity of the proximal sphincter mechanism. This morphology may, in part, explain the association between urethral diverticulum and SUI, with potentially more proximal lesions at risk for postoperative SUI [759].

Urethral diverticulum may also be associated with BOO due to the mass effect of the urethral diverticulum, urinary retention, or urgency and UUI [760]. Pain and dysuria associated with urethral diverticulum may also result in acquired voiding dysfunction.

Pressure–flow studies may have a role in the preoperative assessment of patients with urethral diverticula and coexisting voiding dysfunction or SUI [741, 761-763]. Indeed, urodynamics may evaluate coexisting detrusor dysfunction or document the presence of SUI or obstruction prior to repair [764, 765].

Urethral pressure profilometry has also been used in the assessment or diagnosis of urethral diverticulum, noting a biphasic pattern, or pressure drop at the level of the lesion [761, 763, 766]. Video-urodynamics may be helpful in differentiating SUI from paradoxical UI due to fluid accumulation in the urethral diverticulum. Additionally, resting and straining images obtained during fluoroscopic imaging may document an open bladder neck at rest. This may be a consideration in some patients with an extensive urethral diverticulum at the level of the mid-urethra, and potential implications for postoperative UI due to compromise of both sphincter mechanisms.

*4.9.4 **Disease management***

For women with minimal symptoms who would prefer to avoid invasive treatment, conservative management can be considered. Patients should be warned of the small risk of cancer (1–6%) within the diverticulum [767, 768].

4.9.4.1 Surgical treatment

No RCTs have investigated the effectiveness of surgery in women who have a bothersome urethral diverticulum. Thorough evaluation of the anatomy of the diverticulum is essential in planning reconstructive surgery.

There are three surgical approaches to treatment of diverticulum: marsupialisation, endoscopic incision, and curative treatment with diverticulectomy.

Surgical removal (diverticulectomy) is the most commonly reported treatment in contemporary case series. The principles of successful transvaginal diverticulectomy are to: dissect a well-vascularised vaginal flap; preserve the peri-urethral fascia for closure; remove all the diverticular wall; excise the ostium and close the urethra in a watertight fashion; close the incision in a multi-layered fashion with no overlapping suture lines; and preservation or creation of continence.

The decision to use a labial fat pad flap (commonly known as a Martius flap) varies, and the flap is used more frequently in the following situations: recurrent cases, large urethral defects or for deficient vaginal flaps for closure [742, 746] transection of the urethra required for access to a circumferential diverticulum [755] or in the case of complex configuration [760], and if there is a planned future sling procedure required for UI to facilitate the dissection at that time [742].

Marsupialisation involves incision into the mass on the vaginal side to drain the infected contents. The wall is sutured open with absorbable suture to allow drainage and prevent reaccumulating of infectious materials. This approach leaves the cystic structure in place and can theoretically cause a urethro-vaginal fistula because there is communication with the diverticular ostium, but it is a rapid procedure with little dissection required. This approach has been advocated in pregnant patients to decompress the diverticulum and allow safe vaginal delivery. A small case series suggested that 75% of pregnant women with urethral diverticula managed expectantly eventually required postpartum surgery [769].

Endoscopic incision is a rarely reported treatment option [770, 771]. This procedure involves finding the narrow neck of the ostium and incising it with a resectoscope. This unroofing of the diverticulum transforms the narrow communication with the urethra that causes symptoms when it becomes obstructed into a wide-mouthed sac that drains freely.

4.9.4.2 Management of concomitant stress urinary incontinence

Many women present with concomitant SUI and urethral diverticulum and may request both conditions to be simultaneously treated. A meta-analysis reported that diverticulectomy cured SUI even without a concomitant anti-incontinence procedure. However, no data regarding symptom severity were given and it could be assumed that many of these cured patients had less-severe UI before surgery [748]. Therefore, additional surgical correction may be required [759, 771]. However, there is no consensus on appropriate timing of surgical management of these two conditions. Thus, patients with symptomatic bothersome SUI in association with urethral diverticulum may be offered simultaneous anti-UI surgery. Although historical series have shown good

results with concomitant bladder neck suspension [765], more contemporary series have utilised pubovaginal fascial slings, with satisfactory outcomes [772-775]. Synthetic MUS are not recommended as a concomitant anti-UI procedure at the time of urethral diverticulectomy [776]. Synthetic material adjacent to a fresh suture line following diverticulectomy in the setting of potentially infected urine may place the patient at higher risk for subsequent urethral erosion and vaginal extrusion of the sling material, as well as urethro-vaginal fistula formation and foreign body granuloma formation.

4.9.4.3 Success rate and complications

Transvaginal urethral diverticulectomy has a high success rate (defined by being dry) of 84–98%, with a reoperation rate of 2–13% after primary repair during a mean follow-up of twelve to 50 months [739, 742, 759, 777]. The resolution of symptoms after surgery has been reported to reach 68.8% but less than half of studies comment on symptom improvement [778].

One case series reported a recurrence rate of 33% in U-shaped and of 60% in circumferential diverticula within one year [746], one study found a 10.7% recurrence rate in 122 women undergoing diverticulectomy, with a higher risk of recurrence in those with proximal or multiple diverticula or after previous pelvic surgery [779] or radiation. Recurrent urethral diverticulum following initial successful urethral diverticulectomy may occur as a result of a new infection or traumatic insult such as childbirth, a new urethral diverticulum, or recurrence of the original lesion. Recurrence may be due to incomplete removal of the urethral diverticulum, inadequate closure of the urethra, residual dead space (circumferential diverticula), or other technical factors. Repeat urethral diverticulectomy represents a unique challenge due to altered anatomy, scarring, and difficulty identifying proper anatomical planes.

One case series reported that storage symptoms decreased significantly postoperatively from 60% to 16% following surgery for urethral diverticulum [759]. Other series with long-term follow-up, however, have demonstrated rates of postoperative urgency of 54% [779], and *de novo* UUI in 36% of patients [771]. Such postoperative symptoms indicate persistence of urethral diverticulum, recurrence of urethral diverticulum, or *de novo* OAB syndrome or urethral obstruction.

Stress urinary incontinence can be worsened or occur *de novo* after diverticulectomy. This is most likely due to sphincteric damage from the dissection or scarification preventing urethral closure. *De novo* SUI (10.6% of women) seems to be more common in proximal and large (> 30 mm) diverticula [759]. However, a retrospective review noted at least some *de novo* SUI in 49% of patients following urethral diverticulectomy; most of which was minor and did not require additional therapy [780]. Only 10% of these individuals underwent subsequent SUI surgery. Treatment for SUI after diverticulectomy is not well described in the literature. The most commonly reported operation is an autologous pubovaginal sling [770] followed by retropubic suspension [771]. However, there are two reported cases of synthetic mesh sling to treat SUI, without mesh complications [746, 759], but this is controversial.

Early common postoperative complications include UTI (0–39%), *de novo* SUI (3.8–33%), and *de novo* urinary retention (0–9%), especially in the setting of concomitant placement of an autologous pubovaginal sling [739, 742, 759, 777]. Delayed complications such as urethral stricture are reported in 0–5.2% of cases [739, 742, 771, 777]. Urethro-vaginal fistula is a devastating complication presenting in 0.9–8.3% of cases [781]. A distal fistula located beyond the sphincteric mechanism can present with split urinary stream or vaginal voiding and may not require repair. However, a fistula located anywhere from the mid-urethra to the bladder neck may result in UI. These patients should undergo repair with consideration of an adjuvant tissue flap, such as a Martius flap, to aid in closure. The timing of the fistula repair is not well defined, with a delay of three to six months after the initial repair being a good balance between patient discomfort and optimal tissue quality. Rare complications include: distal urethral necrosis, bladder injury, urethral injury, ureteric injury, and vaginal scarring or narrowing with consequent dyspareunia [781].

4.9.4.4 Pathological findings

Most urethral diverticula are lined with squamous cells, urothelium or columnar epithelium [742, 782, 783]. In a meta-analysis, there was a high prevalence of chronic or acute inflammation (68.6%) and the most commonly reported lesions were nephrogenic metaplasia, which occurred in 8% of cases. Diverticula may undergo neoplastic alterations (6%), including invasive adenocarcinoma [784], followed by squamous cell carcinoma in 0.7%. It is unknown if the diverticulum forms first and then transforms into a malignancy or if the malignancy develops first. These malignancies are treated in a similar fashion to urethral cancer in women.

4.9.5 *Summary of evidence and recommendations for urethral diverticulum*

Summary of evidence	LE
Magnetic resonance imaging has the best sensitivity and specificity for the diagnosis of urethral diverticulum.	3
Surgical removal of symptomatic urethral diverticulum provides good long-term results; however, women should be counselled of the risk of recurrence and *de novo* SUI.	3

Recommendations	Strength rating
Use magnetic resonance imaging for diagnosis and characterisation of urethral diverticula, with urethroscopy, voiding cystourethrogram and ultrasound where necessary.	Weak
Offer surgical removal of symptomatic urethral diverticulum.	Weak
If conservative treatment is adopted, warn patients of the small (1–6%) risk of cancer developing within the diverticulum.	Weak
Carefully question and investigate patients for coexisting voiding dysfunction and urinary incontinence (UI).	Strong
Following appropriate counselling, address bothersome stress urinary incontinence at the time of urethral diverticulectomy with concomitant non-synthetic sling.	Weak
Counsel patients regarding the possibility of *de novo* or persistent LUTS including UI, despite technically successful urethral diverticulectomy.	Strong

6. CONFLICT OF INTEREST

All members of the Non-neurogenic Female LUTS Panel have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website: https://uroweb.org/guideline/non-neurogenic-female-luts/.

This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

7. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Paris 2024. ISBN 978-94-92671-23-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, The Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aim

This guideline plays an important role in the process of consolidation and improvement of care for patients with pelvic pain and associated lower abdominal pain. From both literature and daily practice it has become clear that lower abdominal and pelvic pain are areas still under development. This guideline has been recognised as a cornerstone for important developments that have taken place in the past years.

This guideline aims to expand the awareness of caregivers in the field of abdominal and pelvic pain and to assist those who treat patients with abdominal and pelvic pain in their daily practice. The guideline is a useful instrument not only for urologists, but also for gynaecologists, surgeons, physiotherapists, psychologists and pain doctors.

It must be emphasised that guidelines present the best evidence available to the experts. However following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions whilist taking personal values and preferences/individual circumstances of patients into account through shared decision-making. Guidelines are not mandates and do not purport to be a legal standard of care.

Structure and scope

The panel wishes to take advantage of modern methods of delivering guideline information to clinicians dealing with these patients. In 2016, a stepped information structure was made, in alignment with stepped care protocols, using new digital information sources like websites and apps to aid this process. Furthermore, the guideline was changed according to the template used in all other non-oncology guidelines of the EAU. It was recognised that structuring a guideline on chronic pain is quite different from structuring one on another subject. A multi-disciplinary approach is of utmost importance and demands a broad view. In 2016, the guideline was rewritten to be centred around pain instead of being organ-centred. It is partly theoretical to show the importance of using this pain-centred approach. The biggest part, however, deals with the practical approach to diagnostics, treatment and management of patients with abdominal and pelvic pain.

1.2 Publication history

The EAU Guidelines on Chronic Pelvic Pain were first published in 2003 [1] which formed the basis of a scientific publication in European Urology in 2004 [2]. Also, in the 2003 edition the concept of Chronic Pelvic Pain Syndromes (CPPS) was introduced, which is now referred to as “pain as a disease process”. Partial updates of the Chronic Pelvic Pain Guidelines were published in 2008 and formed the basis for another scientific publication in European Urology in the year 2010 [3, 4]. Two chapters were added at that time: Chapter 5 ‘Gastrointestinal aspects of chronic pelvic pain’ and Chapter 7 ‘Sexological aspects of chronic pelvic pain’. In the 2014 edition minor revisions were made in Chapter 5 ‘Gastrointestinal aspects of chronic pelvic pain’ and Chapter 8 ‘Psychological aspects of chronic pelvic pain’. The next update of the Chronic Pelvic Pain Guidelines will be published in 2024.

For the 2015 edition the panel critically reviewed the sub-chapter on chronic primary bladder pain syndrome (BPS) which is now a comprehensive part of the guideline. The fact that this part was so extensive shows that the roots of talking about abdominal pain and pelvic pain lies in the bladder, where Interstitial Cystitis was one of the first subjects addressed talking about pain in urology. The panel has illustrated this in the publication in European Urology in 2013 [5].

1.3 Available Publications

Alongside the full text version, a quick reference document (Pocket Guidelines) is available in print. This is an abridged version which may require consultation together with the full text version. This reference document follows the updating cycle of the underlying large texts. All available material can be viewed at the EAU website. The EAU website also includes a selection of EAU Guideline articles as well as translations produced by national urological associations: https://uroweb.org/guidelines/chronic-pelvic-pain

1.4 Panel composition

The panel of experts responsible for this guideline include five urologists, (one of whom has a subspecialisation in neuro-urology and one is a sexologist), three consultants in pain medicine, a uro-gynaecologist, a psychologist, a gastroenterologist, a pelvic physiotherapist, health scientist and (clinical) epidemiologist and two patient advocates.

1.5 Terminology

Definitions of chronic pelvic pain terminology

Classification

Much debate over the classification of chronic pelvic pain has occurred, is ongoing and will continue in the future. Classification involves three aspects of defining a condition: phenotyping, terminology and taxonomy.

Phenotyping

Phenotyping is describing the condition. For example, chronic bladder pain may be associated with the presence of Hunner's lesions and glomerulations on cystoscopy, whereas other bladder pain conditions may have a normal appearance on cystoscopy. These are two different phenotypes. The same is true for irritable bowel syndrome (IBS), which may be sub-divided into that associated primarily with diarrhoea or that with constipation. Phenotyping is based upon mechanisms when they are known (e.g., infection, ischaemic, auto-immune, or neuropathic). In the absence of well-defined mechanisms, describing the condition by its symptoms, signs and, where possible, by investigations, has been demonstrated to have clinical and research validity in many situations. When pain is the main symptom and pain as a disease process is considered the cause, the condition is often referred to as a pain syndrome - a well-defined collection of symptoms, signs and investigation results associated with pain mechanisms and pain perception as the primary complaint. The World Health Organization (WHO) International Classification of Diseases 11th Revision (ICD-11) uses the term Chronic Primary Pain to distinguish these conditions from pain associated with another diagnosis that they refer to as Chronic Secondary Pain (see below).

Terminology

Terminology is the word(s) that are used within classification, both to name the phenotype and within the definition of the phenotype. Examples of names for phenotypes associated with the bladder include interstitial cystitis, painful bladder syndrome or BPS. The EAU, the International Society for the study of BPS (known as ESSIC), the International Association for the Study of Pain (IASP) and several other groups have preferred the term BPS. In the pain syndromes, the role of the nervous system in generating the sensations is thought to be pivotal, but the term syndrome is also comprehensive and takes into account the emotional, cognitive, behavioural, sexual and functional consequences of the chronic pain.

When defining the phenotype, the terminology used in that definition must also be clear and if necessary, defined. One of the most important guiding principles is that spurious terminology should be avoided. Terms that end in "itis" should particularly be avoided, unless infection and or inflammation is proven and considered to be the cause of the pain [6]. It must be appreciated that end-organ inflammation may be secondary and neurogenic in origin and not a primary cause of the pain.

Taxonomy

Taxonomy places the phenotypes into a relationship hierarchy. The EAU approach sub-divides chronic pelvic pain into conditions that are pain syndromes with no obvious diagnosis, chronic primary pelvic pain syndromes (CPPPS) (consistent with ICD-11 Chronic Primary Pain) and those that are non-pain syndromes. The latter are conditions that have well-recognised pathology (e.g., infection, neuropathy or inflammation), whereas the former syndromes do not, and pain as a disease process is the mechanism. Other terms for the nonpain syndromes include "classical conditions", "well-defined conditions" and "confusable diseases" and the ICD-11 Chronic Secondary Pain. Although the EAU approach deals primarily with urological conditions, this approach to classification can be applied to all conditions associated with pain perception within the pelvis; the classification has been developed to include non-urological pain and was accepted by the IASP for publication in January 2012.

Classification of chronic pelvic pain

Importance of classification

It should be obvious to all that a condition cannot be treated unless it is defined. However, the reasons for classifying chronic pelvic pain go far beyond that.

Clues to the mechanism

As a result of systematic phenotypic and taxonomic classifications, similarities and differences between conditions become clear. Drawing comparisons between the phenotypes of different disorders allows comparison between disorders such as bladder and bowel pain syndromes, thus facilitating research and treatment.

Guidelines for best treatment options
As conditions become better defined, more specific treatment approaches can be adopted. In particular, there will be a move away from treatments based upon spurious terms (e.g., antibiotics and non-steroidal anti-inflammatory drugs for the "-itis" conditions). Generic treatments aimed at groups of conditions will be more commonplace and based upon research evidence.

Research platform
Only by clearly defining the phenotype being investigated can research be valued or applied to the clinical situation.

Patient needs
A diagnosis, or name, for a set of symptoms can provide patients with a sense of being understood, as well as hope for relief. It may help in acceptance of the problem as chronic, resolution of unfounded fears about its implications (if not life-threatening), and engagement in therapeutic endeavours, as well as assist in self-management. However, it may lead to the accessing of information of variable quality associated with the diagnosis or name, and the possibility of generating new concerns about long-term consequences or about the appropriateness of treatment.

IASP definitions
Sub-dividing pain syndromes
There is much debate on the sub-divisions of the pain syndromes within the hierarchical taxonomy. The EAU has led the way in this regard and the guiding principles are as follows [2]:

1. The pain syndromes are defined by a process of exclusion. In particular, there should be no evidence of infection or inflammation. Investigations by end-organ specialists should therefore be aimed at obtaining a differential diagnosis; repeated, unnecessary investigations are detrimental in the management of chronic pain syndromes.
2. A sub-division phenotype should only be used if there is adequate evidence to support its use. For instance, in non-specific, poorly localised pelvic pain without obvious pathology, only the term chronic primary pelvic pain syndrome (CPPPS) should be used. If the pain can be localised to an organ, then a more specific term, such as rectal pain syndrome, may be used, also potentially with the term primary added. If the pain is localised to multiple organs, then the syndrome is a regional pain syndrome and the term CPPPS should once again be considered. As well as defining the patient by a specific end-organ phenotype, there are several other more general descriptors that need to be considered. These are primarily psychological (e.g., cognitive or emotional), sexual, behavioural and functional. Psychological and behavioural factors are well-established factors which relate to quality of life (QoL) issues and prognosis. A North American research program, the MAPP program (Multi-disciplinary Approach to the study of Chronic Pelvic Pain research) has been devised to investigate the importance of these factors and looks at all types of pelvic pain irrespective of the end-organ where the pain is perceived. It also looks at systemic disorder associations, such as the co-occurrence of fibromyalgia, facial pain, or autoimmune disorders.
3. In 2004 the panel introduced the concept of managing the polysymptomatic nature of CPPPS, since then others have developed their own schemes, such as Nickel's UPOINT [7], modified by Magri *et al.* with the addition of a sexual dysfunction domain [8]. In light of these and other publications, the symptom classification table has been updated (Table 1).

The debate in relation to sub-dividing the pain syndromes continues. As more information is collected suggesting that the central nervous system (CNS) is involved, and indeed may be the main cause of many CPPPS conditions (e.g., bladder, genitalia, colorectal or myofascial), therefore there is a general tendency to move away from end-organ nomenclature. Only time and good research will determine whether this is appropriate. To enable such research, it is essential to have a framework of classification within which to work. Any hierarchical taxonomy must be flexible to allow change.

ICD classification: purpose and uses
The International Classification of Diseases is the foundation for the identification of health trends and statistics globally, and the international standard for reporting diseases and health conditions. It is the diagnostic classification standard for all clinical and research purposes. It defines the universe of diseases, disorders, injuries and other related health conditions, listed in a comprehensive and hierarchical fashion [9]. The latest version, ICD-11, is available for member states to report with from January 2022.

The ICD-11 classification for the first time included chronic pain ("chronic pain is pain that persists or recurs for longer than three months") and divided the coding into Chronic Primary Pain ("chronic primary pain is multi-factorial: biological, psychological and social factors contribute to the pain syndrome") and a number of Chronic Secondary Pain conditions (related to cancer, post surgical, musculoskeletal, visceral, neuropathic, headache/ orofacial, other).

The significance of the inclusion of Chronic Pain as a condition within the ICD-11 should not be underestimated. There are, however, unresolved issues regarding this classification, such as when a condition ends and pain persists, does the term Chronic Secondary Pain become Chronic Primary Pain? [10, 11]. Similarly, the contents of recent drafted National Institute for Health and Care excellence (NICE) guidelines [12] (https://www.nice.org.uk/guidance/GID-NG10069/documents/draft-guideline), were found to be contentious as the guideline considered all Chronic Primary Pain as being essentially the same and the 'biological' nature of the pain appeared to have been missed. Whereas in the final guidelines this may be corrected, it does illustrate the risk behind the term Chronic Primary Pain.

The panel have changed the EAU terminology previously used in the Guidelines to show conformity with ICD 11 definitions. This will include changing terminology used in originally cited works.

.

The classification has been set up according to the axis system used by IASP.

Table 1: EAU Classification of Chronic Pelvic Pain Syndromes

Axis I Region	Axis II System	Axis III End-organ as pain syndrome as identified from Hx, Ex and Ix	Axis IV Referral characteristics	Axis V Temporal characteristics	Axis VI Character	Axis VII Associated symptoms	Axis VIII Psychological symptoms

Chronic secondary pelvic pain syndrome, formally known as specific disease associated pelvic pain OR Chronic primary pelvic pain syndrome, formally known as pelvic pain syndrome							

Hx = History; Ex = Examination; Ix = Investigation; PTSD = post-traumatic stress disorder.

Pain syndromes
The original EAU classification [2] was inspired by the IASP classification [13] and much work around what has become known as "pain as a disease" and its associated psychological, behavioural, sexual, social and organ function aspects. After ten years of work developing the initial ideas, an updated version was accepted by the IASP Council for publication in January 2012.

EAU Definition of chronic pelvic pain
Chronic pelvic pain is chronic or persistent pain perceived* in structures related to the pelvis of either men or women. It is often associated with negative cognitive, behavioural, sexual and emotional consequences as well as with symptoms suggestive of lower urinary tract (LUT), sexual, bowel, pelvic floor or gynaecological dysfunction. [*Perceived indicates that the patient and clinician, to the best of their ability from the history, examination and investigations (where appropriate) have localised the pain as being discerned in a specified anatomical pelvic area.]

In the case of documented nociceptive pain that becomes chronic/persistent through time, pain must have been continuous or recurrent for at least three months (in accordance with ICD-11). For cyclical pain, a longer period of more than six months may be appropriate. Cyclical pain is included in the classification, particularly if there is evidence of central sensitisation and hence dysmenorrhoea (hormonally dependent) needs to be considered as a chronic pain syndrome, if it is persistent and associated with negative cognitive, behavioural, sexual, or emotional consequences.

Chronic pelvic pain may be sub-divided into conditions with well-defined classical pathology (such as infection or cancer) and those with no obvious pathology but still including biological mechanisms. For the purpose of the EAU's classification, the term "specific disease-associated pelvic pain" has been accepted for the former, and "chronic pelvic pain syndrome" for the latter. In the new ICD-11 these conditions have new names: the former will be called Chronic Secondary Pelvic Pain and the latter Chronic Primary Pelvic Pain.

The following classification only deals with Chronic Primary Pelvic Pain Syndromes.

EAU Definition of chronic primary pelvic pain syndrome
Chronic primary pelvic pain syndrome (CPPPS) is the occurrence of chronic pain when there is no proven infection or other obvious local pathology that may account for the pain. It is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of LUT, sexual, bowel or gynaecological dysfunction. Chronic Primary Pelvic Pain Syndrome is a subdivision of chronic pelvic pain. Throughout the text below in the 2021 update, CPPS is replaced with CPPPS if it is appropriate.

Further subdivision of chronic primary pelvic pain syndrome
within a single organ, more than one pelvic organ and even associated with systemic symptoms such as chronic fatigue syndrome (CFS), fibromyalgia (FM) or Sjögren's syndrome. When the pain is localised to a single organ, some specialists may wish to consider using an end organ term such as BPS (Table 2), also using the term primary. The use of such a phrase with the terminology "syndrome" indicates that, although peripheral mechanisms may exist, CNS neuromodulation may be more important and systemic associations may occur. When the pain is localised to more than one organ site, the generic term CPPPS should be used. Many, including some of the panel members never sub-divide by anatomy and prefer to refer to patients with pain perceived within the pelvis, and no specific disease process, as suffering from CPPPS, sub-divided by psychological and functional symptoms.

Psychological considerations for classification
Many CPPPSs are associated with a range of concurrent negative psychological, behavioural and sexual consequences that must be described and assessed. Examples that need to be considered are depression, anxiety, fears about pain or its implications, unhelpful coping strategies, and distress in relationships. Both anxiety and depression can be significant important concomitant symptoms that are relevant to pain, disability and poor QoL. Catastrophic interpretation of pain has been shown to be a particularly salient variable, predicting patients' report of pain, disability, and poor QoL, over and above psychosocial variables such as depression or behavioural factors such as self-reported sexual dysfunction. Many of these biopsychosocial consequences are common to other persistent pain problems but may show varying degrees of importance for any one individual suffering from CPPPS. In all patients with CPPPS, these consequences must be clearly described as part of the phenotype (where the term phenotype is used to indicate the observable characteristics of the syndrome) [14].

Functional considerations for classification

Functional disorders, for the purpose of this document, are pathologies that have arisen secondary to changes in the control mechanisms of an organ or system. That is, they are disorders characterised by disturbance of function. As an example, slow colonic transit is a functional disorder of the bowel - the normal function of the bowel is not occurring as a result of changes in the mechanisms that produce defecation, and therefore bowel control is altered. The term is not used in the sense of a psychiatric functional disorder. Many CPPPSs are associated with functional abnormalities at a local and even systemic level. These also need to be defined as a part of the phenotype.

Functional pain disorders may not include significant pathology in the organs that appear responsible for the primary symptoms, but they are associated with substantial neurobiological, physiological and sometimes anatomical changes in the CNS.

Multi-system sub-division

It is recognised that the end-organ where the pain is perceived may not be the centre of pain generation. This classification is based upon the most effective and accepted method of classifying and identifying different pain syndromes, that is, by site of presentation. It is argued that keeping the end-organ name in the classification is inappropriate because, in most cases, there are multi-systemic causes and effects, with the result that symptoms are perceived in several areas. This is an area in which discussions are ongoing, and despite there being strong arguments for both keeping and dispensing with end-organ classification, the panel have not taken the umbrella approach of referring to all pain perceived in the pelvis as CPPS, primary or secondary.

Dyspareunia

Dyspareunia is defined as pain perceived within the pelvis associated with penetrative sex. It tells us nothing about the mechanism and may be applied to women and men. It is usually applied to penile penetration, but is often associated with pain during insertion of any object. It may apply to anal as well as vaginal intercourse. It is classically sub-divided into superficial and deep.

Primary perineal pain syndrome

Primary perineal pain syndrome is a neuropathic-type pain that is perceived in the distribution area of the pudendal nerve, and may be associated with symptoms and signs of rectal, urinary tract or sexual dysfunction. There is no proven obvious pathology. It is often associated with negative cognitive, behavioural, sexual and emotional consequences, as well as with symptoms suggestive of LUT, sexual, bowel or gynaecological dysfunction. Primary perineal pain syndrome should be distinguished from pudendal neuralgia which is a specific disease associated with perineal pain that is caused by nerve damage.

Table 2: Chronic Primary Pelvic Pain Syndromes (the term primary can be included in any of the following)

Urological Pain Syndromes	
Primary prostate pain syndrome	Primary prostate pain syndrome (PPPS) is the occurrence of persistent or recurrent episodic pain (which is convincingly reproduced by prostate palpation). There is no proven infection or other obvious local pathology. Primary prostate pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction. The term “chronic prostatitis” continues to be equated with that of PPPS. In the authors’ and others’ opinion, this is an inappropriate term, although it is recognised that it has a long history of use. The National Institutes of Health (NIH) consensus [15] includes infection (types I and II), which the authors feel should not be considered under PPPS, but as specific disease-associated pelvic pain. The term prostadynia has also been used in the past but is no longer recommended by the expert panel. Please note that some of the authors of the IASP document disagree with this term and suggest that CPPPS of the male is used instead of PPPS, which has been agreed by the majority.

Primary bladder pain syndrome	Primary bladder pain syndrome is the occurrence of persistent or recurrent pain perceived in the urinary bladder region, accompanied by at least one other symptom, such as pain worsening with bladder filling and day-time and/or night-time urinary frequency. There is no proven infection or other obvious local pathology. Primary bladder pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction. PBPS is believed to represent a heterogeneous spectrum of disorders. There may be specific types of inflammation as a feature in subsets of patients. Localisation of the pain can be difficult by examination, and consequently, another localising symptom is required. Cystoscopy with hydrodistension and biopsy may be indicated to define phenotypes. Recently, ESSIC has suggested a standardised scheme of sub-classifications [16] to acknowledge differences and make it easier to compare various studies. Other terms that have been used include “interstitial cystitis”, “painful bladder syndrome”, and “PBS/IC” or “BPS/IC”. These terms are no longer recommended.
Primary scrotal pain syndrome	Primary scrotal pain syndrome is the occurrence of persistent or recurrent episodic pain localised to the scrotum or the structure within it and may be associated with symptoms suggestive of lower urinary tract or sexual dysfunction. There is no proven infection or other obvious local pathology. Primary scrotal pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences. Primary scrotal pain syndrome is a generic term and is used when the site of the pain is not clearly testicular or epididymal. The pain is not in the skin of the scrotum as such, but perceived within its contents, in a similar way to idiopathic chest pain.
Primary testicular pain syndrome	Primary testicular pain syndrome is the occurrence of persistent or recurrent episodic pain perceived in the testes, and may be associated with symptoms suggestive of lower urinary tract or sexual dysfunction. There is no proven infection or other obvious local pathology. Primary testicular pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences. Previous terms have included orchitis, orchialgia and orchiodynia. These terms are no longer recommended.
Primary epididymal pain syndrome	Primary epididymal pain syndrome is the occurrence of persistent or recurrent episodic pain perceived in the epididymis, and may be associated with symptoms suggestive of lower urinary tract or sexual dysfunction. There is no proven infection or other obvious local pathology. Primary epididymal pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences.
Primary penile pain syndrome	Primary penile pain syndrome is the occurrence of pain within the penis that is not primarily in the urethra, in the absence of proven infection or other obvious local pathology. Primary penile pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction.
Primary urethral pain syndrome	Primary urethral pain syndrome is the occurrence of chronic or recurrent episodic pain perceived in the urethra, in the absence of proven infection or other obvious local pathology. Primary urethral pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. Primary urethral pain syndrome may occur in men and women.
Post-vasectomy scrotal pain syndrome	Post-vasectomy scrotal pain syndrome is a scrotal pain syndrome that follows vasectomy. Post-vasectomy scrotal pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction. The mechanisms are poorly understood and for that reason it is considered by some a special form of primary scrotal pain syndrome.

Primary Gynaecological Pain Syndromes: external genitalia	
Primary vulvar pain syndrome	Primary vulvar pain syndrome is the occurrence of persistent or recurrent episodic vulvar pain. There is no proven infection or other local obvious pathology. It is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. Although pain perceived in the vulva was included under sexual disorders in the DSM-IV-R manual for classifying psychiatric disorders, there is no scientific basis for this classification, and pain perceived in the vulva is best understood as a pain problem that usually has psychological consequences. There is no evidence for its classification as a psychiatric disorder. The International Society for the Study of Vulvovaginal Disease (ISSVD) has used the term vulvodynia, where we use the term primary vulvar pain syndrome. According to the ISSVD, vulvodynia is vulvar pain that is not accounted for by any physical findings. The ISSVD has defined vulvodynia as "vulvar discomfort, most often described as burning pain, occurring in the absence of relevant visible findings or a specific, clinically identifiable, neurologic disorder". If physical findings are present, the patient is said to have vulvar pain due to a specified cause. The ISSVD has sub-divided vulvodynia based on pain location and temporal characteristics of the pain (e.g. provoked or unprovoked). The following definitions are based on that approach.
Primary generalised vulvar pain syndrome	Primary generalised vulvar pain syndrome refers to a vulvar pain syndrome in which the pain/burning cannot be consistently and precisely localised by point-pressure mapping via probing with a cotton-tipped applicator or similar instrument. Rather, the pain is diffuse and affects all parts of the vulva. The vulvar vestibule (the part that lies between the labia minora into which the urethral meatus and vaginal introitus open) may be involved but the discomfort is not limited to the vestibule. This pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences. Previous terms have included "dysesthetic vulvodynia" and "essential vulvodynia", but these are no longer recommended.
Primary localised vulvar pain syndrome	Primary localised vulvar pain syndrome refers to pain that can be consistently and precisely localised by point-pressure mapping to one or more portions of the vulva. Clinically, the pain usually occurs as a result of provocation (touch, pressure or friction). Primary localised vulvar pain syndrome can be sub-divided into primary vestibular pain syndrome and primary clitoral pain syndrome.
Primary vestibular pain syndrome	Primary vestibular pain syndrome refers to pain that can be localised by point-pressure mapping to the vestibule or is well perceived in the area of the vestibule.
Primary clitoral pain syndrome	Primary clitoral pain syndrome refers to pain that can be localised by point-pressure mapping to the clitoris or is well-perceived in the area of the clitoris.
Gynaecological system: internal pelvic pain syndromes	
Endometriosis-associated pain syndrome	Endometriosis-associated pain syndrome is chronic or recurrent pelvic pain in patients with laparoscopically confirmed endometriosis, and the term is used when the symptoms persist despite adequate endometriosis treatment. It is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. Many patients have pain above and beyond the endometriotic lesions; this term is used to cover that group of patients. Endometriosis may be an incidental finding, is not always painful, and the degree of disease seen laparoscopically does not correlate with severity of symptoms. As with other patients, they often have more than one end-organ involved. It has been suggested that this phenotype should be removed from the classification because the endometriosis may be irrelevant.
Chronic primary pelvic pain syndrome with cyclical exacerbations	Chronic primary pelvic pain syndrome with cyclical exacerbations covers the non-gynaecological organ pain that frequently shows cyclical exacerbations (e.g., IBS or PBPS) as well as pain similar to that associated with endometriosis/adenomyosis but where no pathology is identified. This condition is different from dysmenorrhoea, in which pain is only present with menstruation.

Primary dysmenorrhoea	Primary dysmenorrhoea is pain with menstruation that is not associated with well-defined pathology. Dysmenorrhoea needs to be considered as a chronic primary pain syndrome if it is persistent and associated with negative cognitive, behavioural, sexual or emotional consequences.
Gastrointestinal Pelvic Pain Syndromes	
Irritable bowel syndrome	Irritable bowel syndrome is the occurrence of chronic or recurrent episodic (abdominal) pain associated with defecation or change in bowel habits. In routine diagnostic examination, obvious anatomic or physiologic abnormalities are absent. Bowel dysfunction (e.g. constipation) is frequent. Irritable bowel syndrome is often associated with worry and pre-occupation about bowel function, and negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract or gynaecological dysfunction. The classification is based upon the Rome IV Criteria [17]. Reccurent abdominal pain on average at least 1d/week in the last 3 months. Symptom onset at least 6 months prior to diagnosis. The pain is associated with at least two or more of the following criteria: Related to defecation, assocated with a change in frequency of stool or a change in form of stool. Depending on the predominant stool form, based on the Bristol Stool Scale, the IBS can be subdivieded into IBS with predominant constiation (IBS-C), predominant diarrhea (IBS-D) and with mixed bowel habits (IBS-M). Patients whose bowel habits don't fit in one of the above categories are classified as «IBS Unclassified» (IBS-U). Extra-intestinal symptoms include: nausea, fatigue, full sensation after even a small meal, and vomiting.
Chronic primary anal pain syndrome	Chronic primary anal pain syndrome is the occurrence of chronic or recurrent episodic pain perceived in the anus, in the absence of proven infection or other obvious local pathology. Chronic primary anal pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction.
Intermittent chronic primary anal pain syndrome	Intermittent chronic primary anal pain syndrome refers to severe, brief, episodic pain that seems to arise in the rectum or anal canal and occurs at irregular intervals. This is unrelated to the need to or the process of defecation. It may be considered a sub-group of the chronic primary anal pain syndromes. It was previously known as "proctalgia fugax" but this term is no longer recommended.
Musculoskeletal System	
Primary pelvic floor muscle pain syndrome	Primary pelvic floor muscle pain syndrome is the occurrence of persistent or recurrent episodic pelvic floor pain. There is no proven well-defined local pathology. It is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. This syndrome may be associated with over-activity of, or trigger points within, the pelvic floor muscles. Trigger points may also be found in several muscles, such as the abdominal, thigh and paraspinal muscles and even those not directly related to the pelvis.
Primary coccyx pain syndrome	Primary coccyx pain syndrome is the occurrence of chronic or recurrent episodic pain perceived in the region of the coccyx, in the absence of proven infection or other obvious local pathology. Primary coccyx pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. The term "coccydynia" was used but is no longer recommended.
Chronic Pain Post-Surgery	
Chronic post-surgical pain syndrome	The definition of chronic post-surgical pain is chronic pain that develops or increases in intensity after a surgical procedure and persists beyond the healing process, i.e., at least three months after the surgery. There is a separate category for this in the ICD11 classification.

2. METHODOLOGY

2.1 Methods

Additional information can be found in the general Methodology section online at the EAU website: https://uroweb.org/guidelines. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

Recommendations within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [18];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. 4the balance between desirable and undesirable outcomes;
5. the impact and certainty of patient values and preferences on the intervention.

Strong recommendations typically indicate a high degree of evidence quality and / or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [19].

The 2012 full text update was based on a systematic review (SR) of literature using the Embase and Medline databases, the Cochrane Central Register of controlled trials and the PsycINFO and Bandolier databases to identify the best evidence from randomised controlled trials (RCTs) (Level of Evidence 1 [LE: 1]) according to the rating schedule adapted from the Oxford Centre for Evidence-based Medicine Levels of Evidence. Where no LE: 1 literature could be identified the search was moved down to the next lower level on the rating scale.

Extensive use of free text ensured the sensitivity of the searches, resulting in a substantial body of literature to scan. Searches covered the period January 1995 to July 2011 and were restricted to English language publications. In 2017, a scoping search for the previous five years was performed and the guideline was updated accordingly.

In 2021, a new section was included on Post-Surgical Pain Syndrome. In addition, the classifications in the Guideline have been amended to reflect ICD-11 released by WHO. The latest version of ICD-11 will be available for member states to report with from January 2022. For the 2024 print, a scoping search for the previous three years was performed and the guideline was updated accordingly.

2.2 Review

This document was subject to peer review prior to publication in 2021.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOPHYSIOLOGY

3.1 Chronic visceral pain

Definition of pain

Pain is defined as an unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage (IASP Taxonomy) [20].

Introduction to chronic pelvic primary pain syndromes

Over the years much of the focus for chronic pelvic primary pain syndromes (CPPPSs) has been on peripheral-end-organ mechanisms, such as inflammatory or infective conditions. However, both animal and clinical research have indicated that many of the mechanisms for the CPPPSs are based within the CNS. Although a peripheral stimulus such as infection may initiate the start of a CPPPS condition, the condition may become self-perpetuating as a result of CNS modulation. As well as pain, these central mechanisms are associated with several other sensory, functional, behavioural and psychological phenomena. It is this collection of phenomena that form the basis of the pain syndrome diagnosis and each individual phenomenon needs to be addressed in its own right through multispecialty and multi-disciplinary care. Although ongoing peripheral organ pathology can produce persistent and chronic pain, the main focus of these guidelines is on CPPPSs in which no peripheral ongoing pathology (such as infection or neoplastic disease) is detected. The main exception is when pain is due to peripheral nerve damage.

*3.1.1 **Incidence***

No adequate data on incidence were found.

*3.1.2 **Prevalence***

Across the world [21] chronic pain is prevalent, seriously affecting the quality of people's social, family, and working lives, with differences between countries attributable to multiple causes, including study methodology. A UK study found a prevalence of chronic pelvic pain of 14.8% in women 25 years [22, 23].

*3.1.3 **Influence on Quality of Life***

Assessing QoL in pelvic pain patients is challenging due to the complex pathology, the multi-faceted nature of the complaints and the overlap between the different pelvic pain syndromes.

Pelvic pain syndromes have an impact in terms of QoL [24, 25], depression, anxiety, impaired emotional functioning, insomnia and fatigue [24, 26]. If these aspects are identified and targeted early in the diagnostic process, the associated pain symptoms may also improve. Addressing comorbidities will help in further improving QoL. Quality of life assessment is therefore important in patients with pelvic pain and should include physical, psychosocial behavioural and emotional aspects, using standardised instruments where possible. Chronic pain is, in many countries, the leading cause of years lost to disability [21], although these figures are dominated by musculoskeletal pain and headache. Chronic pain is often associated with depression and other psychological problems; with loss or reduction of work and of ability to carry out domestic tasks; and, with substantial use of healthcare, often with disappointing outcomes.

*3.1.4 **Costs***

No adequate data on costs were found.

*3.1.5 **Risk Factors and underlying causes***

3.1.5.1 Risk factors

Risk factors include many different factors from various areas, including genetic, psychological state, recurrent physical trauma and endocrine factors.

The endocrine system is involved in visceral function. Significant life events, and in particular, early life events may alter the development of the hypothalamic-pituitary-adrenal axis and the chemicals released. Increased vulnerability to stress is thought to be partly due to increased corticotrophin-releasing hormone (CRH) gene expression. Up-regulation of CRH has been implicated in several pain states such as rectal hypersensitivity to rectal distension [27]. This model suggests an action of CRH on mast cells. A range of stress-related illnesses have been suggested, e.g., IBS and BPS [28, 29]. There is evidence accumulating to suggest that the sex hormones also modulate both nociception and pain perception [30]. Stress can also produce long-term biological changes which may form the relation between chronic pain syndromes and significant early life and adverse life events [31]. Asking the patient about these events is important as they have an effect on a patient's psychological wellbeing [32, 33].

Genetics also play a role in assessing the risk of developing chronic pain. An individual who has one chronic pain syndrome is more likely to develop another. Family clusters of pain conditions are also observed and animals can be bred to be more prone to apparent chronic pain state. A range of genetic variations have been described that may explain the pain in certain cases; many of these are to do with subtle changes in transmitters and their receptors. However, the picture is more complicated in that developmental, environmental and social factors also influence the situation. Evidence that primary bladder pain syndrome (PBPS) may have

a genetic component has been presented in several identical twin studies, but genetics may contribute to less than one third of total variation in susceptibility to PBPS [34, 35].

Studies about integrating the psychological factors of CPPPSs are few but the quality is high. Psychological factors are consistently found to be relevant in the maintenance of persistent pelvic and urogenital pain [36]. Beliefs about pain contribute to the experience of pain [37] and symptom-related anxiety and central pain amplification may be measurably linked, and worrying about pain and perceived stress predict worsening of urological chronic pain over a year [36, 38]. Central sensitisation has been demonstrated in a small study of symptomatic endometriosis [39] and central changes are evident in association with dysmenorrhoea and increasingly recognised as a risk for female pelvic pain [40]. The various mechanisms of CNS facilitation, amplification and failure of inhibition mean that there is no simple relationship between physical findings, pain experience and resulting distress and restriction of activities. Division of aetiology into organic vs. psychogenic is unscientific. Diagnoses that assign women's pain to psychological origins due to scepticism about the reality or severity of their pain [23, 41] undermines any therapeutic relationship [42]. Pelvic pain and distress is related [43] in both men and women [44]; as are painful bladder and distress [38]. In a large population based study of men, CPPPS was associated with prior anxiety disorder [45]. The only SR [46] of risk factors for chronic non-cyclical pelvic pain in women included, as well as medical variables: sexual or physical abuse (Odds Ratio (OR): 1.51-3.49); psychological problems such as anxiety (OR: 2.28; 95% Confidence Interval (CI): 1.41-3.70) and depression (OR: 2.69; 95% CI: 1.86-3.88); multiple somatic problems (OR: 4.83; 95% CI: 2.50-9.33 and OR: 8.01; 95% CI: 5.16-12.44).

Many studies have reported high rates of childhood sexual abuse in adults with persistent pain, particularly in women with pelvic pain [47]. It is hard to establish a causal role for sexual abuse or trauma history, anxiety or depression in women with CPPPS [48, 49], as the attribution of current pain to past sexual or physical abuse is associated both with current depression [50] and with current overall physical health [51]. There is some evidence for a specific relationship between rape and CPPPS (and with fibromyalgia and functional gastrointestinal disorders) [52]; and, recent sexual assault may prompt presentation of pelvic pain [47, 53]. Few studies have been found of sexual or physical abuse in childhood and pelvic pain in men, although it has known adverse effects on health [52], but men who reported having experienced sexual, physical or emotional abuse had increased odds (3.3 vs. 1.7) for symptoms suggestive of CPPPS [54]. Both sexes should be screened for sexual abuse when presenting with symptoms suggestive of CPPPS, and clinicians should inquire about pelvic pain in patients who have experienced abuse [54].

3.1.5.2 Underlying causes

The mechanisms that serve as an underlying cause for chronic pelvic pain are:

1. Ongoing acute pain mechanisms [55] (such as those associated with inflammation or infection), which may involve somatic or visceral tissue.
2. Chronic pain mechanisms, which especially involve the CNS [6].
3. Emotional, cognitive, behavioural and sexual responses and mechanisms [56, 57]

Symptoms and signs of neuropathic pain appear to be common in CPPPS patients and assessment of neuropathic pain should be considered in that group of patients including those with secondary pelvic pain and other pelvic pathologies [58].

Chronic pain mechanisms may include altered resting state neuromotor connectivity, for instance in men with chronic prostatitis/CPPPS [59].

Table 3 illustrates some of the differences between the somatic and visceral pain mechanisms. These underlie some of the mechanisms that may produce the classical features of visceral pain; in particular, referred pain and hyperalgesia.

Table 3: Comparison between visceral and somatic pain

	Visceral pain	Somatic pain
Effective painful stimuli	Stretching and distension, producing poorly localised pain.	Mechanical, thermal, chemical and electrical stimuli, producing well localised pain.
Summation	Widespread stimulation produces significantly magnified pain.	Widespread stimulation produces a modest increase in pain.
Autonomic involvement	Autonomic features (e.g., nausea and sweating) frequently present.	Autonomic features less frequent.
Referred pain	Pain perceived at a site distant to the cause of the pain is common.	Pain is relatively well localised and well recognised.
Referred hyperalgesia	Referred cutaneous and muscle hyperalgesia is common, as is involvement of other visceral organs.	Hyperalgesia tends to be localised.
Innervation	Low density, unmyelinated C fibres and thinly myelinated Aδ fibres.	Dense innervation with a wide range of nerve fibres.
Primary afferent physiology	Intensity coding. As stimulation increases, afferent firing increases with an increase in sensation and ultimately pain.	Two fibre coding. Separate fibres for pain and normal sensation.
Silent afferents	50-90% of visceral afferents are silent until the time they are switched on.	These fibres are very important in the central sensitisation process. Silent afferents present, but form a lower percentage.
Central mechanisms	Play an important part in the hyperalgesia, viscero-visceral, viscero-muscular and musculo-visceral hyperalgesia.	Sensations not normally perceived become perceived and non-noxious sensations become painful. Responsible for the allodynia and hyperalgesia of chronic somatic pain.
Abnormalities of function	Central mechanisms associated with visceral pain may be responsible for organ dysfunction.	Somatic pain associated with somatic dysfunction, e.g., muscle spasm.
Central pathways and representation	As well as classical pathways, there is evidence for a separate dorsal horn pathway and central representation.	Classical pain pathways.

Ongoing peripheral pain mechanisms in visceral pain

In most cases of chronic pelvic pain, ongoing tissue trauma, inflammation or infection is absent [60, 61]. However, conditions that produce recurrent trauma, infection or ongoing inflammation may result in chronic pelvic pain in a small proportion of cases. For example, out of a large cohort with acute bacterial prostatitis, 10.5% ended up with a state of CPPPS [62]. It is for this reason that the early stages of assessment include looking for these pathologies. Once excluded, ongoing investigations for these causes are rarely helpful and indeed may be detrimental.

When acute pain mechanisms are activated by a nociceptive event, as well as direct activation of the peripheral nociceptor transducers, sensitisation of those transducers may also occur; therefore, magnifying the afferent signalling. Afferents that are not normally active may also become activated by the change, that is, there may be activation of the so-called silent afferents. Although these are mechanisms of acute pain, the increased afferent signalling is often a trigger for the chronic pain mechanisms that maintain the perception of pain in the absence of ongoing peripheral pathology (see below) [63].

There are a number of mechanisms by which the peripheral transducers may exhibit an increase in sensibility:

1. Modification of the peripheral tissue, which may result in the transducers being more exposed to peripheral stimulation.
2. There may be an increase in the chemicals that stimulate the receptors of the transducers [64].
3. There are many modifications in the receptors that result in them being more sensitive.

In general, the effect of 1 and 2 above is to lower the threshold and the effect of 3 above is to increase responsiveness to external stimuli. Some of the chemicals responsible for the above changes may be released from those cells associated with inflammation, but the peripheral nervous system may also release chemicals in the positive and inhibitory loops [65, 66].

Central sensitisation as a mechanism in visceral pain

It is important to appreciate that nociception is the process of transmitting information to centres involved in perception of a stimulus that has the potential to cause tissue damage. Pain is far more complex and involves activation of the nociceptive pathways but also the emotional response. The brain may affect the modulation of pain pathways at the spinal cord level.

Neuronal sensitisation is responsible for a decrease in threshold and an increase in response duration and magnitude of dorsal horn neurons. It is associated with an expansion of the receptive field. As a result, sensitisation increases signalling to the CNS and amplifies what we perceive from a peripheral stimulus. For example, for cutaneous stimuli, light touch would not normally produce pain, however, when central sensitisation is present, light touch may be perceived as painful (allodynia). In visceral hyperalgesia (so called because the afferents are primarily small fibres), visceral stimuli that are normally sub-threshold and not usually perceived, may be perceived and result in a sensation of fullness and a need to void or to defecate. Non-noxious stimuli may be interpreted as pain and stimuli that are normally noxious may be magnified (true hyperalgesia) with an increased perception of pain. As a consequence, one can see that many of the symptoms of PBPS and IBS may be explained by central sensitisation. A similar explanation exists for the muscle pain in FM.

It is now well accepted that there are both descending pain-inhibitory and descending pain-facilitatory pathways that originate from the brain [67]. Several neurotransmitters and neuromodulators are involved in descending pain-inhibitory pathways. The main ones are the opioids, 5-hydroxytryptamine and noradrenaline.

The autonomic nervous system also plays a role in sensitisation. There is good evidence that damaged afferent fibres may develop a sensitivity to sympathetic stimulation, both at the site of injury and more centrally, particularly in the dorsal horns. In visceral pain, the efferent output of the CNS may be influenced by central changes (again, those changes may be throughout the neuraxis), and such modification of the efferent message may produce significant end-organ dysfunction. These functional abnormalities can have a significant effect on QoL and must be managed as appropriate.

Psychological mechanisms in visceral pain

Psychological processes of emotions, thought and behaviour involve networks rather than distinct centres. Some of these processes are sophisticated and others fundamental in evolutionary terms, and their interaction with pain processing is complex.

Various psychological processes affect pain neuromodulation at a higher level. Inhibiting or facilitating both the strength of the nociceptive signal reaching the consciousness and appraisal and interpretation of that signal, will also modulate the response to the nociceptive message and hence the pain experience. Further, descending pathways represent cognitive, emotional and behavioural states at spinal and peripheral levels.

The psychological modulation of visceral pain probably involves multiple pathways: for instance, mood and attentional focus probably act through different areas of the brain when involved in reducing pain [68]. This psychological modulation may act to reduce nociception within a rapid time frame but may also result in long-term vulnerability to chronic visceral pain, through long-term potentiation. This involvement of higher centre learning may be at both a conscious and subconscious level, and is clearly significant in the supratentorial neuroprocessing of nociception and pain. Long-term potentiation [69] may occur at any level within the nervous system, so that pathways for specific or combinations of stimuli may become established, resulting in an individual being vulnerable to feeling pain from sensations that would not normally be experienced as painful.

An important review [31] of chronic pelvic pain in women dismantled the notion that women without relevant physical findings differ in psychological characteristics from women with relevant physical findings. Women with pelvic pain often have other non-pain somatic symptoms and current or lifetime anxiety and depression disorder [22]; they may have a history of physical or sexual abuse in childhood; but this is of unclear significance. Studies should avoid interpreting the absence of physical findings as evidence for psychological origins of the complaint ('psychosomatic' or 'somatoform' disorders). Pain studies describe multiple processes by which pain may spread across sites, or in time, including central sensitisation (see previous section), viscero-visceral cross sensitisation in relation to multiple pain sites [70], activation of the hypothalamic-pituitary axis and dysregulation of serotonergic pathways [71] that can render pain levels responsive to stress. Some pain problems which affect sexual activity are diagnosed as sexual problems (e.g., 'dyspareunia') when pain is the central problem and is not contingent on sexual activity alone [72]. Better integration of sexology and mainstream psychology for pelvic pain in both men and women is needed, building on a biopsychosocial formulation [73, 74].

The term psychosomatic symptoms can best be understood as multiple somatic symptoms not associated with, or indicative of, any serious disease process. Medical and surgical history may also be important [75].

Understanding the psychological components of pain

Psychological processes of emotions, thought and behaviour involve distributed networks, whose interactions with pain processing are complex, producing inhibition and facilitation of signal processing, appraisal, and response. Models that integrate psychological factors involved in maintaining persistent pelvic and urogenital pain with current neurobiological understanding of pain are few, but the quality is high (see Section 3.1.5.1).

There is no evidence that women with CPPPS without physical findings are primarily presenting a psychological problem [31]. Anxiety and post-traumatic stress symptoms are common in some women with CPPPS [23, 76] and with vulvar pain [77], and may account for substantial variance in health status, treatment use and treatment outcome; for instance, women's expectations about vulvar pain on penetration predicted pain, sexual function and sexual satisfaction [78]. Negative investigative findings do not necessarily resolve women's anxieties about the cause of pain [79, 80] and anxiety often focuses on what might be 'wrong'. Depression may be related to pain in various ways, as described above. Until measures are available that are adequately standardised in patients with pain, assessment of anxiety and distress requires questions about the patient's beliefs about the cause of pain, the hope that diagnosis will validate pain, the struggle with unpredictability, and the implications of pain for everyday life [81, 82]. Reference to the studies of the IMMPACT group [83] is recommended for guidance on outcome measures suitable for pain trials.

Stress can modify the nervous system to produce long-term biological changes. These structural changes may be responsible for significant early life and adverse life events which are associated later with chronic pain syndromes [33]. The patient should be asked about adverse life events that may produce these biological responses and affect general psychological well-being [33, 84].

3.1.5.3 Clinical paradigms in visceral pain

Referred pain

Referred pain is frequently observed and its identification is important for diagnosis and treatment. Referral is usually somatic to somatic, or visceral to somatic. However, there is no reason why pain cannot also be perceived within the area of an organ with the nociceptive signal having arisen from a somatic area. Referred pain may occur as a result of several mechanisms but the main theory is one of convergence-projection. In the convergence-projection theory, afferent fibres from the viscera and the somatic site of referred pain converge onto the same second order projection neurons. The higher centres receiving messages from these projection neurons are unable to separate the two possible sites from the origin of the nociceptive signal [63].

Hyperalgesia refers to an increased sensitivity to normally painful stimuli. In patients that have passed a renal stone, somatic muscle hyperalgesia is frequently present, even a year after expulsion of the stone. Pain to non-painful stimuli (allodynia) may also be present in certain individuals. Somatic tissue hyperaesthesia is associated with urinary and biliary colic, IBS, endometriosis, dysmenorrhoea, and recurrent bladder infections. Primary vulvar pain syndromes are examples of cutaneous allodynia that, in certain cases, may be associated with visceral pain syndromes, such as BPS. Referred pain with hyperalgesia is thought to be due to central sensitisation of the converging viscero-somatic neurons. Central sensitisation also stimulates efferent activity that could explain the trophic changes that are often found in the somatic tissues.

Musculo-skeletal system and pelvic pain

In the urogenital pain syndromes, muscle tenderness and trigger points may be implicated as a source of pain. Central mechanisms are of great importance in the pathogenesis of this muscle hyperalgesia. The muscles involved may be a part of the spinal, abdominal or pelvic complex of muscles. It is not unknown for adjacent muscles of the lower limbs and the thorax to become involved. Pain may be localised to the trigger points but it is more often associated with classical referral patterns. As well as trigger points, inflammation of the ligaments and tendons to the bones (enthesitis) and of the bursa (bursitis) may be found [85]. Certain postures affect the different muscles in different ways, and as a consequence, may exacerbate or reduce the pain. Stress, like negative sexual encounters, has been implicated as both an initiator of pelvic myalgia and as a maintenance factor.

Visceral hyperalgesia

The increased perception of stimuli in the viscera is known as visceral hyperalgesia, and the underlying mechanisms are thought to be responsible for IBS, PBPS and dysmenorrhoea. The mechanisms involved are often acute afferent input (e.g., due to infection) followed by long-term central sensitisation. Viscero-visceral hyperalgesia is thought to be due to two or more organs with converging sensory projections and central sensitisation. For instance, overlap of bladder and uterine afferents or uterine and colon afferents.

3.2 Pelvic pain

*3.2.1 **Incidence***

No adequate data on incidence were found.

*3.2.2 **Prevalence***

3.2.2.1 Primary prostate pain syndrome

There is only limited information on the true prevalence of PPPS in the population. As a result of significant overlap of symptoms with other conditions (e.g., benign prostatic enlargement and PBPS), purely symptom based case definitions may not reflect the true prevalence of PPPS [86, 87]. In the literature, population-based prevalence of prostatitis symptoms ranges from 2.2-14.2% [88, 89]. The risk of prostatitis increases with age (men aged 50-59 years have a 3.1-fold greater risk than those aged 20-39 years).

3.2.2.2 Primary bladder pain syndrome

Reports of PBPS prevalence have varied greatly, along with the diagnostic criteria and populations studied. Recent reports range from 0.06-20% [90-96]. There is a female predominance of about 10:1 [94] but possibly no difference in race or ethnicity [86, 97, 98]. The relative proportions of Hunner's lesion and non-lesion disease are unclear. Incidence in studies has ranged from 5-50% [99-102]. There is increasing evidence that children under eighteen may also be affected, although prevalence figures are low; therefore, PBPS cannot be excluded on the basis of age [103].

3.2.2.3 Sexual pain syndrome

In the 1980s, an association between chronic pelvic pain and sexual dysfunction was postulated. In a review the relationship between Primary Prostate Pain Syndrome and health status, with influence on sexual activity, was addressed [104]. In a Chinese study of men with chronic pelvic pain, 1,768 males completed the questionnaires. The overall prevalence of sexual dysfunction was 49%. Erectile dysfunction (ED) is the most investigated sexual dysfunction in PPPS patients. The reported prevalence of ED ranges from 15.1-48%, varying with evaluation tools and populations [105, 106]. Erectile dysfunction was prevalent in 27.4% of Italian men aged 25-50 [107], 15.2% among Turkish men (significantly higher than in the control group) [108] and 43% among Finnish men with PPPS [109]. The prevalence of ED was found to be higher in young men with PPPS than in the general population. A significant correlation between "chronic prostatitis", chronic pelvic pain symptoms (measured by NIH-CPSI) and ED (measured by International Index of Erectile Function [IIEF]) was confirmed while other studies using the same questionnaires were not able to confirm such a correlation [74, 110]. Some studies also report ejaculatory dysfunction, mainly premature ejaculation [105, 106, 111, 112].

In community-based studies in the UK [113], New Zealand [114] and Australia [115], a substantially larger proportion of the women with chronic pelvic pain reported dyspareunia (varying between 29-42%) than women without chronic pelvic pain (varying between 11-14%). Only a few studies have investigated sexual problems within clinical populations [116]. Another study showed that all of the sexual function domains (desire, arousal, lubrication, orgasm, satisfaction, and pain) were significantly lower in women with chronic pelvic pain than in women without chronic pelvic pain [116]. One study of patients enrolled in chronic pain treatment programs in England has reported that 73% had pain-related sexual problems [117].

3.2.2.4 Myofascial pain syndromes

The relationship between muscular dysfunction (especially over-activity) and pelvic pain has been found in several studies [118]. Rectal pain treated with pelvic floor muscle therapy is only relieved when patients learn to relax their pelvic floor muscles [119, 120]. The vast majority (92.2%) of men visiting a tertiary centre for pelvic pain had dysfunction of the pelvic floor muscles. This finding was true regardless of evidence of inflammation (prostatitis or cystitis) [121]. This relationship has been found in chronic prostatitis [122], PBPS [123] and vulvar pain [124]. Dysfunction of the pelvic floor directly affects function of the pelvic viscera and vice versa. Both systems can act as the primary signal to the spinal cord, with a cascade of reactions ascending to the CNS as a result. The muscle itself ends up shortened, leading to restrictions even in a relaxed state.

*3.2.3 **Influence on Quality of Life***

Data on the influence on QoL will be included in a future version of the guidelines.

*3.2.4 **Costs***

No adequate data on costs were found.

*3.2.5 **Risk factors and underlying causes***

The risk factors are unspecific for most of the pain syndromes in the pelvic area. They are described in Section 3.1.5.1. The underlying causes, including the mechanisms for the different clinical pain syndromes are described here.

3.2.5.1 Primary prostate pain syndrome

Pain is the main symptom in PPPS. As a common feature of primary chronic pain syndromes, no single aetiological explanation has been found. One explanation is that the condition probably occurs in susceptible men exposed to one or more initiating factors, which may be single, repetitive or continuous. Several of these potential initiating factors have been proposed, including infectious, genetic, anatomical, neuromuscular, endocrine, immune (including autoimmune), or psychological mechanisms. These factors may then lead to a peripheral self-perpetuating immunological, inflammatory state and/or neurogenic injury, creating acute and then chronic pain. A study showed that chronic but not acute histological inflammation of the prostate was significantly associated with symptomatic progression [125]. Based on the peripheral and the CNS, sensitisation involving neuroplasticity may lead to a centralised neuropathic pain state. This could also explain why tissue damage is not usually found in PPPS. There is growing evidence for a neuropathic origin and association with CNS changes of pain in PPPS, and anxiety appears to be a risk factor for its development [45].

3.2.5.2 Primary bladder pain syndrome

An initial unidentified insult to the bladder, leading to urothelial damage, neurogenic inflammation and pain is thought to be a trigger of PBPS. However, PBPS might be a local manifestation of a systemic disorder. No infection has as yet been implicated. Nevertheless, urinary infections are significantly more frequent during childhood and adolescence, in patients with PBPS in adulthood [126]. Experimental induction of chronic pelvic pain by O-antigen deficient bacterial strains supports the bacterial hypothesis [127]. Pancystitis, with associated perineural inflammatory infiltrates, and mast cell count increase is an essential part of PBPS type 3 C [128], but is rare in non-lesion PBPS [33, 68, 129, 130]. Cystoscopic and biopsy findings in both lesion and non-lesion PBPS are consistent with defects in the urothelial glycosaminoglycan (GAG) layer, which might expose submucosal structures to noxious urine components [131-135] and a consequent cytotoxic effect [136, 137]. Basic and clinical studies indicate that autonomic dysfunction with sympathetic predominance may be implicated in PBPS [138, 139].

An association has been reported between PBPS and non-bladder syndromes such as FM, CFS, IBS, vulvodynia, depression, panic disorders, migraine, sicca syndrome, temporomandibular joint disorder, allergy, asthma and systemic lupus erythematosus [140-145]. Psychological comorbidities, especially depression, has been found to be related to symptom severity [140]. Risk of PBPS correlates with a number of non-bladder syndromes in each patient [146]. Recent work showing non-lesion PBPS to have significantly more FM, migraine, temporomandibular joint disorder and depression than PBPS type 3 C patients, which emphasises, the need for subtyping [147].

3.2.5.3 Primary scrotal pain syndrome

Often scrotal pain is not associated with any specific pathology. Pain is perceived in the testes, epididymis, or the vas deferens. As the ilioinguinal, genitofemoral and the pudendal nerves intervate the scrotum [148], any pathology or intervention at the origin or along the course of these nerves may result in pain perceived in the scrotum [149].

Two special forms of scrotal pain syndrome can be described. The first is post-vasectomy scrotal pain syndrome which occurs following vasectomy. The mechanisms are poorly understood, and for that reason it is considered by some a special form of primary scrotal pain syndrome. Incidence of post-vasectomy pain is 2-20% among all men who have undergone a vasectomy. In men with post-vasectomy pain, 2-6% have a Visual Analogue Scale (VAS) score > 5 [150]. In a large cohort study of 625 men, the likelihood of scrotal pain after six months was 14.7%. The mean pain severity on a VAS score was 3.4/10. In the pain group, 0.9% had quite severe pain, noticeably affecting their daily life. In this cohort, different techniques were used to perform the vasectomy. The risk of post-vasectomy pain was significantly lower in the no-scalpel vasectomy group (11.7% vs. the scalpel group 18.8%) [151].

The second special form of scrotal pain is post-inguinal hernia repair pain. It is seen as a complication of hernia repair, but in trials it is seldom reported, or it is put under the term chronic pain (not specified). In studies that have explicitly mentioned scrotal pain, there was a difference in incidence between laparoscopic and open hernia repair. In almost all studies, the frequency of scrotal pain was significantly higher in the laparoscopic than in the open group [149, 152]. In one particular study, there was no difference at one year but after five years, the open group had far fewer patients with scrotal pain [153]. Inguinal hernia repair can lead to chronic post-surgical pain (CPSP) in up to 10% of patients at six months [154] and may present with groin and/ or scrotal pain. Testicular injury is uncommon (< 1%) but if associated with pain, orchidectomy can lead to symptomatic relief in 2/3 of patients [155]. Careful identification and preservation of nerves has been found to be associated with a reduced risk of chronic pain.

3.2.5.4 Primary urethral pain syndrome

Several mechanisms for the development of primary urethral pain syndrome have been proposed. The intimate relationship of the urethra with the bladder (both covered with urothelium) suggests that primary urethral pain syndrome may be a form of PBPS. Mechanisms thought to be basic for PBPS may also apply to the urethra. This means that the specific testing with potassium has been used to support the theory of epithelial leakage [156, 157]. Another possible mechanism is neuropathic hypersensitivity following urinary tract infection. The relationship with gynaecological and obstetric aspects is unclear. In a small group of patients with urethral pain, it has been found that grand multi-parity and delivery without episiotomy were more often seen in patients with urethral syndrome, using univariate analysis [158].

3.2.5.5 Primary vaginal and vulvar pain syndromes

Pain in the vagina or the female external genital organs is often due to infection or trauma, as a consequence of childbirth or surgery. Pain is usually a precedent to dyspareunia. When the pain persists for more than three months, it can be diagnosed as primary vulvar pain syndrome previously known as “vulvodynia” or “chronic vaginal pain” with no known cause. It is still a poorly understood condition, and therefore difficult to treat.

There are two main sub-types of primary vulvar pain syndrome: generalised, where the pain occurs in different areas of the vulva at different times; and focal, where the pain is at the entrance of the vagina. In primary generalised vulvar pain syndrome, the pain may be constant or occur occasionally, but touch or pressure does not initiate it, although it may make the pain worse. In primary focal vulvar pain syndrome, the pain is described as a burning sensation that comes on only after touch or pressure, such as during intercourse.

The possible causes of primary vulvar pain syndrome involve a complex interplay between affective, behavioural and interpersonal factors such as:
psychological factors, i.e. depressive symptoms, anxiety, pain-related fear and catastrophising [159, 160]

- history of physical or sexual abuse;
- history of chronic antibiotic use;
- hypersensitivity to yeast infections, allergies to chemicals or other substances;
- abnormal inflammatory response (genetic and non-genetic) to infection and trauma;
- nerve or muscle injury or irritation;
- hormonal changes.

3.2.5.6 Chronic pelvic pain and prolapse/Incontinence mesh

Continence and prolapse mesh implants were developed as simple flexible polypropylene plastic acting as a scaffold to treat stress urinary incontinence (SUI) and uterovaginal prolapse, respectively. They were deemed easy to insert, but no credence was given as to how safe they were, whether they could be removed should they cause complications, or what to do should they not be effective [161, 162]. Most meshes took less than an hour to implant surgically and most patients were treated as day cases, allowing women to leave hospital quickly and get on with their lives. Therefore, rather than undergo complex traditional surgery, women were

offered permanent mesh implants, particularly in the treatment of SUI where they were considered to be the gold standard [163, 164]. However, over the last few years the insertion of mesh has come with significant 'health and safety warnings' [165, 166].

For many, mesh was initially seen not just as an effective treatment but as a permanent one. Complications were not thought to be a significant issue and the figure of 1-3% was often quoted. However, we now know the complication rate was closer to 10% [167]. They included chronic pain [168, 169], as well as chronic infections [170], erosion into the surrounding organs including the vagina, urethra and bladder, as well as nerve and musculoskeletal damage affecting mobility [168, 169, 171, 172]. All had a significant impact on the patients' QoL.

It is as a result of severely debilitating complications following mesh implantation [168], that the field of mesh removal medicine and surgery emerged [173].

Early recognition of possible mesh complications is very important. It is normal to wake up in some degree of discomfort after any surgery. However, if the pain after the operation is very severe and much more than expected after this type of surgery, it can be a sign that there was added trauma to the surrounding organs during the procedure. Most pain is often managed with analgesia, but some women might not fully respond to therapy. If the pain is difficult to treat and does not improve over time, it may become necessary to remove the mesh. Leaving a painful mesh in the pelvis, can lead to chronic pelvic pain. The precise mechanism is unknown but it is thought to be a 'neuro-inflammatory' process [174], as has been proposed in hernia mesh neuralgia. The impact of the mesh, regardless of site, appears to be similar.

3.2.5.7 Chronic post-surgical pain

Chronic post-surgical pain

Chronic pain may develop following surgical procedures and has a significant impact on the individual. The ICD-11 has recently classified chronic post-surgical pain (CPSP) as a chronic pain condition. The definition of CPSP is chronic pain that develops or increases in intensity after a surgical procedure and persists beyond the healing process, i.e., at least three months after the surgery [175].

Chronic post-surgical pain may occur in a significant number of patients, and is more prevalent following some operations rather than others. Procedures with a higher risk of CPSP include limb amputation (30-85%), thoracotomy (5-65%) and mastectomy (11-57%) [176].

Risk factors for CPSP include a number of pre-, peri- and post-operative factors. Younger age, female gender, chronic pain pre-operatively elsewhere, higher number of previous operations, use of opioids and a higher post-operative pain score have been found to be associated with a higher risk of CPSP in a prospective cohort of patients undergoing laparoscopy and laparotomies. Older age, malignant indication for surgery, a higher pre-operative mental health score and the use of epidural analgesia in addition to general anaesthesia were protective [177, 178].

There are a number of procedures specific to the abdomen and pelvis that are associated with an increased risk of chronic pain post-surgery, including bariatric procedures, inguinal hernia repair, vasectomy, hysterectomy and caesarean section. Adhesions are a common cause of chronic abdominal pain but despite this, a SR identified only low level evidence to help guide management of affected individuals [179].

The estimated prevalence of CPSP following bariatric surgery is 30% [180]. In affected individuals careful assessment that may include laparoscopy could identify a treatable cause (such as adhesions, mesenteric defect or cholecystitis) and lead to a significant reduction in post-operative pain [181].

Inguinal hernia repair can lead to CPSP in up to 10% of patients at six months [154] and may present with groin and/or scrotal pain. The incidence of post-vasectomy pain ranges from 2-20% [150, 182]. The risk is significantly lower following the no scalpel technique [151].

The incidence of post-surgical pain following hysterectomy is difficult to determine as pain is a common indication for the operation. When defined as CPSP, rates are estimated at 28-30% [183, 184]. Careful case selection and management of patient expectation is therefore important.

The frequency of caesarean section has increased over time. A meta-analysis has shown a significant incidence of CPSP both at three months and at more than twelve months (15% and 11% respectively) [185], therefore careful counselling is needed in non-emergency cases.

3.2.5.8 Associated conditions in pelvic pain syndromes

Nerve damage

Spinal pathology and any pathology along the course of the nerve involved may result in neuropathic pain in the distribution of these nerves. Neoplastic disease, infection, trauma, surgical incisions and post-operative scarring may result in nerve injury [186].

Pudendal neuralgia is the most often mentioned form of nerve damage in the literature. Anatomical variations may pre-dispose the patient to developing pudendal neuralgia over time or with repeated low-grade trauma (such as sitting for prolonged periods of time or cycling) [187, 188].

The pudendal nerve may be damaged at the level of:

1. The piriformis muscle. For example, as part of a piriformis syndrome: in some cases, the nerve may pass through the muscle and hence be trapped; or in other cases, muscle hypertrophy or spasm is implicated.
2. The sacrospinal/sacrotuberous ligaments, possibly accounting for 42% of cases.
3. Within Alcock's canal (medial to the obturator internus muscle, within the fascia of the muscle), possibly accounting for 26% of cases.
4. Multiple levels in 17% of cases.
5. The site of injury determines the location of perceived pain and the nature of associated symptoms (e.g., the more distal the damage, the less likely the anal region will be involved).

The clinical presentation depends on different factors. There is a wide age range, as one would expect, with a condition that has so many potential causes. It is suggested that, the younger the patient, the better the prognosis. Essentially, the sooner the diagnosis is made, as with any compression nerve injury, the better the prognosis, and older patients may have a more protracted problem [189]. Six out of ten cases are observed in women. Some special situations can be listed:

- In orthopaedic hip surgery, pressure from the positioning of the patient, where the perineum is placed hard against the brace, can result in pudendal nerve damage [190, 191]. The surgery itself may also directly damage the nerve. Pelvic surgery such as sacrospinous fixation is clearly associated with pudendal nerve damage in some cases [192, 193]. In many types of surgery, including colorectal, urological and gynaecological, pudendal nerve injury may be implicated.
- Fractures of the sacrum or pelvis may result in pudendal nerve/root damage and pain. Falls and trauma to the gluteal region may also produce pudendal nerve damage if associated with significant tissue injury or prolonged pressure.
- Tumours in the pre-sacral space must be considered. Tumours invading the pudendal nerve may occur and there may also be damage from surgery for pelvic cancer [194].
- The pudendal neuralgia of birth trauma is thought to resolve in most cases over a period of months. However, rarely, it appears to continue as painful neuropathy. Multiple pregnancies and births may predispose to stretch neuropathy in later life. This is more difficult to be certain about [195].
- Child birth and repeated abdominal straining associated with chronic constipation [196] are thought to pre-dispose elderly women to post-menopausal pelvic floor descent and stretching of the pudendal nerve with associated pain. Changes in the hormone status may also be a factor. In Urogenital Pain Management Centres, the commonest associations with pudendal neuralgia appear to be: history of pelvic surgery; prolonged sitting; and post-menopausal older women.

Sexual dysfunction

Chronic pelvic pain is a clinical condition that results from complex interactions of physiological and psychological factors and has a direct impact on the social, personal and professional lives of men and women.

Men

Men

Chronic pain as well as its treatment can impair our ability to express sexuality. In an England study, 73% of patients with any chronic pain had some degree of sexual problems as a result of the pain [117]. These problems can occur because of several factors. Psychological factors like pain catastrophising, a decrease in self-esteem, depression and anxiety can contribute to the problem severity [197]. Physiological factors like fatigue, nausea and pain itself can cause sexual dysfunction. Pain medications (opioids, and the selective serotonin re-uptake inhibitors [SSRIs]) can also decrease libido [198] and delay ejaculation. The number of

studies on the effects of CPPPS on sexual function is limited. Sexual dysfunction is often ignored because of a lack of standardised measurements. At present, the most commonly used tool is the IIEF questionnaire [110].

The presence of pelvic pain may increase the risk for ED independent of age [199]. On the other hand, cross-sectional data suggest no improvement of lower urinary tract symptoms (LUTS) by an increased frequency of ejaculation [200]. Although mental distress and impaired QoL related to illness could contribute to sexual dysfunction observed in patients with PPPS, the presence of erectile and ejaculatory disorders is more frequently related to symptoms suggestive of a more severe inflammatory condition [112]. These arguments are important for the understanding of the close relationship between CPPPS symptoms, disturbed sexuality, impact on QoL, and psychological implications including depression and more failure anticipation thoughts [104-106, 200-202]. Sexual dysfunction heightens anger, frustration and depression, all of which place a strain on the patients' relationships. The female partners of men with sexual dysfunction and depression often present with similar symptoms including pain upon intercourse and depressive symptoms. Men with CPPPS have reported a high frequency of sexual relationship dissolution and psychological symptoms, such as depression and suicidal thinking [104, 203]. On the other hand, it was found that men with PPPS did not report significantly decreased sexual satisfaction compared to controls [204]. There is consensus that therapeutic strategies reducing symptoms of pelvic pain are of relevance in relation to changes in sexual function. Also intimacy and having sex can yield positive experiences that will reduce the pain. The CNS plays an important role in this mechanism.

Women

Chronic pelvic pain leads to substantial impairment in QoL and several sexual dysfunctions [205]. It seems reasonable to expect that pain, extreme fatigue, depressive mood and pain drugs will affect women's sexuality. Women with CPPPS reported significantly more pain, depression, and anxiety symptoms and were physically more impaired than women in the control group. In comparison with controls, women with CPPPS reported significantly more sexual avoidance behaviour, non-sensuality, and complaints of "vaginismus" [206]. Patients with CPPPS reported more sexual problems than women with any other type of chronic pain problem [207]. The quality of intimate relationships is closely connected with sexual function [208]. Satisfaction with sexual relationships appears to be associated with higher marital functioning [209]. In addition sexual dissatisfaction is related to sexual dysfunction. When one partner suffers from chronic pain, the ability of both partners to cope with the pain and the extent to which partners are supportive of the chronic pain sufferer have been found to be a predictor of sexual functioning [209].

Approximately two-thirds of patients in another study reported reduced frequency in their sexual relations as a result of CPPPS [210]. One study demonstrated that CPPPS patients reported worse sexual function with regard to desire, arousal, lubrication, orgasm, satisfaction, and more frequent and severe pain with vaginal penetration than women without CPPPS [211]. In an interview with 50 chronic pain sufferers and their spouses, 78% of the pain sufferers and 84% of partners described deterioration, including cessation of their sex life [212]. In a study in patients with back pain, half reported decreased frequency of sex since the onset of chronic pain [117]. The Female Sexual Function Index (FSFI) has been developed as a brief, multi-dimensional self-report instrument for assessing the key dimensions of sexual function in women, which includes desire, subjective arousal, lubrication, orgasm, satisfaction, and pain. Using the FSFI, women with CPPPS reported worse sexual function in all subscales and total score than women without CPPPS. The largest differences between women with CPPPS and without CPPPS, were seen for the domains of pain and arousal. The total score and the subscales of the FSFI had high levels of internal consistency and test-retest reliability when assessed in a sample of women with CPPPS. The FSFI also showed good ability to discriminate between women with and without CPPPS [211].

Myofascial pain

Myalgia is too often overlooked as a form of chronic pelvic pain. The pelvic floor and adjacent muscles are used in an abnormal way. Studies in the field of chronic prostatitis support the idea that patients with CPPPS have more muscle spasm and increased muscle tone and report pain when the pelvic floor muscles are palpated [213]. Learning pelvic floor muscle relaxation can diminish spasm and pain [214]. Repeated or chronic muscular overload can activate trigger points in the pelvic floor muscles. A report from the Chronic Prostatitis Cohort Study showed that 51% of patients with prostatitis and only 7% of controls had any muscle tenderness. Tenderness in the pelvic floor muscles was only found in the CPPPS group [122].

The first ideas about the neurological aspects of the pelvic floor muscles in relation to chronic pelvic pain were published in 1999. The possibility of CNS changes in the regulation of pelvic floor function was suggested as a mechanism for development of CPPPS. Of the patients presenting with pelvic pain, 88% had poor to absent pelvic floor muscle function [121]. Animal studies on the role of neurogenic inflammation have also elucidated

some important phenomena. Irritation of the prostate, bladder and pelvic floor muscles results in expression of C-fos-positive cells in the CNS. There appears to be convergence of afferent information onto central pathways. Once the central changes have become established, they become independent of the peripheral input that initiated them [215].

Repeated or chronic muscular overload can activate trigger points in the muscle. Trigger points are defined as hyper-irritable spots within a taut band. Other criteria for trigger points are recognition of the pain as 'familiar', and pain on stretching the muscle. Apart from pain, trigger points prevent full lengthening of the muscle, thereby restricting the range of movement. Pain as a result of these trigger points is aggravated by specific movements and alleviated by certain positions. Positions and movements in which the shortened muscle is stretched are painful. Patients know which activities and postures influence pain. Trigger points can be located within the pelvic floor muscles and in adjacent muscles such as the abdominal, gluteal and iliopsoas muscles. Pain is aggravated by pressure on the trigger point (e.g., pain related to sexual intercourse). Pain also worsens after sustained or repeated contractions of pelvic floor muscles (e.g., pain related to voiding or defecation).

3.3 Abdominal aspects of pelvic pain

3.3.1 ***Incidence***

Epidemiological data on IBS and CPPPS are scarce [216]. Chronic Pelvic Pain has been shown to be one of the most common functional disorders in women of reproductive age. The monthly incidence rate of CPPPS published by Zondervan *et al.* was 1.58/1000 [217].

3.3.2 ***Prevalence***

Using a vague definition of continuous or episodic pa*in situ*ated below the umbilicus over six months, one study reported that CPPPS was one of the most common diagnoses in primary care units in Great Britain [217]. The monthly prevalence rate of CPPPS in this study was 21.5/1,000, with an annual prevalence of 38.3/1,000. The prevalence rates increase significantly with older age and vary significantly between regions in the UK. The overall prevalence of anorectal pain in a sample of USA householders was 11.6% for functional anorectal pain and 6.6% for Levator Ani Syndrome. The difference between male and female was small (11.1 vs 12.1%) [218]. Irritable bowel syndrome is associated with common gynaecologic problems (endometriosis, dyspareunia, and dysmenorrhoea) [219]. Fifty per cent of women who presented with abdominal pain to the gynaecologic clinic or were scheduled for laparoscopy due to CPPPS had symptoms of IBS [220]. In a survey from Olmsted county, 20% of women reported CPPPS and 40% of those met the criteria for IBS [221]. This overlap of CPPPS and IBS was associated with an increased incidence of somatisation. Not gynaecological surgical procedures but only psychosocial variables predict pain development without a different incidence of IBS in a prospective and controlled study [222]. Clinical features of pelvic floor dysfunction, gynaecological and psychological features, are related to disordered anorectal function in IBS patients, but do not predict physiological anorectal testing.

3.3.3 ***Influence on Quality of Life***

There is little known on health related quality of life (HRQoL) in patients with CPPPS. There is a need to develop validated disease specific HRQoL instruments for CPPPS in addition to sound measurement properties. More data are available in patients with IBS treated at referral centres who have comparable HRQoL scores as patients with other common disorders such as diabetes, end-stage renal disease, and inflammatory bowel disease [223]. Sub-groups of IBS with predominance of diarrhoea or constipation show no difference in HRQoL. Multi-variate analysis shows that HRQoL in patients with IBS is affected by sex and psychological conditions.

3.3.4 ***Costs***

Costs combine direct health-care costs and societal costs (productivity loss) such as under-performance and absenteeism from work. The annual costs to society can be calculated by using the average population earnings. In Germany direct care costs are estimated at €791 and societal costs €995 per patient with IBS per year which may be comparable to patients with CPPPS [224].

3.3.5 ***Risk factors & underlying causes***

Risk factors are covered in Section 3.1.5.

3.4 Summary of evidence and recommendations: CPPPS and mechanisms

Summary of evidence	LE
CPPPS mechanisms are well defined and involve mechanisms of neuroplasticity and neuropathic pain.	2
The mechanisms of neuroplasticity and neuropathic pain result in increased perception of afferent stimuli which may produce abnormal sensations as well as pain.	1
End-organ function can also be altered by the mechanisms of neuroplasticity so that symptoms of function can also occur.	1
The diagnosis of a CPPPS as a pain syndrome is essential as it encourages a holistic approach to management with multi-specialty and multi-disciplinary care.	2

Recommendations	Strength rating
All of those involved in the management of chronic pelvic pain should have knowledge of peripheral and central pain mechanisms.	Strong
The early assessment of patients with chronic pelvic pain should involve investigations aimed at excluding disease-associated pelvic pain.	Strong
Assess functional, emotional, behavioural, sexual and other quality of life issues, such as effect on work and socialisation, early in patients with chronic pelvic pain and address these issues as well as the pain.	Strong
Build up relations with colleagues so as to be able to manage CPPPS comprehensively in a multi-specialty and multi-disciplinary environment with consideration of all their symptoms.	Strong

4. DIAGNOSTIC EVALUATION

4.1 General evaluation

4.1.1 History

History is very important for the evaluation of patients with chronic pelvic pain. Pain syndromes are symptomatic diagnoses, which are derived from a history of pain perceived in the region of the pelvis, and absence of other pathology, for a minimum of three months. This implies that specific disease-associated pelvic pain caused by bacterial infection, cancer, drug-induced pathology (e.g., ketamine use) [225], primary anatomical or functional disease of the pelvic organs, and neurogenic disease must be ruled out.

4.1.1.1 Anxiety, depression, and overall function

Distress is best understood in the context of pain and of the meaning of pain to the individual and is best assessed ideographically rather than normatively. Almost all diagnostic measures and standardised instruments of anxiety and depression are designed for people without significant physical problems, so are difficult to interpret in chronic pelvic pain [226].

Anxiety about pain often refers to fears of missed pathology (particularly cancer) as the cause of pain [37], or to uncertainties about treatment and prognosis. These can drive healthcare seeking behaviour. The question: "What do you believe or fear is the cause of your pain?" has been suggested [227]. Anxiety may also concern urinary urgency and frequency that are problematic in social settings.

Depression or depressed moods are common in chronic pain [228], often related to losses consequent to chronic pain (work, leisure activities, social relationships, etc.). Due to the lack of suitable assessment instruments, it is better to ask a simple question such as "How does the pain affect you emotionally?" If the answer gives cause for concern about the patient's emotional state, further assessment should be undertaken by an appropriately qualified colleague.

Most measures of restricted function are designed primarily for musculoskeletal pain and may emphasise mobility problems rather than the difficulties of the individual with pelvic or urogenital pain. A promising specific measure, UPOINT, was introduced and in a later version the sexological aspects were added [229]. However, it may underassess relevant psychological variables [44]. Generic QoL measures are helpful. If such an instrument

is not already used in the clinic, the Brief Pain Inventory [230] provides a broad and economical assessment of interference of pain with various aspects of life, and is available in multiple languages. (For further suggested instruments see [231]).

4.1.1.2 Urological aspects

Pain may be associated with urological symptoms. A detailed history of LUT functions should be taken. Dysfunctions of the LUT may exacerbate symptoms, as pain may interfere with the function of the LUT. Micturition in all its aspects should be addressed. Special attention should be paid to the influence of micturition on the experience of pain.

Primary prostate pain syndrome

Primary prostate pain syndrome is diagnosed from a history of pain perceived in the region of the prostate (convincingly reproduced by prostate palpation), and absence of other LUT pathology, for a minimum of three months. As mentioned above, specific disease-associated pelvic pain must be ruled out. A thorough history is an important first step in the evaluation of PPPS. It should include type of pain and localisation. Pain is often reported in other pelvic areas outside the prostate such as perineum, rectum, penis, testicles and abdomen [50]. In addition, associated LUT symptoms, sexual function, psychological, social and economic factors should be addressed. Determination of the severity of disease, its progression and treatment response can be assessed only by means of a validated symptom-scoring instrument (see Section 4.2.3). These subjective outcome measures are recommended for the basic evaluation and therapeutic monitoring of patients in urological practice.

Primary bladder pain syndrome

Primary bladder pain syndrome should be diagnosed on the basis of pain, pressure or discomfort associated with the urinary bladder, accompanied by at least one other symptom, such as daytime and/or night-time increased urinary frequency, the exclusion of confusable diseases as the cause of symptoms, and if indicated, cystoscopy with hydrodistension and biopsy (Table 4) [16].

The nature of pain is key to disease definition:

1. pain, pressure or discomfort perceived to be related to the bladder, increasing with increasing bladder content;
2. located suprapubically, sometimes radiating to the groins, vagina, rectum or sacrum
3. relieved by voiding but soon returns [232, 233];
4. aggravated by food or drink [233].

Primary bladder pain syndrome type 3 can lead to a small capacity fibrotic bladder with or without upper urinary tract outflow obstruction.

4.1.1.3 Gynaecological aspects

A detailed medical history outlining the nature, frequency and site of pain; its relationship to precipitating factors and the menstrual cycle, may help define the aetiology. A menstrual and sexual history, including a history of sexually transmitted diseases, vaginal discharge, as well as previous sexual trauma is mandatory as well as up to date cervical cancer screening. A history of obstetric and/or gynaecological surgery is also warranted, particularly if devices such as synthetic mesh were used.

4.1.1.4 Gastrointestinal aspects

The predominant symptoms that patients are interviewed about are discomfort or pain in relation to their bowel habits, daily activities, and eating. A precise history of dysfunctional voiding or defecation should be asked, ideally applying symptom questionnaires for urinary and anorectal symptoms (e.g., Rome IV criteria for anorectal pain). Excessive straining at most defecations, anal digitations in dyssynergic defecation, and a sensation of anal blockage may be found in patients with chronic anal pain. History of anxiety and depression with impaired QoL is often encountered in anorectal functional disorders and should be evaluated.

Diagnostic criteria for primary chronic anal pain syndrome (chronic proctalgia) according to the Rome IV criteria are as follows and must include all of the following: chronic or recurrent rectal pain or aching, episodes last at least thirty minutes and exclusion of other causes of rectal pain such as ischaemia, inflammatory bowel disease, cryptitis, intramuscular abscess and fissure, haemorrhoids, prostatitis, and Coccyx Pain Syndrome. These criteria should be fulfilled for the past three months with symptom onset at least six months before diagnosis [17, 234].

The primary chronic anal pain syndrome includes the above diagnostic criteria and exhibits exquisite tenderness during posterior traction on the puborectalis muscle (previously called “Levator Ani Syndrome”). Pathophysiology of pain is thought to be due to over-activity of the pelvic floor muscles and probably recto-anal incoordination.

Primary intermittent chronic anal pain syndrome (proctalgia fugax) consists of all the following diagnostic criteria, which should be fulfilled for three months: recurrent episodes of pain localised to the anus or lower rectum, episodes last from several seconds to minutes and there is no anorectal pain between episodes. Stressful life events or anxiety may precede the onset of the intermittent chronic anal pain syndrome. The attacks may last from a few seconds to as long as 30 minutes. The pain may be cramping, aching or stabbing and may become unbearable. However, most patients do not report it to their physicians and pain attacks occur less than five times a year in 51% of patients.

4.1.1.5 Peripheral nerve aspects

A proportion of patients will be able to relate the onset of pain to an acute event such as surgery, sepsis or trauma, and occasionally, cycling for a prolonged period. Chronic injury is more frequent, such as associated with sitting for prolonged periods over time. Many will be idiopathic.

The pain is classically perceived in the perineum from anus to clitoris/penis. However, less-specific pain distribution may occur, and this may be due to anatomical variation, involvement of branches of the nerve rather that the main nerve, CNS central sensitisation, and consequently, the involvement of other organs and systems in a regional pain syndrome. Other nerves in the vicinity may also be involved, for example, inferior cluneal nerve and perineal branches of the posterior femoral cutaneous nerve. The musculoskeletal system may become involved, confusing the pain picture as aches and pain developing in the muscles due to immobility and disability, possibly magnified by the CNS changes.

Burning is the most predominant adjective used to describe the pain. Crushing and electric may also be used, indicating the two components - a constant pain often associated with acute sharp episodes. Many patients may have the feeling of a swelling or foreign body in the rectum or perineum, often described as a golf or tennis ball. The term pain has different meanings to patients and some would rather use the term discomfort or numbness.

Aggravating factors include any type of pressure being applied, either directly to the nerve or indirectly to other tissue, resulting in pudendal traction. Allodynia is pain on light touch due to involvement of the CNS, and may make sexual contact and the wearing of clothes difficult. These patients often remain standing, and as a consequence, develop a wide range of other aches and pains. Soft seats are often less well-tolerated, whereas sitting on a toilet seat is said to be much better tolerated. If unilateral, sitting on one buttock is common. The pain may be exacerbated by bowel or bladder evacuation.

Pudendal nerve damage may be associated with a range of sensory phenomena. In the distribution of the nerve itself, as well as unprovoked pain; the patient may have paraesthesia (pins and needles); dysaesthesia (unpleasant sensory perceptions usually but not necessarily secondary to provocation, such as the sensation of running cold water); allodynia (pain on light touch); or hyperalgesia (increased pain perception following a painful stimulus, including hot and cold stimuli). Similar sensory abnormalities may be found outside of the area innervated by the damaged nerve, particularly for visceral and striated muscle hyperalgesia.

The cutaneous sensory dysfunction may be associated with superficial dyspareunia, but also irritation and pain associated with clothes brushing the skin. There may also be a lack of sensation and pain may occur in the presence of numbness. Visceral hypersensitivity may result in an urge to defecate or urinate. This is usually associated with voiding frequency, with small amounts of urine being passed. Pain on visceral filling may occur. Anal pain and loss of motor control may result in poor bowel activity, with constipation and/or incontinence. Ejaculation and orgasm may also be painful or reduced.

Many of those suffering from pudendal neuralgia complain of fatigue and generalised muscle cramps, weakness and pain. Being unable to sit is a major disability, and over time, patients struggle to stand and they often become bedbound. The immobility produces generalised muscle wasting, and minimal activity hurts. As a consequence of the widespread pain and disability, patients often have emotional problems, and in particular, depression. Patients with chronic pelvic pain are also often anxious and have the tendency to catastrophise. Depression, catastrophising and disability are all poor prognostic markers. Cutaneous colour may change due to changes in innervation but also because of neurogenic oedema. The patient may describe the area as swollen due to this oedema, but also due to the lack of afferent perception.

4.1.1.6 Myofascial aspects

When taking a history from a patient with pelvic pain, it is important to address the function of all the organs in the pelvic area. The following items certainly should be addressed: lower urinary tract function, anorectal function, sexual function, gynaecological items, presence of pain and psychosocial aspects. One cannot state that there is a pelvic floor dysfunction based only on the history. But there is a suspicion of pelvic floor muscle dysfunction when two or more pelvic organs show dysfunction, for instance a combination of micturition and defecation problems.

*4.1.2 **Physical Evaluation***

The clinical examination often serves to confirm or refute the initial impressions gained from a good history. The examination should be aimed at specific questions where the outcome of the examination may change management. Prior to an examination, best practice requires the medical practitioner to explain what will happen and what the aims of the examination are to the patient. Consent to the examination should occur during that discussion and should cover an explanation around the aim to maintain modesty as appropriate and, if necessary, why there is a need for rectal and/or vaginal examination. Finally, the risk of exacerbating the pain should form a part of that request. A record of the discussion should be noted. The possibility of the presence of a chaperone should be discussed with the patient. As well as a local examination, a general musculoskeletal and neurological examination should be considered an integral part of the assessment and undertaken. Following the examination, it is good practice to ask the patient if they had any concerns relating to the conduct of the examination and that discussion should be noted.

There is no specific diagnostic test for CPPPS, therefore, procedures are on the one hand directed towards identification and exclusion of specific diseases associated with pelvic pain, and on the other hand may be used for phenotypic description. Abdominal and pelvic examination to exclude gross pelvic pathology, as well as to demonstrate the site of tenderness is essential. It is important to look for abnormalities in muscle function.

Examination of the external genitalia is a part of the evaluation. In patients with scrotal pain, gentle palpation of each component of the scrotum is performed to search for masses and painful spots. The penis and urethra may be palpated in a similar way. Many authors recommend that one should assess cutaneous allodynia along the dermatomes of the abdomen (T11-L1) and the perineum (S3), and the degree of tenderness should be recorded. The bulbocavernosus reflex in the male may also provide useful information concerning the intactness of the pudendal nerves. Clinical pelvic examination should be a single digit examination if possible. The usual bi-manual examination can generate severe pain so the examiner must proceed with caution. A rectal examination is done to look for prostate abnormalities in male patients including pain on palpation and to examine the rectum and the pelvic floor muscles regarding muscle tenderness and trigger points as well as the ability to contract and relax these muscles.

At clinical examination, perianal dermatitis may be found as a sign of faecal incontinence or diarrhoea. Fissures may be easily overlooked and should be searched for thoroughly in patients with anal pain. A rectal digital examination findings may show high or low anal sphincter resting pressure, a tender puborectalis muscle in patients with the Levator Ani Syndrome, and occasionally increased perineal descent. The tenderness during posterior traction on the puborectalis muscle differentiates between Levator Ani Syndrome and unspecified Functional Anorectal Pain and is used in most studies as the main inclusion criterion. Dyssynergic (paradoxical) contraction of the pelvic muscles when instructed to strain during defecation is a frequent finding in patients with pelvic pain. Attention should be paid to anal or rectal prolapse at straining, and ideally during combined rectal and vaginal examination to diagnose pelvic organ prolapse.

A full clinical examination of the musculo-skeletal, nervous and urogenital systems is necessary to aid in diagnosis of pudendal neuralgia, especially to detect signs indicating another pathology. Often, there is little to find in pudendal neuralgia and frequently findings are non-specific. The main pathognomonic features are the signs of nerve injury in the appropriate neurological distribution, for example, allodynia or numbness. Tenderness in response to pressure over the pudendal nerve may aid the clinical diagnosis. This may be elicited by per rectal or per vaginal examination and palpation in the region of the ischial spine and/or Alcock's canal. Muscle tenderness and the presence of trigger points in the muscles may confuse the picture. Trigger points may be present in a range of muscles, both within the pelvis (levator ani and obturator internus muscles) or externally (e.g., the piriformis, adductors, rectus abdominis or paraspinal muscles).

4.2 Supplemental evaluation

If history is suggestive of lower urinary tract, gynaecological, anorectal or other disease of known aetiology, diagnostic work-up should follow respective guidelines.

*4.2.1 **Assessing pelvic pain and related symptoms***

Determination of the severity of pain and associated symptoms, its progression and treatment response can be assessed only by means of a reliable and validated symptom-scoring instrument. These subjective outcome measures are recommended for the basic evaluation and therapeutic monitoring of patients. Pain should always be assessed at presentation and (see below) to identify progression and treatment response. As well as doing this in the clinic, the patient can keep a daily record (pain diary). This may need to include other relevant variables such as voiding, sexual activity, activity levels, or analgesic use.

Increased attention to patient reported outcomes gives prominence to patients' views on their disease and pain diaries, in patients' own environments, improve data quality.

Quality of life should also be measured because it can be very poor compared to other chronic diseases [235, 236]. In a study more pain, pain-contingent rest, and urinary symptoms were associated with greater disability (also measured by self-report), and pain was predicted by depression and by catastrophising (helplessness subscale) [57].

Where the primary outcome of treatment is pain relief, it is useful before starting treatment to agree a clinically useful level of relief [237]. The most reliable methods are:

- a five point verbal scale: none, mild, moderate, severe, very severe pain;
- a VAS score from one to ten;
- an eleven point numerical scale (as below).

Pain assessment ratings are not independent of cognitive and emotional variables [56]. Target outcomes of pain severity, distress and disability co-vary only partly, and improvement in one does not necessarily imply improvement in the others. When the primary outcome is pain its meaning should be anchored in discussion of clinically important difference [237].

Primary prostate pain syndrome

Reliable, valid indices of symptoms and QoL are the NIH-CPSI [238] and the International Prostate Symptom Score (I-PSS) [239].

Primary bladder pain syndrome

Symptom scores may help to assess the patient and act as outcome measures. The O'Leary-Sant Symptom Index, also known as the Interstitial Cystitis Symptom Index (ICSI) was validated in a large study [240].

Gastrointestinal questionnaire

Functional anorectal pain disorders (anorectal pelvic pain) are defined and characterised by duration, frequency, and quality of pain. More complex questionnaires are used in the setting of IBS. The validated IBS Symptom Severity Scale (IBS-SSS) includes the broadest measurement of pain-related aspects [241, 242]. However, as different instruments measure different endpoints of chronic abdominal pain in IBS, a comparison of published studies is often impossible.

Sexual function assessment

In males the most frequent effects on sexual function are ED and premature ejaculation. These can be evaluated by proper questionnaires namely IIEF and PEDT (Premature Ejaculation Diagnostic Tool). In comparison with controls, women with chronic pelvic pain reported significantly more sexual avoidance behaviour, non-sensuality, and complaints of "vaginismus" [196]. The Female Sexual Function Index (FSFI) has been developed as a brief, multi-dimensional self-report instrument for assessing the key dimensions of sexual function in women, which includes desire, subjective arousal, lubrication, orgasm, satisfaction, and pain. The corresponding evidence in men is lacking.

*4.2.2 **Focused myofascial evaluation***

Pelvic floor muscle testing can be done by the medical doctor but a consultation of the pelvic floor by a physiotherapist is a good alternative, but either should have had appropriate training in pelvic assessment. A vaginal or rectal examination is performed to assess the function of the pelvic floor muscles, according to the International Continence Society (ICS) report. This assessment has been tested and shows satisfactory validity and intra-observer reliability. It can therefore be considered suitable for use in clinical practice [243]. Rectal examination is a good way to test the pelvic floor function in men [244]. There is a growing number of reports on the use of ultrasound (US) in establishing the function of the pelvic floor muscles. The exact place in the diagnostic setting needs to be addressed in the future [245]. In a cohort study of 72 men with chronic pelvic pain, the relationship between the locations of the trigger point and the referred pain was examined. Ninety percent of the patients showed tenderness in the puborectalis muscle and 55% in the abdominal wall muscles. Of the patients in whom trigger points were found in the puborectalis, 93% reported pain in the penis and 57% in the suprapubic region. Patients with trigger points in the abdominal muscles reported pain in the penis (74%), perineum (65%) and rectum (46%) [246]. In addition, a broad musculoskeletal (tender point) evaluation, including muscles outside the pelvis, helps to diagnose the myofascial pain aspects of the pelvic pain in phenotyping pelvic pain patients [247, 248].

*4.2.3 **Neurological***

Injections

An injection of local anaesthetic and steroid at the site of nerve injury may be diagnostic. Differential block of the pudendal nerve helps to provide information in relation to the site where the nerve may be trapped [249, 250]. Infiltration at the ischial spine requires the use of a nerve stimulator/locator. Both motor (anal contraction) and sensory endpoints may be noted. The anatomical target may be localised by fluoroscopy, computed tomography (CT) guidance, or the use of US. Ultrasound avoids any form of radiation, whereas CT guidance involves a significant amount of radiation. As well as injecting around the pudendal nerve, specific blocks of other nerves arising from the pelvis may be performed.

Electrophysiological studies

These may reveal signs of perineal denervation, increased pudendal nerve latency, or impaired bulbocavernosus reflex [251, 252]. However, for an abnormality to be detected, significant nerve damage is probably necessary. Pain may be associated with limited nerve damage, therefore, these investigations are often normal.

*4.2.4 **Imaging***

Ancillary studies should be performed according to appropriate guidelines for exclusion of diseases with known aetiology presenting with symptoms identical to those of CPPS. Once the latter diagnosis is established, studies can be useful to assess functional abnormalities and phenotype conditions such as PBPS, and primary chronic anal pain syndrome.

Ultrasound

Ultrasound has limited value but may reassure patients. However, over-investigating may be detrimental.

MRI

Magnetic resonance neurography has been increasingly used in specialised centres for the diagnosis of the location (proximal vs. peripheral) and degree (total vs. partial) of nerve injury in the peripheral nervous system, earlier and with higher specificity than conduction studies. This may show benefits for CPPPS in the coming years.

MR defecating proctogram

Magnetic resonance imaging in conjunction with MR defecography has become the most valuable imaging technique to assess anorectal function dynamically. Magnetic resonance imaging studies simultaneously outline the anatomy of the pelvic floor and visualise different structural and functional pathologies, by applying dynamic sequences after filling of the rectum with a viscous contrast medium (e.g., US gel). The following pathologies can be visualised: pelvic floor descent, an abnormal anorectal angle while squeezing and straining, rectal intussusception, rectocele, enterocele and cystocele. However, limitations of MR defecography are the left lateral or supine position and the limited space for the patient, which may reduce the ability to strain and thereby reduce the sensitivity of the method, underestimating the size of entero- and rectoceles as well as the amount of intussusception.

Functional neuroimaging

Functional neuroimaging, functional magnetic resonance imaging (fMRI) is currently being re-evaluated as a research tool and some groups have raised issues around over interpretation [253]. With regards to pain, fMRI findings may represent a pain matrix or may represent non-specific threat processing [254]. Currently this panel cannot recommend fMRI as a clinical tool [255].

*4.2.5 **Laboratory Tests***

Microbiology tests

Primary prostate pain syndrome

Laboratory diagnosis of prostatitis has been classically based on the four-glass test for bacterial localisation [256]. Besides sterile pre-massage urine (voided bladder urine-2), PPPS shows < 103 cfu/mL of uropathogenic bacteria in expressed prostatic secretions and insignificant numbers of leukocytes or bacterial growth in ejaculates. However, this test is too complex for use by practising urologists. Diagnostic efficiency may be enhanced cost-effectively by a simple screening procedure, that is, the two-glass test or pre-post-massage test (PPMT) [257, 258]. Overall, these tests help only a little in the diagnosis of PPPS, because 8% of patients with suggested PPPS have been found to have positive prostatic localisation cultures, similar to the percentage of asymptomatic men [259].

Primary bladder pain syndrome

Urine dipstick and urine culture (including culture for Tuberculosis if sterile pyuria) are recommended in all patients suspected of having PBPS. Urine cytology is also recommended in risk groups.

Gynaecological aspects of chronic pelvic pain

Vaginal and endocervical swabs to exclude infection are recommended. In specific cases, imaging may be required to help rule out a defined pathology such as sacral neuropathy in endometriosis [260]

*4.2.6 **Invasive tests***

Anorectal pain

Anorectal manometry with sensory testing (pressure volume measurement: barostat) may be useful to diagnose dyssynergic defecation and hypersensitivity of the rectum which are typical for patients with CPPPS and IBS. Anorectal manometry and the ballon expulsion test (BET) may also help to predict the response to biofeefback therapy in Levator Ani Syndrome [119]. Flexible rectosigmoidoscopy or colonoscopy should be considered in patients with anorectal pain to rule out coincidental colorectal pathology.

Laparoscopy for females

Laparoscopy is perhaps the most useful invasive investigation to exclude gynaecological pathology [261, 262] and to assist in the differential diagnosis of CPPPS in women [263, 264]. Often, it is combined with cystoscopy [265, 266] and/or proctoscopy to help identify the site of multi-compartment pain.

Psychological considerations around laparoscopy

Three very different studies of laparoscopy suggest that it can improve pain through resolving concerns about serious disease [267]. Integrating somatic and psychological assessment from the start rather than dealing with psychological concerns only after excluding organic causes of pelvic pain is helpful [268].

Cystoscopy and bladder biopsy

Despite controversy on the diagnostic and follow-up value of cystoscopy in PBPS [269-273] the panel believes that objective findings are important for diagnosis, prognosis and ruling out other treatable conditions (a standardised scheme of diagnostic criteria will also contribute to uniformity and comparability of different studies) [274]. Endoscopically, PBPS type 3 displays reddened mucosal areas often associated with small vessels radiating towards a central scar, sometimes covered by a small clot or fibrin deposit - the Hunner's lesion [232]. The scar ruptures with increasing bladder distension, producing a characteristic waterfall type of bleeding. There is a strong association between PBPS type 3 and reduced bladder capacity under anaesthesia [275]. Non-lesion disease displays a normal bladder mucosa at initial cystoscopy. The development of glomerulations after hydrodistension is considered to be a positive diagnostic sign although they can be observed without PBPS [276]. Biopsies are helpful in establishing or supporting the clinical diagnosis of both classic and non-lesion types of the disease [131, 156, 274, 277, 278]. Important differential diagnoses to exclude, by histological examination, are carcinoma *in situ* and tuberculous cystitis [279].

Table 4: ESSIC classification of PBPS types according to results of cystoscopy with hydrodistension and biopsies [16]

	Cystoscopy with hydrodistension			
	Not done	**Normal**	**Glomerulations[a]**	**Hunner's lesion[b]**
Biopsy				
Not done	XX	1X	2X	3X
Normal	XA	1A	2A	3A
Inconclusive	XB	1B	2B	3B
Positive[c]	XC	1C	2C	3C

[a]*Cystoscopy: glomerulations grade 2-3.*
[b]*Lesion per Fall's definition with/without glomerulations.*
[c]*Histology showing inflammatory infiltrates and/or detrusor mastocytosis and/or granulation tissue and/or intrafascicular fibrosis.*

4.3 Diagnostic algorithm

Figure 1: Diagnosing chronic pelvic pain

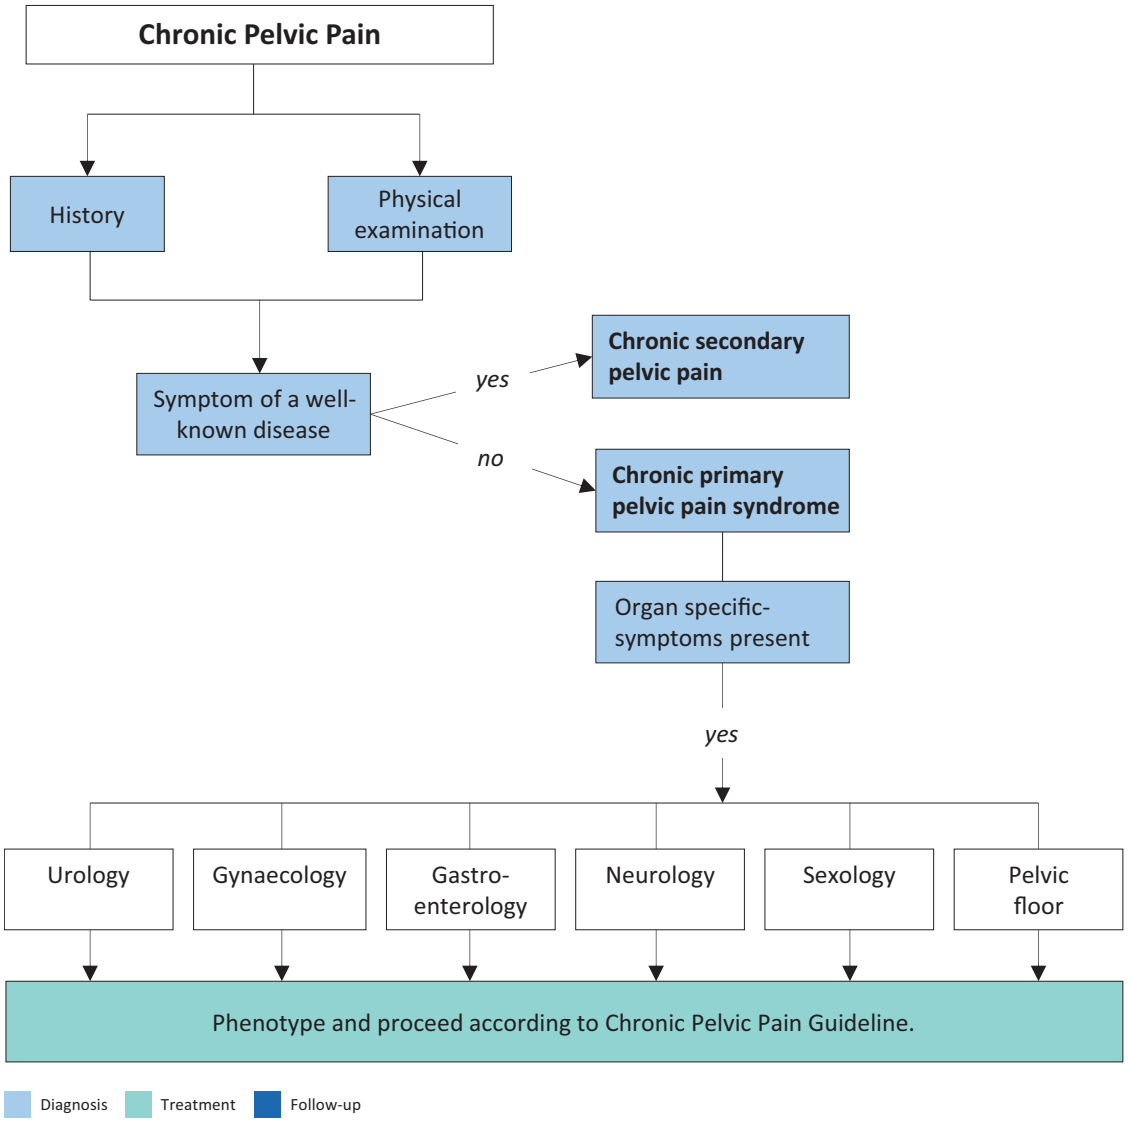

Figure 2: Phenotyping of pelvic pain - UPOINT classification

Phenotyping	Assessment
Urology	Urinary flow, micturition diary, cystoscopy, ultrasound, uroflowmetry.
Psychology	Anxiety about pain, depression and loss of function, history of negative sexual experiences.
Organ specific	Ask for gynaecological, gastro-intestinal, ano-rectal, sexological complaints. Gynaecological examination, rectal examination.
Infection	Semen culture and urine culture, vaginal swab, stool culture.
Neurological	Ask for neurological complaints (sensory loss, dysaesthesia). Neurological testing during physical examination: sensory problems, sacral reflexes and muscular function.
Tender muscle	Palpation of the pelvic floor muscles, the abdominal muscles and the gluteal muscles.
Sexological	Erectile function, ejaculatory function, post-orgasmic pain.

4.4 Other painful conditions without a urological cause

Dysmenorrhoea

Menstrual pain or 'dysmenorrhoea' may be primary or secondary. Primary dysmenorrhoea classically begins at the onset of ovulatory menstrual cycles and tends to decrease following childbirth [263]. Secondary dysmenorrhoea suggests the development of a pathological process, such as endometriosis [262], adenomyosis or pelvic infection, which need to be excluded.

Infection

In pre-menopausal women, a history of Pelvic Inflammatory Disease (PID) must be excluded. A patient's sexual history should be taken along with swabs to exclude chlamydia and gonorrhoea infection. Bacterial and viral genital tract pathogens should also be excluded [280], as they can cause severe pelvic/vaginal/vulvar pain [281] and are associated with ulcerating lesions and inflammation, which may lead to urinary retention [282]. If there is any doubt about the diagnosis, laparoscopy may be helpful, as one of the differential diagnoses is endometriosis.

Endometriosis and adenomyosis

The incidence of endometriosis is rising in the developed world. It has widespread impact on women's lives [283], with pain more important than physical findings in determining QoL [284]. The precise aetiology is unknown, but an association with infertility is recognised [285]. A diagnosis is usually made when a history of secondary dysmenorrhoea and/or dyspareunia exists [286]. On examination, there is often tenderness in the lateral vaginal fornices, reduced uterine mobility, tenderness in the recto-vaginal septum, and on occasion, adnexal masses. Laparoscopy is the most useful diagnostic tool [287]. Adenomyosis is associated with augmented pain during menses [288]. It is diagnosed by an US scan of the uterus, which often shows cystic dilatation of the myometrium [289].

Gynaecological malignancy

The spread of gynaecological malignancy of the cervix, uterine body or ovary will cause pelvic pain depending on the site of spread.

Injuries related to childbirth

Trauma occurring at the time of childbirth may lead to chronic pelvic pain related to the site of injury [290]. Female sexual dysfunction is perhaps the commonest presenting problem [291], though increasingly women are reporting other symptoms such as pelvic girdle pain and other genito-pelvic pain of different aetiology [292]. There is often a transient problem with oestrogen deficiency in the post-partum period and during breastfeeding, which can compound this situation. Denervation of the pelvic floor can similarly compound the situation [293].

Pain associated with pelvic organ prolapse and prolapse surgery
Pelvic organ prolapse is often asymptomatic, unless it is so marked that it causes back pain, vaginal pain and skin excoriation [294]. Prolapse is often a disease of older women, and it is often associated with post-menopausal oestrogen deficiency, which may lead to pain associated with intercourse. Prolapse surgery has entailed the use of non-absorbable mesh (usually in the form of "mesh kits"). Although they may have a role in supporting the vagina, they are also associated with several complications including bladder, bowel and vaginal trauma [295], chronic pain [296] and neuropathy [297]. Patients need to be fully evaluated and may need specialised imaging, using contrast mediums if necessary, to make a diagnosis of the possible cause of the pain [298-301].

Haemorrhoids
Chronic pelvic pain is rare in haemorrhoidal disease because endoscopic and surgical treatment is mostly effective in acute disease. The most frequent aetiology of pain without significant bleeding is thrombosed external haemorrhoids or an anal fissure. Haemorrhoidal pain on defecation associated with bleeding is usually due to prolapse or ulceration of internal haemorrhoids. Anaemia from haemorrhoidal bleeding is rare but may arise in patients on anti-coagulation therapy, or those with clotting disorders.

Anal fissure
Anal fissures are tears in the distal anal canal and induce pain during and after defecation. The pain can last for several minutes to hours. Persistence of symptoms beyond six weeks or visible transversal anal sphincter fibres define chronicity. Fissures located off the midline are often associated with specific diseases such as Crohn's disease or anal cancer. Internal anal sphincter spasms and ischaemia are associated with chronic fissures.

Proctitis
Abdominal and pelvic pain in patients with inflammatory bowel disease and proctitis are often difficult to interpret. Faecal calprotectin may help to differentiate between inflammation and functional pain, to spare steroids.

Irritable bowel syndrome
Although IBS can be associated with pelvic pain, the panel consider a full discussion of this topic beyond the scope of these guidelines. A number of high quality clinical guidelines address this topic [234, 302].

4.5 Summary of evidence and recommendations: diagnostic evaluation

4.5.1 Diagnostic evaluation - general

Summary of evidence	LE
Clinical history and examination are mandatory when making a diagnosis.	2a

Recommendation	Strength rating
Take a full history and evaluate to rule out a treatable cause in all patients with chronic pelvic pain.	Strong

4.5.2 Diagnostic evaluation of primary prostate pain syndrome

Summary of evidence	LE
Primary prostate pain syndrome is associated with negative cognitive, behavioural, sexual, or emotional consequences, as well as with symptoms suggestive of LUT and sexual dysfunction.	2b
Primary prostate pain syndrome has no known single aetiology.	3
Pain in PPPS involves mechanisms of neuroplasticity and neuropathic pain.	2a
Primary prostate pain syndrome has a high impact on QoL.	2b
Depression and catastrophic thinking are associated with more pain and poorer adjustment.	3
The prevalence of PPPS-like symptoms is high in population-based studies (> 2%).	2b
Reliable instruments assessing symptom severity as well as phenotypic differences exist.	2b

Recommendations	Strength rating
Adapt diagnostic procedures to the patient. Exclude specific diseases with similar symptoms.	Strong
Use a validated symptom and quality of life scoring instrument, such as the National Institutes of Health Chronic Prostatitis Symptom Index, for initial assessment and follow-up.	Strong
Assess primary prostate pain syndrome-associated negative cognitive, behavioural, sexual, or emotional consequences, as well as symptoms of lower urinary tract and sexual dysfunctions.	Strong

4.5.3 Diagnostic evaluation of primary bladder pain syndrome

Summary of evidence	LE
Primary bladder pain syndrome has no known single aetiology.	3
Pain in PBPS does not correlate with bladder cystoscopic or histologic findings.	2a
Primary bladder pain syndrome Type 3 C can only be confirmed by cystoscopy and histology.	2a
Lesion/non-lesion disease ratios of PBPS are highly variable between studies.	2a
The prevalence of PBPS-like symptoms is high in population-based studies.	2a
Primary bladder pain syndrome occurs at a level higher than chance with other pain syndromes.	2a
Primary bladder pain syndrome has an adverse impact on QoL.	2a
Reliable instruments assessing symptom severity as well as phenotypical differences exist.	2a

Recommendations	Strength rating
Perform general anaesthetic rigid cystoscopy in patients with bladder pain to subtype and rule out confusable disease.	Strong
Diagnose patients with symptoms according to the EAU definition, after primary exclusion of specific diseases, with primary bladder pain syndrome (PBPS) by subtype and phenotype.	Strong
Assess PBPS-associated non-bladder diseases systematically.	Strong
Assess PBPS-associated negative cognitive, behavioural, sexual, or emotional consequences.	Strong
Use a validated symptom and quality of life scoring instrument for initial assessment and follow-up.	Strong

4.5.4 Diagnostic evaluation of scrotal pain syndrome

Summary of evidence	LE
The nerves in the spermatic cord play an important role in scrotal pain.	2b
Ultrasound of the scrotal contents does not aid in diagnosis or treatment of scrotal pain.	2b
Post-vasectomy pain is seen in a substantial number of men undergoing vasectomy.	2b
Scrotal pain is more often noticed after laparoscopic than after open inguinal hernia repair.	1b

4.5.5 Diagnostic evaluation of urethral pain syndrome

Summary of evidence	LE
Primary urethral pain syndrome may be a part of BPS.	2a
Urethral pain involves mechanisms of neuroplasticity and neuropathic pain.	2b

4.5.6 Diagnostic evaluation of gynaecological aspects chronic pelvic pain

Summary of evidence	LE
Laparoscopy is well-tolerated and does not appear to have negative psychological effects.	1b

Recommendations	Strength rating
Take a full uro-gynaecological history in those who have had a continence or prolapse non-absorbable mesh inserted and consider specialised imaging of the mesh.	Strong
Refer to a gynaecologist following complete urological evaluation if there is a clinical suspicion of a gynaecological cause for pain. Laparoscopy should be undertaken in accordance with gynaecological guidelines.	Strong

4.5.7 Diagnostic evaluation of anorectal pain syndrome

Summary of evidence	LE
Tenderness on traction is the main criterion of the chronic anal pain syndrome.	1a

Recommendation	Strength rating
Anorectal function tests are recommended in patients with anorectal pain.	Strong

4.5.8 Diagnostic evaluation of nerves to the pelvis

Summary of evidence	LE
Multiple sensory and functional disorders within the region of the pelvis/urogenital system may occur as a result of injury to one or more of many nerves. The anatomy is complex.	2
There is no single aetiology for the nerve damage and the symptoms and signs may be few or multiple.	1
Investigations are often normal.	2
The peripheral nerve pain syndromes are frequently associated with negative cognitive, behavioural, sexual, or emotional consequences.	1

Recommendations	Strength rating
Rule out confusable diseases, such as neoplastic disease, infection, trauma and spinal pathology.	Strong
If a peripheral nerve pain syndrome is suspected, refer early to an expert in the field, working within a multidisciplinary team environment.	Weak
Imaging and neurophysiology help diagnosis but image and nerve locator guided local anaesthetic injection is preferable.	Weak

4.5.9 Diagnostic evaluation of sexological aspects in chronic pelvic pain

Summary of evidence	LE
Chronic pain can lead to decline in sexual activity and satisfaction and may reduce relationship satisfaction.	2a
Men who reported having sexual, physical or emotional abuse show a higher rate of reporting symptoms of CPPPS.	2b
Sexual dysfunctions are prevalent in men with PPPS.	2b
In men with PPPS the most prevalent sexual complaints are ED and ejaculatory dysfunction.	3
In females with CPPPS all sexual function domains are lower. The most reported dysfunctions are sexual avoidance, dyspareunia and “vaginismus”.	2a
Vulvar pain syndrome is associated with PBPS.	2a
Women with PBPS suffer significantly more from fear of pain, dyspareunia and decreased desire.	2a
Pelvic floor muscle function is involved in the excitement and orgasm phases of sexual response.	3
Chronic pain can cause disturbances in each of the sexual response cycle phases.	2b

Recommendation	Strength rating
Screen patients presenting with symptoms suggestive for chronic primary pelvic pain syndrome for abuse, without suggesting a causal relation with the pain.	Weak

4.5.10 Diagnostic evaluation of psychological aspects of chronic pelvic pain

Summary of evidence	LE
There is no evidence that distress generates complaints of pelvic pain, or that multiple symptoms suggest unreality of pain.	2b
Current or recent sexual abuse are possible contributory factors in pelvic pain.	2a

Recommendations	Strength rating
Assess patient psychological factors related to the pain, e.g. pain-related fear, anxiety and depressive symptoms.	Strong
Ask patients what they think is the cause of their pain and other symptoms to allow the opportunity to inform and reassure.	Strong

4.5.11 Diagnostic evaluation of pelvic floor function

Summary of evidence	LE
The ICS classification is suitable for clinical practice.	2a
Over-activity of the pelvic floor muscles is related to chronic pelvic pain, prostate, bladder and vulvar pain.	2a
Over-activity of the pelvic floor muscles is an input to the CNS causing central sensitisation.	2b
There is no accepted standard for diagnosing myofascial trigger points.	2a
There is a relation between the location of trigger point and the region where the pain is perceived.	3

Recommendations	Strength rating
Use the International Continence Society classification on pelvic floor muscle function and dysfunction.	Strong
In patients with Chronic Primary Pelvic Pain Syndrome it is recommended to actively look for the presence of myofascial trigger points.	Weak

5. MANAGEMENT

The philosophy for the management of chronic pelvic pain is based on a bio-psychosocial model. This is a holistic approach with patients' active involvement. Single interventions rarely work in isolation and need to be considered within a broader personalised management strategy, including self-management. Pharmacological and non-pharmacological interventions should be considered with a clear understanding of the potential outcomes and endpoints. These may well include: psychology, physiotherapy, drugs and more invasive interventions.

Treatment philosophy

Providing information that is personalised and responsive to the patient's problems, conveying belief and concern, is a powerful way to allay anxiety [303]. Additional written information or direction to reliable sources of information is useful; practitioners tend to rely on locally produced material or pharmaceutical products of variable quality while endorsing the need for independent materials for patients [304].

5.1 Conservative management

5.1.1 Pain education

It is always valuable to include education about the causes of pain, including eliciting from patients their anxieties about undiscovered pathology and addressing them. Information improves adherence to treatment and underpins self-management, as shown in bladder pain syndrome and in many other painful and nonpainful disorders [305].

5.1.2 Physical therapy

The physiotherapist is part of the pain management team; (including doctors, psychologists and nurses). The therapeutic options for physiotherapists may not be the same in every country. Physiotherapists can either specifically treat the pathology of the pelvic floor muscles, or more generally treat myofascial pain if it is part of the pelvic pain syndrome. In most studies that have been done looking at the effect of physiotherapy in pelvic pain, the treatment of the pelvic floor is only part of the pain management. In a review about physiotherapy in women with pelvic pain, it was concluded that recommendations for physiotherapy should be given with caution [306]. The review found six RCTs, of which three showed level 1b evidence with low-risk of bias. One of these three found that Mensendieck somatocognitive therapy showed a pain reduction after one year follow-up of 64%. This approach consists of myofascial relaxation and tension, improving posture and movement in combination with cognitive behaviour therapy (CBT) [307].

Pelvic floor muscle pain

Treating pelvic floor over-activity and myofascial trigger points should be considered in the management of chronic pelvic pain. Treatment should be done by specialised physiotherapists who are trained not only in the musculoskeletal aspects of pain, but also in the psychological mechanisms and the role of the CNS in chronic pain.

For patients with chronic pelvic pain and dysfunction of the pelvic floor muscles, it is very helpful to learn how to relax the muscles when the pain starts. By doing this, the circle of pain-spasm-pain can be interrupted. In the case of shortened muscles, relaxation alone is not enough. Stretching of the muscle is mandatory to regain length and function. Studies on physical therapy for pelvic floor pain syndrome have been sparse. A single blinded RCT with myofascial physical therapy and general body massage was carried out in patients with prostate or bladder pain. The global response rate (RR) to treatment with massage was significantly better in the prostate than in the bladder pain group (57% vs. 21%). In the prostate pain group, there was no difference between the two treatment arms. In the bladder pain group, myofascial treatment did significantly better than massage. Massage only improved complaints in the prostate pain group. The fact that gender distribution was different in each group is mentioned as a possible confounding factor [308]. In an RCT of 84 patients with PPPS comparing so-called conventional therapy (α-blockers, anti-inflammatory drugs and sitz baths) with biofeedback and pelvic floor muscle relaxation therapy, the authors were able to demonstrate an improvement in both groups after three months, but three months after the end of treatment, the effects only persisted in the biofeedback and pelvic floor muscle relaxation therapy patients [309].

Myofascial trigger point release

Treatment of myofascial trigger points can be done by manual therapy, dry needling and wet needling. The evidence for all the different treatments is weak, with most studies showing no significant difference between these techniques, though most studies were small and heterogeneous with regards to the patients and methods. There is no evidence that manual techniques are more effective than no treatment [310]. Most studies of dry needling have compared with wet needling. Different SRs have come to the conclusion that, although there is an effect of needling on pain, it is neither supported nor refuted that this effect is better than placebo [311].

Physiotherapy in PBPS

Transvaginal manual therapy of the pelvic floor musculature (Thiele massage) in PBPS patients with high-tone dysfunction of the pelvic floor significantly improved several assessment scales [312]. The role of specific levator ani trigger point injections in women with chronic pelvic pain has been studied [313]. Each trigger point was identified by intravaginal palpation and injected with bupivacaine, lidocaine and triamcinolone. Seventy-two percent of women improved with the first trigger point injection, with 33% being completely pain-free. Efficacy and safety of pelvic floor myofascial physical therapy has been compared with global therapeutic massage in women with PBPS; global response assessment (GRA) rate was 59% and 26%, respectively. Pain, urgency and frequency ratings, and symptoms decreased in both groups during follow-up, and did not differ significantly between the groups. This suggests that myofascial physical therapy is beneficial in women with PBPS [314].

Primary Anal Pain Syndrome

An RCT demonstrated that biofeedback treatment was superior to electrogalvanic stimulation and massage of the Levator muscle for treating chronic primary anal pain syndrome [119]. One hundred and fifty-seven patients who had at least weekly rectal pain were investigated, but only patients with tenderness on traction of the pelvic floor showed a significant treatment benefit. In patients with tenderness of the puborectalis muscle (Rome II: "Highly likely Levator Ani Syndrome"), 87% reported adequate relief after one month of biofeedback vs. 45% for electrogalvanic stimulation, and 22% for massage. These results were maintained at twelve months with adequate relief after nine sessions of biofeedback in 58% of the whole group (Rome II: "Highly likely" and "Possible Levator Ani Syndrome"), after galvanic stimulation in 27% and massage in 21% of patients. As previously described in dyssynergic defecation, the ability to expel a 50 mL water filled balloon and to relax pelvic floor muscles after biofeedback treatment were predictive of a favourable therapeutic outcome [119]. The pathophysiology of the chronic primary anal pain syndrome is therefore similar to that of dyssynergic defecation, and this favours the role of the pelvic floor muscles in the pathophysiology of both conditions. Other treatment modalities have been less successful.

Treatment of sexual dysfunctions and chronic pelvic pain

Couples often benefit from early referral for relationship and sexual counselling during their treatment course [315]. It needs to be remembered that sexual difficulties will arise as a result of pelvic pain syndromes as well as those disorders potentially being primary. Specific behavioural strategies for women who have urogenital complaints and female sexual dysfunction often include exploring alternatives to sexual intercourse (manual or oral pleasuring), different coital positions (female superior or side lying), and pacing, such as limiting the activity to less than that which causes pain. Planning for the time of intercourse is important, and scheduling a clinic visit after intercourse might be useful to identify specific sites and causes of post-coital flares. The corresponding evidence in men is lacking, but similar principles would apply. Other behavioural changes involve pre- and post-coital voiding, application of ice packs to the genital or suprapubic area [315, 316], and increased use of vaginal dilators, fingers or sex toys. Lubricants can also be used and women with signs of vulvovaginal atrophy may benefit from oestrogen cream [317]. Optimising the pelvic floor muscle is indicated when dysfunction is present and will relieve the pain [318-320].

Other physical therapy interventions

Electromagnetic therapy. A small, sham-controlled, double-blind study of four weeks showed a significant, sustained effect over a one-year period for CPPPS [321].

Microwave thermotherapy. In uncontrolled studies significant symptomatic improvement has been reported from heat therapy, for example, transrectal and transurethral thermotherapy [322, 323].

Extracorporeal shockwave therapy. A small sham-controlled double-blind study of four times weekly perineal extracorporeal shockwave therapy (n=30) in men with CPPPS showed significant improvement in pain, QoL, and voiding compared to the control group (n=30), over twelve weeks [324]. Two other randomised sham-controlled studies, have been published more recently, one comparing ten treatment sessions over two weeks (n=40 vs. n=40) [325], another with four times weekly treatments (n=20 vs. n=20) [326]. Both concluded there was a significant effect in terms of total NIH-CPSI score and pain at twelve weeks. Unfortunately, no long term effects at 24 weeks could be shown in a published follow-up study of the second [327]. A Cochrane review of non-pharmacological interventions for chronic pelvic pain reported a reduction in symptoms following treatment compared with control and concluded that extracorporeal shockwave therapy may improve symptoms without an increase in adverse events [328]. In addition, a recent SR and meta-analysis concluded that extracorporeal shockwave therapy is effective for the improvement of pain and quality of life, but longterm efficacy was non-significant [329]. Publications show a potential role for external shock wave lithotripsy applied to the bladder. In an RCT enrolling 54 patients, improvement in the VAS > 3 was 57.1% vs. 19.0% (ESWT vs. placebo; P =.011), at 12 weeks post treatment. However, the primary endpoint did not reach significance [330].

Acupuncture. An RCT comparing acupuncture (n=50) vs. shamcontrolled (n=50), once weekly treatment for six weeks showed significant long lasting improvement at 24 weeks in terms of RR and overall symptom scores [331]. Another RCT showed a significant effect for a follow-up of 32 weeks [332]. Two SRs and meta-analyses were published in 2016 analysing seven RCTs on a total of 471 participants comparing acupuncture to sham control or oral medical treatment [333, 334]. Both came to the conclusion that acupuncture was effective and safe, significantly reducing total NIH-CPSI scores compared to sham or medical treatment, and should be considered as a treatment option. This is in line with the conclusion of a Cochrane review [328] on non-pharmacological treatment options. In a large multicentre RCT comparing acupuncture (N=220) with sham acupuncture (N=220) in patients with PPPS over a period of 8 weeks (20 sessions), the authors could show a superior improvement of symptoms in the acupuncture group with durable effects 24 weeks after treatment [335]. In a more recently published SR and meta-analysis of only high quality trials (JADAD score >=4), the authors concluded that acupuncture compared to sham acupuncture was superior in terms of pain score, NIH-

CPSI score, quality of life score, urinary symptom, and efficacy rate [336].
Posterior tibial nerve stimulation. See section 5.3.2, Neuromodulation.
Transcutaneous electrical nerve stimulation. See section 5.3.2, Neuromodulation.

5.1.3 Psychological therapy

Psychological interventions may be directed at pain itself or at adjustment to pain in terms of function and mood and reduced health-care use, with or without pain reduction. Ideally, treatment follows general principles and practice in the field of chronic pain [337, 338] but these have been neglected in pelvic pain. Three SRs and meta-analyses of the few heterogeneous trials of psychologically based treatment for pelvic pain [339-341] found benefits for pain comparable to those from pharmacotherapy over a few months, but this was not sustained at follow-up. Exposure to pain-related fears in women with chronic pelvic pain proved superior to manual therapy in reducing those fears and overall pain disability, albeit assessed only by self-report [342]. The importance of multi-disciplinary treatment is emphasised by several reviews [44, 343, 344] of intervention for diverse chronic pains, but standard multi-component psychologically-based programmes for pelvic pains are mostly in the pilot stages [345], with mixed findings so far [346]. For primary focal vulvar pain syndrome, multimodal physiotherapy integrating psychological components has shown beneficial effects, although more research on the effects of psychological therapy and multi-component psychologically-based programmes is needed in this patient group [347]. For less disabled and distressed patients treatment can be delivered remotely [348, 349].

5.1.4 Dietary treatment

Scientific data are limited and dietary restriction alone does not produce significant symptomatic relief; however, consider the involvement of a dietician.

5.2 Pharmacological management

5.2.1 Drugs for chronic primary pelvic pain syndrome

In this section the evidence available for specific CPPPSs is presented. Where there is no evidence the reader is directed to the section on analgesics below (Section 5.2.2) where more generic use is discussed. There is a large discrepancy in the treatment effects reported in case series and controlled trials that results from a large placebo effect or publication bias. As a result of the multifactorial origin of for example PPPS, one reason for treatment failure in some large placebo-controlled RCTs, may be the heterogeneity of the patient population [350]. One strategy for improving treatment effects may be stratification of patient phenotypes. A prospective series of phenotypically directed treatment for CPPPS has shown significant improvement of symptoms and QoL [351]. Monotherapeutic strategies for the treatment of CPPPS may fail [352], therefore, most patients require multimodal treatment aimed at the main symptoms, and taking comorbidity into account. In the past ten years, results from RCTs have led to advances in standard and novel treatment options.

5.2.1.1 Mechanisms of action

Mechanisms of action are discussed as appropriate under the drugs headings below.

5.2.1.2 Comparisons of agents used in pelvic pain syndromes

Primary Prostate Pain Syndrome (PPPS)

Anti-inflammatory drugs

For non-steroidal anti-inflammatory agents (NSAIDs), a trial with celecoxib reported that the pain sub-score, QoL sub-score, and total NIH-CPSI score were in favour of the treatment arm vs. placebo, but effects were limited to the duration of therapy [353]. In a meta-analysis, two studies of NSAIDs [259, 353] and one with prednisolone [354] were pooled. Anti-inflammatory drugs were 80% more likely to have a favourable response than placebo. In an updated network meta-analysis with more restrictive inclusion criteria regarding documented outcome measures but a wider spectrum of drugs (including glycosaminoglycans, phytotherapy and tanezumab), a significant effect on total NIH-CPSI scores and treatment response rates could be demonstrated. A Cochrane SR from 2019 concluded that anti-inflammatories may reduce prostatitis symptoms compared to placebo [355]. Overall, a moderate treatment effect has been shown for anti-inflammatory drugs, but larger studies are needed for confirmation, and long-term side-effects have to be taken into account.

α-blockers

Positive results from RCTs of α-blockers, i.e. terazosin [356, 357], alfuzosin [358], doxazosin [359, 360], tamsulosin [361, 362], and silodosin [363] have led to widespread use of α-antagonists in the treatment of PPPS in recent years. Whereas one SR and meta-analysis has not reported a relevant effect of α-blockers due to study heterogeneity [364], another network meta-analysis of α-blockers [363] has shown significant improvement in total symptoms, pain, voiding, and QoL scores. In addition, they had a higher rate of favourable response compared to placebo [relative risk (RR): 1.4; 95% CI: 1.1-1.8, p=0.013]. However, treatment responsiveness, i.e., clinically perceptive or significant improvement, may be lower than expected from the change in mean symptom scores. Overall, α-blockers seem to have moderate but significant beneficial effects. This probably is not the case for long-standing PPPS patients [365]. A Cochrane Systematic review published in 2019 reported an uncertain treatment effect of α-blockers on "prostatitis" symptoms, and little to no difference in sexual dysfunction, quality of life, anxiety and depression [355]. Future studies should show if longer duration of therapy or some sort of phenotypically directed (e.g., patients with PPPS and relevant voiding dysfunction) treatment strategies will improve treatment outcomes.

Antibiotic therapy

Empirical antibiotic therapy is widely used because some patients have improved with antimicrobial therapy. Patients responding to antibiotics should be maintained on medication for four to six weeks or even longer. Unfortunately, culture, leukocyte and antibody status of prostate-specific specimens do not predict antibiotic response in patients with PPS [366], and prostate biopsy culture findings do not differ from those of healthy controls [367]. The only placebo-controlled RCTs of sufficient quality have been done for oral antibiotic treatment with ciprofloxacin (six weeks) [368], levofloxacin (six weeks) [369], and tetracycline hydrochloride (twelve weeks) [370]. The studies have been analysed in meta-analyses [363, 371]. Although direct meta-analysis has not shown significant differences in outcome measures, network meta-analysis has suggested significant effects in decreasing total symptom, pain, voiding, and QoL scores compared with placebo. Combination therapy of antibiotics with α-blockers has shown even better outcomes in network meta-analysis. Despite significant improvement in symptom scores, antibiotic therapy did not lead to statistically significant higher response rates [371]. In addition, the sample sizes of the studies were relatively small and treatment effects only modest, mostly below clinical significance. It may be speculated that patients profiting from treatment had some unrecognised uropathogens. A Cochrane SR reported that antibiotics may reduce "prostatitis" symptoms compared to placebo [355]. If antibiotics are used, other therapeutic options should be offered after one unsuccessful course of a quinolone or tetracycline antibiotic over six weeks. In addition, it is very important that unnecessary antibiotic use is avoided and local resistance patterns are considered. In this regard, the relevant recommendations of the EAU Guidelines on Urological Infections should be followed [372].

5-α-reductase inhibitors

Although a few small pilot studies with 5-α-reductase inhibitors supported the view that finasteride may improve voiding and pain, the first RCT published in a peer-reviewed journal did not support this, although the study lacked power [373]. In another RCT, finasteride provided better amelioration of symptoms compared to saw palmetto over a one-year period, but lacked a placebo-control arm [374]. A six-month placebo-controlled study showed a non-significant tendency towards better outcome in favour of finasteride, possibly because of a lack of statistical power [362]. A Cochrane review concluded that finasteride probably reduces prostatitis symptoms compared to placebo [355]. The NIH-CPSI scores decreased significantly in a subgroup of men enrolled in a prostate cancer risk reduction study treated with dutasteride compared to placebo [363]. Patients (n=427, age 50 to 75, with elevated prostate-specific antigen [PSA]) were included if they had significant "prostatitis like" symptoms at baseline. Based on the evidence, 5-α-reductase inhibitors cannot be recommended for use in PPPS in general, but symptom scores may be reduced in a restricted group of older men with an elevated PSA [363].

Phytotherapy

Phytotherapy applies scientific research to the practice of herbal medicine. An adequately powered placebocontrolled RCT of a pollen extract (Cernilton) showed clinically significant symptom improvement over a twelve week period in inflammatory PPPS patients (NIH Cat. IIIA) [375]. The effect was mainly based on a significant effect on pain. Another pollen extract (DEPROX 500) has been shown to significantly improve total symptoms, pain and QoL compared to ibuprofen [376]. In an RCT of patients treated with pollen extract suppositories (n=70) vs. oral ibupofen (n=71) over a period of ten days, the authors could find a clinically significant effect up to six months of follow-up including fewer adverse events in the pollen extract group [377]. A SR and meta-analysis of pollen extract for the treatment of PPPS showed significant improvement in overall QoL [378]. As an adjunct to α-blocker therapy, cernitin pollen extract proved superior to tadalafil in terms of pelvic pain and discomfort [379]. Quercetin, a polyphenolic bioflavonoid with documented antioxidant and anti-inflammatory properties, improved NIH-CPSI scores significantly in a small RCT [380]. In a large multicentre

trial of 221 patients over twelve weeks, saw palmetto extract (Serenoa repens) led to statistically significant improvement in the NIH-CPSI total score and sub-scores compared to placebo [381]. In a SR and meta-analysis, patients treated with phytotherapy were found to have significantly lower pain scores than those treated with placebo [363]. In addition, overall RR in network meta-analysis was in favour of phytotherapy (RR: 1.6; 95% CI: 1.1-1.6).

Pregabalin is an anti-epileptic drug that has been approved for use in neuropathic pain. In an adequately powered placebo-controlled RCT, which was the only report included in a published Cochrane review [382], a six-week course of pregabalin (n=218) compared to placebo (n=106) did not result in a significant reduction of NIH-CPSI total score [383]. This group thinks it may have a role in selected patients and should be used in accordance with the paragraph 5.2.22

Pentosane polysulphate is a semi-synthetic drug manufactured from beech-wood hemicellulose. One study using oral high-dose (3 x 300 mg/day) demonstrated a significant improvement in clinical global assessment and QoL over placebo in men with PPPS, suggesting a possible common aetiology [384].

Muscle relaxants (diazepam, baclofen) are claimed to be helpful in sphincter dysfunction or pelvic floor/perineal muscle spasm, but there have been few prospective clinical trials to support these claims. In one RCT, a triple combination of a muscle relaxant (thiocolchicoside), an anti-inflammatory drug (ibuprofen) and an α-blocker (doxazosin) was effective in treatment-naïve patients, but not superior to an α-blocker alone [360].

Botulinum toxin type A (BTX-A) for the treatment of CPPPS is an off-label use, but a recent SR identified two RCTs and one non-randomised comparative study assessing intraprostatic BTX-A injections (100-200 units) for treatment of PPPS [385]. All three papers used the NIH-CPSI to score pain. Although two of the studies reported a statistically significant reduction in pain, incomplete data and differences in dose and study methodology precluded calculation of a summary effect estimate for BTX-A-related improvement in pain. No definitive conclusions could be drawn from the review.

Zafirlukast, a leukotriene antagonist, and prednisone in two low-power placebo-controlled studies failed to show a benefit [354, 386]. More recently, a placebo-controlled phase II a study of tanezumab, a humanised monoclonal antibody that specifically inhibits the pain mediating neurotrophin, nerve growth factor, failed to demonstrate significant effect [387] and should only be used in clinical trials.

Allopurinol
There is insufficient evidence for the use of allopurinol in PPPS [388, 389].

Primary Bladder Pain Syndrome (PBPS)

Treatments of significant value for PBPS

Anti-histamines
Mast cells may play a role in PBPS. Histamine is one of the substances released by mast cells. Histamine receptor antagonists have been used to block the H1 and H2 receptor subtypes, with variable results. A prospective placebo-controlled RCT of hydroxyzine or oral pentosane polysulphate did not show a significant effect [390].

Amitriptyline
Amitriptyline is a tricyclic antidepressant. Several reports have indicated improvement of PBPS symptoms after oral amitriptyline. Amitriptyline has been shown to be beneficial when compared with placebo plus behavioural modification [391]. Drowsiness is a limiting factor with amitriptyline, nortriptyline is sometimes considered instead.

Pentosane polysulphate
Pentosan polysulphate is a semi-synthetic drug manufactured from beech-wood hemicellulose. Subjective improvement of pain, urgency, frequency, but not nocturia, has been reported [392, 393]. Pentosane polysulphate had a more favourable effect in PBPS type 3 C than in non-lesion disease [394]. Response was not dose dependent but related more to treatment duration. At 32 weeks, about half the patients responded. Combination therapy showed a RR of 40% compared to 13% with placebo. For patients with an initial minor response to pentosane polysulphate, additional subcutaneous heparin was helpful [395, 396].

Immunosuppressants
Azathioprine treatment has resulted in disappearance of pain and urinary frequency [397]. Initial evaluation of methotrexate [398] showed good analgesic effect but limited efficacy for urgency and frequency. Corticosteroids are not recommended in the management of patients with PBPS because of a lack of evidence.

Intravesical Treatments
Intravesical drugs are administered due to poor oral bio-availability establishing high drug concentrations within the bladder, with few systemic side-effects. Disadvantages include the need for intermittent catheterisation which can be painful in PBPS patients, cost and risk of infection.

- **Local anaesthetics**

There are sporadic reports of successful treatment of PBPS with intravesical lidocaine [399, 400]. Alkalisation of lidocaine improves its pharmacokinetics [401]. Combination of heparin, lidocaine and sodium bicarbonate gave immediate symptom relief in 94% of patients and sustained relief after two weeks in 80% [402]. Intravesical instillation of alkalised lidocaine or placebo for five consecutive days resulted in significantly sustained symptom relief for up to one month [403].

- **Hyaluronic acid and chondroitin sulphate**

These are described to repair defects in the GAG layer. Despite the fact that intravesical GAG replenishment has been in use for about twenty years for PBPS/IC, most of the studies are uncontrolled and with a small number of patients. Based on the studies available there are differences by virtue of substance classes, whether they are natural GAG layer components, dosage formulations, or concentrations. An RCT seems to reinforce the case for GAG layer replenishment, however it lacks a placebo arm [404]. A meta-analysis confirms usefulness of GAG layer replenishment [412]. However, most retrieved studies are non-randomised and with scarce numbers.

- **Intravesical heparin**

Primary bladder pain syndrome patients were treated with heparin for three months, and over half had control of symptoms, with continued improvement after one year of therapy [405]. Intravesical heparin plus peripheral neuromodulation in patients with refractory PBPS was studied and it was shown that voiding frequency, pain score and maximum cystometric capacity were significantly better after two and twelve months [406].

- **Hyperbaric oxygen**

This has a moderate effect on a small subgroup of PBPS patients. Disadvantages include high cost, limited availability of treatment sites, and time-consuming treatment [395].

<u>Treatments of limited value for PBPS</u>

Cimetidine
There are limited data to suggest that cimetidine improves symptoms of PBPS in the short-term. Compared with placebo for three months, cimetidine significantly improved symptom scores, pain and nocturia, although the bladder mucosa showed no histological changes in either group [407].

Prostaglandins
Misoprostol is a prostaglandin that regulates various immunological cascades. After three months of treatment with misoprostol, fourteen out of 25 patients had significantly improved, with twelve showing a sustained response after a further six months [408]. The incidence of adverse drug effects was 64%.

L-Arginine
Oral treatment with the nitric oxide (NO) synthase substrate L-arginine was suggested to decrease PBPS-related symptoms. However, no symptomatic relief or change in NO production could be shown after treatment [409, 410].

Oxybutynin is an anti-cholinergic drug used in overactive detrusor dysfunction. Intravesical oxybutynin combined with bladder training improves functional bladder capacity, volume at first sensation, and cystometric bladder capacity [411]. However, an effect on pain has not been reported.

Duloxetine (a serotonin-noradrenaline re-uptake inhibitor antidepressant with a licence for the management of neuropathic pain) did not significantly improve symptoms of PBPS [412]. Administration was safe. Based on these preliminary data, duloxetine cannot be recommended for treatment of PBPS.

PDE5 inhibitors are drugs currently used for erectile dysfunction. In different RCT improved all parameters evaluated at twelve weeks, but at 24 weeks results were not consistent for pain VAS score [413]. Using a PDE5i, theoretically, the activation of C fiber is decreased, bladder afferent activity is reduced and detrusor muscle tone relaxes.

Primary Scrotal Pain Syndrome (PSPS)

Treatment of primary scrotal pain syndrome is based on the principles of treating chronic pain syndromes, as described throughout these guidelines.

In men with pain post inguinal hernia repair, there is limited evidence from case series showing that neurectomy of the damaged nerves can lead to symptomatic benefit [185, 414].

For scrotal pain post vasectomy, affected men may find that reversal of vasectomy can cure symptoms especially in those in whom patency is achieved [415]. In a prospective RCT, pulsed radio-frequency to the ilioinguinal and genitofemoral nerves is associated with high rates of symptomatic improvement (80%) but follow up was limited to three months [416]. The evidence for epididymectomy is poor but if considered, is less likely to provide benefit if the epididymis has a normal sonographic appearance [417].

Chronic gynaecological pain

It is difficult to compare the wide variation of drugs from an efficacy and safety perspective as they have such diverse uses/indications. In those gynaecological patients where chronic pelvic pain is unrelated to any of the well-defined conditions, it is often difficult to determine a therapeutic pathway other than a multidisciplinary chronic abdomino-pelvic pain management plan. A Cochrane review suggests there may be some evidence (moderate) supporting the use of progestogens [340]. Though efficacious, physicians need to be knowledgeable of progestogenic side effects (e.g., weight gain, bloatedness - the most common adverse effects) which can stop some patients from accepting such medication. Gonadotropin-releasing hormone (GnRH), such as goserelin, are also thought to help such pain. However, when compared with progestogens, their efficacy remains limited. The quality of evidence is generally low and drawn from single studies [340]. Gonadotropin-releasing hormone on the other hand binds to specific receptors on pituitary gonadotrophs, leading to desensitisation and consequently to suppressed gonadotropin secretion. By contrast, GnRH antagonists compete with GnRH for receptors thus gonadotrophin secretion, which may be beneficial in certain clinical applications, such as reducing the size of fibroids, endometrial bleeding and endometriosis [418].

Pelvic Floor, Abdominal and Chronic Anal Pain

Botulinum toxin type A (pelvic floor)

Pelvic floor muscle over-activity plays a role in CPPPS. Botulinum toxin type A, as a muscle relaxant, can be used to reduce the resting pressure of the pelvic floor muscles and injection of the puborectalis and pubococcygeus muscles has been used to treat spasm of the levator ani A pilot study of twelve women with pelvic floor muscle overactivity as defined by a vaginal resting pressure > 40 cm H2O on vaginal manometry reported a reduction in resting pressure with improvement in dyspareunia and dysmenorrhoea, but no significant changes in non-menstrual pelvic pain scores [419]. A SR including three RCTs comparing BTX-A with saline injections into the pelvic floor found no benefit in pain scores at six months follow-up despite a reduction in pelvic floor pressure [385].

Botulinum toxin type A has been injected into trigger points. It is more expensive than lidocaine and has not been proven to be more effective [420]. Reviews do not support the injection of BTX-A into trigger points [421].

Botulinum toxin type A can also be injected at the sphincter level to improve urination or defecation. Relaxation of the urethral sphincter alleviates bladder problems and secondarily the spasm. In a cohort study of thirteen patients with CPPPS, BTX-A was injected into the external urethral sphincter. Subjectively, eleven patients reported a substantial change in pain symptoms, from a score of 7.2 to 1.6 on a VAS [422].

Intermittent chronic primary anal pain syndrome

Due to the short duration of the episodes, medical treatment and prevention is often not feasible. Inhaled β-2 adrenergic agonist salbutamol was effective in an RCT in patients with frequent symptoms and shortened pain duration [423]. Other treatment options are topic diltiazem and BTX-A [424]. However, there is still some controversy regarding the duration of pain of intermittent chronic and chronic primary anal pain syndrome. Randomised controlled trials often use different definitions, extending the pain duration (with a shift to chronic pain) in order to include more patients and to better evaluate the study-drug action.

Abdominal pain associated with Irritable Bowel Syndrome

Linaclotide, a minimally absorbed peptide guanylate cyclase-C agonist at a dose of 290 µg once daily significantly improved abdominal pain (48.9% vs. 34.5% placebo-treated) and bowel symptoms associated with IBS with constipation over 26 weeks of treatment [425]. Diarrhoea was the most common adverse event in patients treated with linaclotide (4.5%). Although it is known to overlap with IBS pelvic pain, effect on the latter was not assessed in this study.

In a Cochrane Meta-analysis antispasmodics had a beneficial effect for improvement of abdominal pain compared to placebo (58% improved on antispasmodic compared to 46% on placebo) in IBS [426]. Peppermint oil showed in a meta-analysis of nine RCT's improvement in abdominal pain in patients with IBS [427].

*5.2.2 **Analgesics***

If the use of simple analgesics fails to provide adequate benefit, then consider using neuropathic agents, and if there is no improvement, consider involving a specialist pain management centre with an interest in pelvic pain. Chronic pelvic pain is well defined and involves multiple mechanisms as described in previous sections.

The management requires a holistic approach with biological, psychological and social components. Few studies have specifically looked at medications used in CPPPS [428], therefore, a wider look at the literature has been undertaken and further specific research is required. The agents concerned are divided for ease of description. Combinations often provide a greater benefit than individual agents [429]. They may also allow lower individual dosages and thus minimise side-effects. The aim of using these drugs is to allow patients to improve their QoL. This is best measured by assessing their function as well as pain severity. If the use of these agents does not allow this, then they should be withdrawn. Unfortunately, the failure of one agent does not exclude potential benefit of an alternative. If the benefit is limited by side-effects, then the lowest effective dose should be found (by dose titration). Sometimes, patients will prefer a higher level of pain and have fewer side effects.

5.2.2.1 Mechanisms of action

Mechanisms of action are discussed as appropriate under the drug headings below.

5.2.2.2 Comparisons within and between groups in terms of efficacy and safety

Paracetamol (acetaminophen)

Paracetamol is a well-tolerated analgesic in a class of its own. This is an antipyretic analgesic with a central mechanism of action [430]. It is often available over the counter without prescription. A review questions its routine use as a first-line analgesic based on inadequate evidence of efficacy in many pain conditions including dysmenorrhoea [431]. It will not be effective for all patients and individual responses should be reviewed when deciding on longer term use.

Non-steroidal anti-inflammatory agents

These agents are anti-inflammatory, antipyretic analgesics that act by inhibiting the enzyme cyclooxygenase (COX). They have a peripheral effect, hence their use in conditions involving peripheral or inflammatory mechanisms. They are commonly used for pelvic pain; many are available over the counter and are usually well-tolerated. There is insufficient evidence to suggest one NSAID over another for pelvic pain. Guidelines for use of NSAIDs and COX-2 selective agents have been developed. They have more side-effects than paracetamol, including indigestion, headaches and drowsiness.

The evidence for their benefit in chronic pelvic pain is weak or non-existent and is often limited by side-effects. For pelvic pain in which inflammatory processes are considered important, such as dysmenorrhoea [432], NSAIDs are more effective than placebo and paracetamol, but with a higher incidence of side-effects. For pelvic pain in which central mechanisms may be incriminated, such as endometriosis [433] then the evidence is lacking for NSAIDs despite their common use.

At a practical level, if NSAIDs are considered for use, they should be tried (having regard for the cautions and contraindications) and the patient reviewed for improvement in function as well as analgesia. If this is not achieved, or side-effects are limiting, then they should be withdrawn.

Neuromodulators

These agents are not simple analgesics but used to modulate neuropathic or centrally mediated pain. There are several classes commonly used with recognised benefits in pain medicine. They are taken on a regular basis and all have side-effects that may limit their use and have the potential to be dependence-forming. In the UK, NICE has reviewed the pharmacological management of neuropathic pain [434]. The evidence for treatment of CPPPS is lacking but is present for other painful conditions. For this chapter, most of the evidence is from non-pelvic pain sources. The general method for using these agents is by titrating the dose against benefit and side-effects. The aim is for patients to have an improvement in their QoL, which is often best assessed by alterations in their function. It is common to use these agents in combination but studies comparing different agents against each other, or in combination, are lacking. Some of these agents are also used for specific conditions. Early identification of neuropathic pain with a simple questionnaire could facilitate targeted therapy with neuromodulators [58].

Antidepressants

Tricyclic antidepressants

The tricyclic antidepressants (TCAs) have multiple mechanisms of action and are frequently limited by their side-effects. Tricyclic antidepressants have a long history of use in pain medicine and have been subjected to a Cochrane review [435], suggesting that they are effective for neuropathic pain. Amitriptyline is the most commonly used at doses from 10-75 mg/day (sometimes rising to 150 mg/day). This is titrated against benefit or side-effects and should be taken at night [434]. Nortriptyline and imipramine are used as alternatives.

Other Antidepressants

Duloxetine is a SNRI antidepressant licensed for use in depression, SUI and neuropathic pain. There is evidence of benefit in diabetic neuropathy and fibromyalgia at a dose of 60 mg/day [436, 437]. Side-effects are common and may result in its discontinuation.

Anticonvulsants

Anticonvulsants are commonly used in the management of neuropathic pain. There are general studies and some looking more particularly at pelvic pain. Individual agents have been systematically reviewed. Their use is suggested in the NICE Neuropathic Pain Guidelines [434].

Carbamazepine has a long history of use in neuropathic pain. Evidence exists for its benefit [438]. Trials trend to be of short duration, showing only moderate benefit. There are side-effects; some of which may be serious. It is no longer a first choice agent. Other anticonvulsant agents are available with fewer serious side-effects.

Gabapentinoids

There is a growing awareness and evidence of the risk for dependence and misuse of gabapentinoids [439]. A formal assessment of efficacy against benefit and side-effects (both pain and QoL) is required with the patient in order to determine the lowest effective dose and if longer-term treatment is to be used.

Gabapentin is commonly used for neuropathic pain and has been systematically reviewed [440, 441]. This demonstrates good evidence for postherpetic neuralgia and diabetic neuropathy but evidence for other neuropathies is limited. A double-blind RCT looking at CPPPS in women with no obvious pathology demonstrated no benefits but higher levels of side effect [441].

Pregabalin is a commonly used neuromodulator with good evidence of efficacy in some neuropathic conditions [442]. The dose for benefit is in the range of 300-600 mg/day. Evidence for central neuropathic pains is inadequate. Some patients do gain moderate to significant benefit but most will gain no benefit and then the drug should be discontinued. Other agents can be used in the management of neuropathic pain but they are best administered by specialists in the management of pain whom are familiar with their use. They tend to be considered after the standard options have been exhausted. As with all good pain management, they are used as part of a comprehensive multi-dimensional management plan.

Opioids

Over recent years opioids have been used extensively for managing chronic non-cancer pain. There is increasing evidence that their role is limited in this population, but may be beneficial for a small number of patients at a low dose in a managed setting [443]. There is clear evidence of harm and significant professional, public and political interest. Their use is beneficial for both acute pain and for cancer pain management particularly towards the end of life.

Often patients will stop taking oral opioids due to side effects or insufficient analgesic effect [444]. There is clear evidence of harm including effects on the endocrine and immune systems as well as a growing understanding of opioid-induced hyperalgesia [445]. There is limited guidance on the best method for tapering the dose of opioids with the aim of stopping or finding the lowest effective dose [446].

Opioids should only be used in conjunction with a management plan with consultation between clinicians experienced in their use. It is suggested that a pain management unit should be involved along with the patient and their primary care physician. Ensure there are arrangements for formal monitoring, follow-up and review. If opioids are used and the pain remains, then they are not working and should be stopped even if there is no alternative [445].

The risk of harm increases substantially at doses above 120 mg/day morphine equivalence [445] and guidance suggests regular (at least annual) review for patients with over 50 mg/day morphine equivalence and pain specialist involvement above 90 mg/day morphine equivalence [447].

There are well-established guidelines for the use of opioids in pain management as well as considering the potential risks [445, 447]. Opioid reduction and optimisation should be undertaken where opioids are not providing clear measurable benefit. There is also information available online for patients [445]. Opioids Aware is a web-based resource for patients and healthcare professionals, jointly produced by the Faculty of Pain Medicine of Royal College of Anaesthetists and Public Health England, to support prescribing of opioid medicines for pain. https://fpm.ac.uk/opioids-aware.

Cannabinoids

There has been increasing interest and changes in national regulations regarding the use of cannabinoids for medicinal use. Regarding pain the evidence base for the use of cannabinoids is weak [448-450] and further well conducted clinical trials are necessary. This is an area where further guidance and research is likely in the coming years.

5.3 Further management

5.3.1 ***Nerve blocks***

Nerve blocks for pain management are usually carried out by specialists in pain medicine as part of a broader management plan [451]. They may have a diagnostic or therapeutic role. Textbooks have been written on the subject and practitioners using them should be trained in appropriate patient selection, indications, risks and benefits. Many such interventions also require understanding and expertise in using imaging techniques to perform the blocks accurately. Diagnostic blocks can be difficult to interpret due to the complex mechanisms underlying the painful condition or syndrome. Sustained but limited benefit may lead to more permanent procedures (e.g., radiofrequency procedures). There is a weak evidence base for these interventions for chronic non-malignant pain [452].

Pudendal Neuralgia

The role of injections may be divided into two. First, an injection of local anaesthetic with or without steroids at the sight of nerve injury or nerve entrapment may produce a therapeutic action [453, 454]. The second possible benefit is diagnostic. It has already been indicated that when the pudendal nerve is injured there are several sites where this may occur. Differential block of the pudendal nerve helps to provide information in relation to the site where the nerve may be trapped [250, 455-457].

Infiltration at the ischial spine requires the use of a nerve stimulator/locator. Both motor (anal contraction) and sensory endpoints may be noted. The anatomical endpoint may be localised by fluoroscopy, CT guidance, or the use of US, the latter avoids any radiation, whereas CT guidance involves a significant amount of radiation. Fluoroscopy and ultrasound guidance imaging are the most frequently used techniques for performing nerve block because it is readily available to most anaesthetists. Pulsed radio frequency lesioning for pudendal neuralgia is being developed with a paper demonstrating potential benefit. Follow-up is short term and further research is required to better elucidate its place in management [458].

5.3.2 ***Neuromodulation***

The role of neuromodulation in the management of pelvic pain should only be considered by specialists in pelvic pain management. These techniques are used as part of a broader management plan and require regular follow-up. The research base is developing and the techniques broadening (e.g., spinal cord stimulation, sacral root stimulation, dorsal root ganglion stimulation or peripheral nerve stimulation). These are expensive interventional techniques for patients refractory to other therapies. Neuromodulation is still finding its role in pelvic pain

management. There has been growing evidence but more detailed, high quality research is required [459]. Its role in overactive bladder (OAB) and faecal incontinence is more robust but is limited for pain. Two SRs have evaluated neuromodulation techniques for CPPS [460, 461]. Both studies concluded that neuromodulation may be effective in reducing pain and improving QoL in patients with CPPS; however, studies were of a low quality and long-term results were needed.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) is a non-invasive technique used in many pain conditions. A SR identified twelve studies of TENS in chronic pelvic pain conditions including four RCTs [460]. All RCTs demonstrated a significant reduction in pain following twelve weeks of treatment for pain conditions including dysmenorrhoea and CPPPS. Pain was also found to improve following TENS for provoked vestibular pain. There was conflicting data with regard to improvement of QoL following TENS; where validated questionnaires were used, no significant improvement was found, whereas in trialist-defined studies, an improvement was seen in TENS for dysmenorrhea and CPPPS. The beneficial effects of a course of TENS may be sustained; one study demonstrating a persistent benefit at 43 months in 73% of men with CPPPS and another demonstrating a prolonged significant improvement in women with provoked vestibular pain at ten months post-treatment. Where reported there were no adverse events recorded. Transcutaneous electrical nerve stimulation could offer an effective non-invasive treatment option for patients with CPPPS.

Percutaneous Tibial Nerve Stimulation

Percutaneous tibial nerve stimulation (PTNS) is a minimally invasive technique that can be use in an outpatient setting. Two SRs have shown that PTNS is effective in reducing pain in patients with CPPPS [460, 461]. Three RCTs identified showed a significant improvement in pain scores and QoL as measured by validated questionnaires. Where recorded, adverse events were rare and minor including temporary slight pain at application site and haematoma.

Sacral Nerve Stimulation

Sacral nerve stimulation (SNS) is an invasive technique requiring sedation or general anaesthesia for implantation of a device following trial stimulation. A SR review identified ten studies of SNS in CPPPS, either retrospective case series or prospective cohort studies and no RCTs. Where reported, a mean of 69% of participants progressed to implantation of device following test stimulation (range 52-91%). All studies reported an improvement in pain, statistically significant in five studies. Quality of Life was measured in three studies and a significant improvement demonstrated in two of three studies. There was a large variation in adverse events reported ranging from 0-50%. Complications not requiring surgical intervention included pain, failure of device, wound infection and seroma. Re-operation rate ranged between 11-50% for complications including lead migration, systemic infection, intrathecal implantation, loss of efficacy and erosion. In clinical practice, a patient should be appropriately counselled regarding the need for a period of trial stimulation and whilst there may be an improvement in symptoms, this should be weighed against a notable complication rate.

A SR review in 2018 identified fourteen studies. In all, 403 patients had undergone percutaneous nerve evaluation and/or SNM stage 1 and 54.8%) had progressed to the permanent implantation stage, which is similar to that reported previously. The cause of pain was reported to be IC/BPS in 170 cases (42.2%). Visual Analogue Scale pain scores were available pre- and post-SNM in 210 patients and overall improvement in pain scores was significant. Sacral nerve stimulation is a promising treatment option for refractory chronic pelvic pain. This is mainly supported by level 2b studies. Randomised prospective studies are warranted to compare SNS vs. other modalities for chronic pelvic pain treatment. Further studies are needed to compare antegrade vs. retrograde approaches [462].

Other neuromodulation techniques

A variety of other techniques of neuromodulation for patients with CPPPS were identified by SRs [460, 463]. These techniques include intravaginal electrical stimulation for women with CPPPS, pudendal nerve stimulation for CPPPS, spinal cord stimulation for pudendal neuralgia, transcutaneous interferential electrical stimulation for IBS, electrical acupuncture for dysmenorrhoea and electrical stimulation/biofeedback and electromagnetic stimulation for men with CPPPS. Whilst an improvement in pain has been reported in these studies, it is noted that they are largely of low quality and further work is needed in this area to enable robust clinical recommendations to be made. Neuromodulation in combination with hormonal treatment in deep endometriosis may have some benefit [464].

*5.3.3 **Surgery***

Primary Bladder Pain Syndrome (PBPS)

Bladder distension
Although bladder hydrodistension is a common treatment for PBPS, the scientific justification is scarce. It can be part of the diagnostic evaluation, but has limited therapeutic role [465].

Hydrodistension and Botulinum toxin type A
Botulinum toxin type A may have an anti-nociceptive effect on bladder afferent pathways, producing symptomatic and urodynamic improvements [466]. Treatment with hydrodistension and hydrodistension plus intravesical BTX-A has been compared [467]. There was symptomatic improvement in all patients. However, in the hydrodistension-only group, 70% returned to their previous symptoms after one month, while in the BTX-A-treated patients, VAS score and functional and cystometric bladder capacity improved at three months. Botulinum toxin type A trigonal-only injection seems effective and long-lasting as 87% of patients reported improvement after three months follow-up [468]. Over 50% reported continued benefit nine months after the first treatment. When re-treatment was needed, similar results were obtained. Up to 59% of patients remain responders after 9 treatments. The sustained duration of the effect, despite the increase in the number of procedures, suggests that intratrigonal sensory neurons do not develop tolerance to OnaBotA, even during long periods of administration [469]. Adverse effects of BTX-A administration for IC/PBPS were significantly less than for OAB syndrome, namely in increased postvoid residual volumes and decreased voiding efficiency [470]. Recent RCTs have reported benefits and long efficacy of BTX-A administration [471-474], but a summary estimate for overall change in pain following BTX-A injections was not possible in a recent SR [385]. Conflicting data on results hinders issuance of a clear guideline for the use of Botox in PBPS phenetypes [475].

Results of treatment with intravesical plasma rich (PRP) injections are also being explored. A recent prospective trial, showed that patients with GRA (global response assessment) > 2, had success rates at one month and at three months after the fourth PRP injection, of 70.6% and 76.7%, respectively. The VAS pain score, frequency, and nocturia showed a significant decrease (all $p < 0.05$). However, further studies are needed to validate findings [476].

Transurethral resection, coagulation and laser ablation
Endourological destruction of bladder tissue aims to eliminate urothelial Hunner lesions. Coagulation of glomerulations or petequiae area is not recommended. Since the 1970s, resection and fulguration have been reported to achieve symptom relief, often for more than three years [477-479]. Repeated resection or fulguration treatments should be wisely indicated. A more recent study has shown no difference in therapeutic benefit between transurethral laser ablation or resection [479].

Major Surgery for PBPS [480]
Primary bladder pain syndrome is a benign condition that can severely impact quality of life but does not shorten life expectancy. Consequently major operative procedures are ranked last in the therapeutic algorithm and are only appropriate as a last resort for patients with severe refractory disease. The level of evidence underpinning reconstructive surgery is weak with no consensus regarding the optimal surgical approach. A systematic review with 450 patients (90% female, median age 54.5 years) from 20 eligible studies reported symptomatic improvement in 77.2% of patients with an overall complication rate of 26.5% and a mortality of 1.3% [480]. This complication rate is likely to be an underestimate as a third of the procedures did not specify their complication data. All the studies included the systematic review were retrospective and observational with no control groups. There was also heterogeneity in the diagnostic criteria and outcome measures used. The main surgical options performed comprised:

1. Urinary diversion without cystectomy is performed to minimise the duration and complexity of surgery and preserve sexual function and fertility, but complications related to the retained bladder commonly occur with the incidence of pyocystis reported to range between 3.3% and 67%.

2. Subtotal (supratrigonal) cystectomy with substitution cystoplasty is the preferred reconstructive approach particularly in younger patients [481] and the use of various intestinal segments has been reported [482-484].

3. Total (subtrigonal) cystectomy and orthotopic neobladder formation has the benefit of removing the trigone as a possible disease site, but requires ureteric re-implantation. Trigonal disease is reported in 50% of patients and surgical failure has been blamed on the trigone being left in place [485], especially in patients with non-lesion type disease [486, 487]. Incomplete emptying of the orthotopic bladder augmentation is most likely to occur following trigonal resection so intermittent self-catheterisation may be required [488]. A study on female sexuality after cystectomy and orthotopic ileal neobladder showed pain relief in all patients and improvement in sexual function items in women who remained sexually active [489]. Pregnancies with subsequent lower-segment Caesarean section have been reported after ileocystoplasty [490].

4. Cystectomy and ileal conduit formation avoids the increased surgical complexity of a continent urinary diversion and is the favoured approach in patients with significantly impaired renal function. The technique is considered for patients with PBPS who develop recurrent pain in the augmented bladder, continent pouch after enterocystoplasty or continent urinary diversion. Re-tubularisation of a previously used bowel segment to form a urinary conduit has been recommended [491].

Complete removal of the bladder is more likely to lead to symptom improvement compared with leaving part (subtotal cystectomy) or the whole bladder *in situ* [480]. In keeping with this, reports that un-resected PBPS bladders cease to induce symptoms after loss of contact with urine are limited [100, 492].

Major surgery should be preceded by thorough pre-operative evaluation, with an emphasis on determining the relevant disease location and subtype. If major surgery is being considered the patient should be referred to a specialist centre experienced in managing CPPPS with a multi-disciplinary team approach.

Primary Prostate Pain Syndrome

There is no evidence for surgical management, including transurethral incision of the bladder neck, radical transurethral resection of the prostate or, in particular, radical prostatectomy in the management of chronic pain in patients with PPPS. A large Chinese RCT of circumcision combined with a triple oral therapy (ciprofloxacin, ibuprofen, tamsulosin) vs. oral therapy alone has been published for patients with PPPS (total n=774) [493]. It is hypothesised that there may be some immunological interaction via pathogenic antigen presenting cells in the foreskin with CD4+ T cells causing auto-immunity to the prostate gland. They reported an improvement in total NIH-CPSI score and subdomain scores at twelve weeks. However, despite a large cohort, the study results are questionable because of the weak theoretical background, and a potential large placebo effect lacking a sham control. In addition, no long-term effectiveness has been reported. Before having an impact on recommendations, the results of this study have to be independently confirmed and the treatment effect must persist.

Primary Testicular Pain Syndrome

Microsurgical denervation of the spermatic cord can be offered to patients with testicular pain. In a long-term follow-up study, patients who had a positive result on blocking the spermatic cord were found to have a good result following denervation [494, 495].

Chronic Primary Anal and Abdominal Pain Syndrome

Chronic primary anal pain syndrome after stapled procedures, such as hemorrhoidopexy or stapled transanal rectal resection may respond to excision of the scarred staple line as shown in 21 consecutive patients with an overall improvement of pain in 85.7% of patients undergoing scar excision surgery [496]. An early scar excision before three to six months after pain onset was associated with better pain relief. Adhesiolysis is still in discussion in the pain management after laparotomy/laparoscopy for different surgical indications in the pelvis and entire abdomen. An RCT has shown, that adhesiolysis is associated with an increased risk of operative complications, and additional operations and increased health care costs as compared to laparoscopy alone [497].

Primary Urethral Pain Syndrome

There is no specific treatment that can be advised. Management should be multi-disciplinary and multi-modal [498]. Laser therapy of the trigonal region may be a specific treatment. One trial comparing two forms of laser reported good results, but did not compare with sham treatment [499]. The majority of publications on treatment of primary urethral pain syndrome have come from psychologists [500, 501].

Presumed intra-abdominal adhesions

In gynaeocological patients with CPPPS and presumed adhesions, there is no consensus as to whether adhesiolysis should be performed to improve pain [501].

Extensive surgery for endometriosis is challenging and is still considered to be controversial, as there is at least one RCT showing no benefit in pain relief after the removal of early extensive endometriosis vs. sham surgery [262, 502]. Increasingly treatment algorithms are being developed using a multi-disciplinary approach, although none have thus far been proven clinically [503]. In patients with adenomyosis, the only curative surgery is hysterectomy but patients can benefit from hormonal therapy and analgesics (see Section 5.2.2).

Pudendal neuralgia and surgery

Decompression of an entrapped or injured nerve is a routine approach and probably should apply to the pudendal nerve as it applies to all other nerves. There are several approaches and the approach of choice probably depends upon the nature of the pathology. The most traditional approach is transgluteal; however, a transperineal approach may be an alternative, particularly if the nerve damage is thought to be related to previous pelvic surgery [250, 504-508]. Currently, there has been only one prospective RCT (transgluteal approach) [507]. This study suggests that, if the patient has had the pain for less than six years, 66% of patients will see some improvement with surgery (vs. 40% if the pain has been present for more than six years). Surgery is not the answer for all patients. On talking to patients that have undergone surgery, providing the diagnosis was clear-cut, most patients were grateful to have undergone surgery but many still have symptoms that need management.

Chronic Pelvic Pain and Prolapse/Incontinence Mesh

Removing an existing mesh is a complex procedure [509]. Each patient is approached on an individual basis depending on the type of mesh and extent of complications [510]. The complexity of surgery often involves removal of dense scar tissue, reformation of inflamed vaginal skin and surgical reconstruction of the urethra and bladder [511]. Such surgery requires specialist skills, best provided within a multi-disciplinary tertiary setting. Possible complications as a result of this surgical removal include bleeding, infection, damage to surrounding organs as well as LUTS, persistent chronic pain and recurrent SUI, which occurs after mesh removal [512].

Removal of mesh, whilst complex, does have beneficial outcomes generally, which are also durable particularly for chronic pain [513]. However, the long-term consequences after the mesh is removed still can include, not only chronic persistent pain but also autoimmune responses and complex neuropathies affecting the pelvis and lower limbs [514, 515]. Some of these can be treated effectively using a multi-disciplinary pain medicine approach [516]. In other cases, the residual symptoms may require the input of an immunologist, rheumatologist or other symptom-defined specialist. The alternative to continence and prolapse mesh surgery is dependent on the clinical findings at the time. They include behavioural change, physiotherapy (for SUI and Grade I-II uterovaginal prolapse) or traditional surgical techniques. Studies have shown that over 70% who committed to physiotherapy for SUI often did not need any further intervention [517]. Many clinicians are reverting to conservative measures first, before re-considering surgery. Clinicians are also now retraining in traditional continence surgical techniques, which existed in the pre-mesh era, such as the Burch colposuspension and autologous fascial sling; as well as traditional utero-vaginal prolapse techniques such as vaginal hysterectomy, sacrospinous fixation and fascial repair of vaginal wall prolapse.

5.4 Summary of evidence and recommendations: management

*5.4.1 **Management of primary prostate pain syndrome***

Summary of evidence	**LE**
Phenotypically directed treatment may improve treatment success.	3
α-blockers have moderate treatment effect regarding total pain, voiding, and QoL scores in PPPS.	1a
Antimicrobial therapy has a moderate effect on total pain, voiding, and QoL scores in PPPS.	1a
Non-steroidal anti-inflammatory drugs have moderate overall treatment effects on PPPS.	1a
Phytotherapy has some beneficial effect on pain and overall favourable treatment response in PPPS.	1a
Pentosane polysulphate improves global assessment and QoL score in PPPS.	1b
There are insufficient data on the effectiveness of muscle relaxants in PPPS.	2b
Pregabalin is not effective for the treatment of PPPS.	1b

Botulinum toxin type A injection into the pelvic floor (or prostate) may have a modest effect in PPPS.	2b
Acupuncture is superior to sham acupuncture in improving symptoms and QoL.	1a
Posterior tibial nerve stimulation is probably effective for the treatment of PPPS.	1b
Extracorporeal shock wave therapy is probably effective over the short term.	1b
There are insufficient data supporting the use of other surgical treatments, such as transurethral incision of the bladder neck, transurethral resection of the prostate, or radical prostatectomy in patients with PPPS.	3
Cognitive behavioural therapy designed for PPPS may improve pain and QoL.	3

Recommendations	**Strength rating**
Offer multimodal and phenotypically directed treatment options for Primary Prostate Pain Syndrome (PPPS).	Weak
Use antimicrobial therapy (quinolones or tetracyclines) over a minimum of six weeks in treatment-naïve patients with a duration of PPPS less than one year.	Strong
Use α-blockers for patients with a duration of PPPS less than one year.	Strong
Offer high-dose oral pentosane polysulphate in PPPS.	Weak
Offer acupuncture in PPPS.	Strong
Offer non-steroidal anti-inflammatory drugs in PPPS, but long-term side-effects have to be considered.	Weak

5.4.2 Management of primary bladder pain syndrome

Summary of evidence	**LE**
There is insufficient data for the long-term use of corticosteroids.	3
Limited data exist on effectiveness of cimetidine in PBPS.	2b
Amitriptyline is effective for pain and related symptoms of PBPS.	1b
Oral pentosane polysulphate is effective for pain and related symptoms of PBPS.	1a
Oral pentosane polysulphate plus subcutaneous heparin is effective for pain and related symptoms of PBPS, especially in initially low responders to pentosane polysulphate alone.	1b
Intravesical lidocaine plus sodium bicarbonate is effective in the short term.	1b
Intravesical pentosane polysulphate is effective, based on limited data, and may enhance oral treatment.	1b
There are limited data on the effectiveness of intravesical heparin.	3
Intravesical chondroitin sulphate may be effective.	2b
There is insufficient data for the use of bladder distension as a therapeutic intervention.	3
Hydrodistension plus BTX-A is superior to hydrodistension alone.	1b
Intravesical BCG is not effective in PBPS.	1b
Transurethral resection (coagulation and laser) may be effective in PBPS type 3 C.	3
Sacral neuromodulation may be effective in PBPS.	3
Pudendal nerve stimulation is superior to sacral neuromodulation for treatment of PBPS.	1b
Avoidance of certain foods and drink may reduce symptoms.	3
Outcome of cystectomy for PBPS is variable.	3

Recommendations	**Strength rating**
Offer subtype and phenotype-oriented therapy for the treatment of Primary Bladder Pain Syndrome (PBPS).	Strong
Always consider offering multimodal behavioural, physical and psychological techniques alongside oral or invasive treatments of PBPS.	Strong
Offer dietary advice.	Weak
Administer amitriptyline for treatment of PBPS.	Strong

Offer oral pentosane polysulphate for the treatment of PBPS.	Strong
Offer oral pentosane polysulphate plus subcutaneous heparin in low responders to pentosane polysulphate alone.	Weak
Do not recommend oral corticosteroids for long-term treatment.	Strong
Offer intravesical hyaluronic acid or chondroitin sulphate before more invasive measures.	Weak
Offer intravesical lidocaine plus sodium bicarbonate prior to more invasive methods.	Weak
Offer intravesical heparin before more invasive measures alone or in combination treatment.	Weak
Do not use bladder distension alone as a treatment of PBPS.	Weak
Consider submucosal bladder wall and trigonal injection of botulinum toxin type A plus hydrodistension if intravesical instillation therapies have failed.	Strong
Offer neuromodulation before more invasive interventions.	Weak
Only undertake ablative and/or reconstructive surgery as the last resort and only by experienced and PBPS-knowledgeable surgeons, following a multi-disciplinary assessment including pain management.	Strong
Offer transurethral resection (or coagulation or laser) of bladder lesions, but in PBPS type 3 C only.	Strong

*5.4.3 **Management of scrotal pain syndrome***

Summary of evidence	**LE**
Microsurgical denervation of the spermatic cord is an effective therapy for primary scrotal pain syndrome.	2b
Vasovasostomy is effective in post-vasectomy pain.	2b

Recommendations	**Strength rating**
Inform about the risk of post-vasectomy pain when counselling patients planned for vasectomy.	Strong
Do open instead of laparoscopic inguinal hernia repair, to reduce the risk of scrotal pain.	Strong
In patients with testicular pain improving after spermatic block, offer microsurgical denervation of the spermatic cord.	Weak

*5.4.4 **Management of primary urethral pain syndrome***

Summary of evidence	**LE**
There is no specific treatment for primary urethral pain syndrome.	4

*5.4.5 **Management of gynaecological aspects of chronic pelvic pain***

Summary of evidence	**LE**
Therapeutic options, including pharmacotherapy and surgery, can treat endometriosis effectively.	1b
Psychological treatment (CBT or supportive psychotherapy) can improve pain and sexual and emotional function in vaginal and vulvar pain syndrome.	1b
Most gynaecological pain conditions (including dysmenorrhea, post-mesh insertion and gynaecological malignancy) can be treated effectively using pharmacotherapy.	3
All other gynaecological conditions (including obstetric injury, pelvic organ prolapse) can be treated effectively using surgery.	2

Recommendations	Strength rating
Involve a gynaecologist to provide therapeutic options such as hormonal therapy or surgery in well-defined disease states.	Strong
Provide a multi-disciplinary approach to pain management in persistent disease states.	Strong
All patients who have developed complications after mesh insertion should be referred to a multi-disciplinary service (incorporating pain medicine and surgery).	Strong

5.4.6 Management of primary anorectal pain syndrome

Summary of evidence	LE
Biofeedback is the preferred treatment for Chronic Primary Anal Pain Syndrome.	1a
Electro stimulation is less effective than biofeedback.	1b
Available evidence fails to confirm effectiveness of BTX-A in management of Chronic Primary Anal Pain Syndrome.	3
Percutaneous tibial nerve stimulation is effective in anal pain.	3
Sacral neuromodulation is effective in anal pain.	3
Inhaled salbutamol is effective in intermittent Chronic Primary Anal Pain Syndrome.	3

Recommendations	Strength rating
Undertake biofeedback treatment in patients with chronic anal pain.	Strong
Offer percutaneous tibial nerve stimulation in Chronic Primary Anal Pain Syndrome.	Weak
Offer sacral neuromodulation in Chronic Primary Anal Pain Syndrome.	Weak
Offer inhaled salbutamol in intermittent Chronic Primary Anal Pain Syndrome.	Weak

5.4.7 Management of pudendal neuralgia

Summary of evidence	LE
There are multiple treatment options with varying levels of evidence.	3

Recommendation	Strength rating
Neuropathic pain guidelines are well-established. Use standard approaches to management of neuropathic pain.	Strong

5.4.8 Management of sexological aspects in chronic pelvic pain

Summary of evidence	LE
Pelvic floor muscle physical therapy may offer relief of pain and reduction in sexual complaints.	2b

Recommendations	Strength rating
Offer behavioural strategies to the patient and his/her partner to reduce sexual dysfunctions.	Weak
Offer pelvic floor muscle therapy as part of the treatment plan to improve quality of life and sexual function.	Weak

5.4.9 Management of psychological aspects in chronic pelvic pain

Recommendation	Strength rating
For chronic pelvic pain with significant psychological distress, refer patient for chronic pelvic pain-focused psychological treatment.	Strong

*5.4.10 **Management of pelvic floor dysfunction***

Summary of evidence	LE
Myofascial treatment is effective.	1b
Biofeedback improves the outcome of myofascial therapy.	1a

Recommendations	Strength rating
Apply myofascial treatment as first-line treatment.	Weak
Offer biofeedback as therapy adjuvant to muscle exercises, in patients with anal pain due to an overactive pelvic floor.	Strong

*5.4.11 **Management of chronic/non-acute urogenital pain by opioids***

Recommendations	Strength rating
Opioids and other drugs of addiction/dependency should only be prescribed following multi-disciplinary assessment and only after other reasonable treatments have been tried and failed.	Strong
The decision to instigate long-term opioid therapy should be made by an appropriately trained specialist in consultation with the patient and their family doctor.	Strong
Where there is a history or suspicion of drug abuse, involve a psychiatrist or psychologist with an interest in pain management and drug addiction.	Strong

6. EVALUATION OF TREATMENT RESULTS

6.1 Evaluation of treatment

For patients with chronic primary visceral pain, a visit to the clinician is important because they can ask questions, talk about how the process is going and have some time with the caregiver who understands the nature of their pain. First evaluation should take place after about six weeks to see if the treatment has been successful or not. When necessary adaptations are made and a next evaluation is planned.

*6.1.1 **Treatment has not been effective***

6.1.1.1 Alternative treatment

In cases where the treatment initiated did not have enough effect, an alternative approach is advised. The first thing to do is a thorough evaluation of the patients' or care providers' adherence to the treatment that was initiated. Ask the patient if they have taken the medication according to the prescription, if there were any side effects and if there were any changes in pain and function. Adjustment of medication or dose schemes might help. Another important thing to do is to read the reports of other caregivers, for example, the physiotherapist and the psychologist. Has the therapy been followed until the end, what was the opinion of the therapist about the changes that were observed? In cases where the sessions had been terminated by the patient, ask the patient why they made that decision. Check if the patient has understood the idea behind the therapy that had been prematurely stopped.

6.1.1.2 Referral to next envelope of care

If patients and doctors conclude that none of the therapies given showed enough effect, then referral to a next envelope of care is advised. Unfortunately, the terminology used to describe the nature and specialisation level of centres providing specialised care for visceral pain patients is not standardised and is country-based. This does not facilitate easy referral schemes. It is advised that patients are referred to a centre that is working with a multi-disciplinary team and nationally recognised as specialised in pelvic pain. Such a centre will re-evaluate what has been done and when available, provide specialised care.

6.1.1.3 Self-management and shared care

Patients who find themselves confronted with CPPPS, for which there is no specific treatment option available, will have to live with their pain. They will need to manage their pain, meaning that they will have to find a way to deal with the impact of their pain on daily activities in all domains of life. Self-help programmes may be advised and can be of help. The patient may also benefit from shared care, which means that a caregiver is available for supporting the self-management strategies. Together with this caregiver, the patient can optimise and use the management strategies.

*6.1.2 **Treatment has been effective***

In cases where treatment has been effective, the caregiver may pay attention to fall-back prevention. If the patient feels the same pain again, it helps to start at an early stage with the self-management strategies that he/she has learned during the former treatment. By doing so they will have the best chance of preventing the re-development of pelvic pain syndromes.

8. CONFLICT OF INTEREST

All members of the EAU Chronic Pelvic Pain Guidelines working panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of conflict of interest. This information is publically accessible through the European Association of Urology website https://uroweb.org/guidelines/.

This document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

9. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Paris 2024. ISBN 978-94-92671-12-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, The Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aim and objectives

The European Association of Urology (EAU) Neuro-Urology Guidelines aim to provide information for clinical practitioners on the incidence, definitions, diagnosis, therapy, and follow-up of neuro-urological disorders. These Guidelines reflect the current opinion of experts in this specific pathology and represent a state-of-the-art reference for all clinicians, as of the publication date.

The terminology used and the diagnostic procedures advised throughout these Guidelines follow the recommendations for investigations of the lower urinary tract (LUT) as published by the International Continence Society (ICS) [1-3]. Readers are advised to consult other EAU Guidelines that may address different aspects of the topics discussed in this document.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition

The EAU Neuro-Urology Guidelines Panel consists of an international multidisciplinary group of neuro-urological experts. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guideline/neuro-urology/.

1.3 Available publications

A quick reference document, the Pocket Guidelines, is available in print and as an app for iOS and Android devices. These are abridged versions which may require consultation with the full text version. A guideline summary has also been published in European Urology [4]. All are available through the EAU website: http://www.uroweb.org/guideline/neurourology/.

1.4 Publication history and summary of changes

*1.4.1 **Publication history***

The EAU Guidelines on Neuro-Urology were first published in 2003. Standard procedure for EAU Guidelines includes an annual assessment of newly published literature in the field to guide future updates. This 2024 Neuro-Urology Guidelines present an update of the 2022 publication.

*1.4.2 **Summary of changes***

All chapters of the 2024 Neuro-Urology Guidelines have been updated, based on the 2023 version of the Guidelines. References have been added throughout the document resulting in various text updates and changes in evidence summaries and recommendations including but not limited to:

- Updates throughout Table 1 and the inclusion of data for Myasthenia gravis.
- A new recommendation for blood pressure and heartrate monitoring in section 3.3.7.4
- A new paragraph on other drugs used as medical therapy for neuro-urological symptoms in section 3.4.2.3 as well as a new summary of evidence (SOE) and recommendation for mirabegron in section 3.4.2.4
- Multiple text updates in section 3.4.3. on the various surgical intervention options for SUI in neuro-urological patients.
- A new SOE and recommendation for sacral neuromodulation in section 3.4.3.6
- A new recommendation against the use of dipstick urine analysis to screen for UTI in neuro-urological patients in section 3.5.4.

1.5 Background

The function of the LUT is mainly storage and voiding of urine, which is regulated by the nervous system that co-ordinates the activity of the urinary bladder and bladder outlet. The part of the nervous system that regulates LUT function is disseminated from the peripheral nerves in the pelvis to highly specialised cortical areas. Any disturbance of the nervous system involved, can result in neuro-urological symptoms. The extent and location of the disturbance will determine the type of LUT dysfunction, which can be symptomatic or asymptomatic. Neuro-urological symptoms can cause a variety of long-term complications; the most significant being deterioration of renal function. Since symptoms and long-term complications do not correlate [5], it is important to identify patients with neuro-urological symptoms, and establish if they have a low or high risk of subsequent

complications. The risk of developing upper urinary tract (UUT) damage and renal failure is much lower in patients with slowly progressive non-traumatic neurological disorders than in those with spinal cord injury or spina bifida [6]. In summary, treatment and intensity of follow-up examinations are based on the type of neuro-urological disorder and the underlying cause.

2. METHODS

2.1 Introduction

For the 2024 Neuro-Urology Guidelines, new and relevant evidence has been identified, collated, and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the Neuro-Urology Guidelines was performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between the 1st of May 2021 and 1st May 2023. A total of 1,896 unique records were identified, retrieved, and screened for relevance. A detailed search strategy is available online: http://uroweb.org/guideline/neuro-urology/?type=appendices-publications.

Recommendation within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [7];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact and certainty of patient values and preferences on the intervention.

Strong recommendations typically indicate a high degree of evidence quality and / or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [8].

Additional methodology information and a list of associations endorsing the EAU Guidelines can be found in the online: https://uroweb.org/eau-guidelines/methodology-policies.

2.2 Review

Publications ensuing from panel-lead systematic reviews (SR) have all been peer-reviewed. The 2024 Neuro-Urology Guidelines were subject to peer review prior to publication.

3. THE GUIDELINE

3.1 Epidemiology, aetiology and pathophysiology

3.1.1 Introduction

Neuro-urological symptoms may be caused by a variety of diseases and events affecting the nervous system controlling the LUT. The resulting neuro-urological symptoms depend predominantly on the location and the extent of the neurological lesion. There are no exact figures on the overall prevalence of neuro-urological disorders in the general population, but data are available on the prevalence of the underlying conditions and the relative risk of these for the development of neuro-urological symptoms. It is important to note that the majority of the data shows a very wide range of prevalence/incidence. This reflects the variability in the cohort (e.g., early or late-stage disease) and the frequently small sample sizes, resulting in a low level of evidence in most published data (summarised in Table 1).

Table 1: Epidemiology of Neuro-Urological Disorders

Suprapontine and pontine lesions and diseases		
Neurological Disease	**Frequency in General Population**	**Type and Frequency of Neuro-Urological Symptoms**
Cerebrovascular accident (Strokes)	450 cases/100,000/yr (Europe) [9], 10% of cardiovascular mortality.	Nocturia - overactive bladder (OAB) - urgency urinary incontinence (UUI) – neurogenic detrusor overactivity (NDO), other patterns less frequent [10]. 57-83% of neuro-urological symptoms at one month post-stroke, 71-80% spontaneous recovery at six months [11]. Persistence of urinary incontinence (UI) correlates with poor prognosis [12].
Dementias: Alzheimer's disease (80%), Vascular (10%), Other (10%).	6.4% of adults > 65 yrs [13].	OAB - UUI – NDO, 25% of incontinence in Alzheimer's disease, > 25% in other dementias: Lewy body, NPH, Binswanger, Nasu-Hakola, Pick Disease [14]. Incontinence three times more frequent in geriatric patients with dementia than without [15].
Parkinsonian syndrome (PS) Idiopathic Parkinson's disease (IPD): 75-80% of PS.	Second most prevalent neurodegenerative disease after Alzheimer's disease. Rising prevalence of IPD with age [16].	LUTS affect 50% at onset, with urgency and nocturia being the most common. Patients with LUTS at presentation have worse disease progression in Parkinson's disease [17]. LUTS prevalence data depend on gender, age, and Hoehn and Yahr stage [18].
Non-IPD: Parkinson's-plus (18%): - Multiple system atrophy (MSA), - Progressive supranuclear palsy, - Corticobasal degeneration, - Dementia with Lewy bodies. Secondary Parkinson's (2%)	MSA is the most frequent non-IPD PS.	Infections account for a major cause of mortality in MSA [19]. Impaired detrusor contractility with post-void residual (PVR) > 150 mL seems to be the urodynamic finding distinguishing MSA from IPD [20-22].
Brain tumours	26.8/100,000/yr in adults (> 19 yrs), (17.9 benign, 8.9 malignant) [23].	Incontinence occurs mainly in frontal location (part of frontal syndrome or isolated in frontal location) [24].
Cerebral palsy	Cerebral palsy: 3.1-3.6/1,000 in children aged 8 yrs [25].	32-46% of patients with cerebral palsy suffer from UI, with 85% of patients having abnormal urodynamic studies (NDO most common 59%). Upper tract deterioration is rare (2.5%) [26, 27].
Traumatic brain injury	235/100,000/yr [28].	44% storage dysfunction, 38% voiding dysfunction, 60% urodynamic abnormalities [29].
Normal pressure hydrocephalus	0.5% of the population > 60, up to 2.9% of those > 65 [30].	Classic triad of gait and cognitive disturbance along with neurogenic lower urinary tract dysfunction (NLUTD). The latter is mainly related to NDO and affects 76-83% of patients [30].

Lesions and diseases between caudal brainstem and sacral spinal cord		
Spinal cord injury (SCI)	Prevalence of traumatic SCI in developed countries ranges from 280 to 906/million [31].	NDO and detrusor sphincter dyssynergia (DSD) (up to 95%) and detrusor underactivity (DU) (up to 83%) depending on the level of the lesion [32].
Spina bifida (SB)	Spina bifida 3-4/10,000 Lumbar and lumbosacral form are the most common (60%) [33].	Bladder function is impaired in up to 96% of SB patients [34]. Over 50% of patients are incontinent [35]. Patients with open and closed defects can have equally severe NLUTD [36].
Hereditary spastic paraplegia (HSP)	Prevalence 1.3-9/100,000 [37].	LUTS in about 75%, mainly urgency and voiding dysfunction NDO in 81% (of whom 76% with DSD) [37]
Lesions and diseases of the peripheral nervous system		
Lumbar spine Degenerative disease Disk prolapse Lumbar canal stenosis	Male (5%) and female (3%) > 35 yr. have had a lumbosciatic episode related to disc prolapse. Incidence: approx. 5/100,000/yr More common in females > 45 yr.	26% difficulty to void and acontractile detrusor [38]. Detrusor underactivity (up to 83%) [32]. Tarlov cysts: early sensation of filling (70%), NDO (33%), and stress urinary incontinence (SUI) (33%) [39].
Iatrogenic pelvic nerve lesions	Rectal cancer. Cervical cancer (multimodal therapy, radiotherapy and surgery). Endometriosis surgery.	After abdomino-perineal resection: 50% urinary retention. After total mesorectal excision: 10-30% voiding dysfunction [40].
Peripheral neuropathy Diabetes Other causes of peripheral neuropathy causing neuro-urological symptoms: - Alcohol abuse; - Lumbosacral zone and genital herpes; - Guillain Barre syndrome; - Porphyria; - and Sarcoidosis.	Worldwide, prevalence of pharmacologically treated diabetes 8.3% [41].	OAB +/- UUI [42]. Hypersensitivity and DU at later phase [42].
Myasthenia gravis	Prevalence 20/100,000 [43]	Increased daytime frequency, nocturia, incontinence [43]
Disseminated central diseases		
Multiple sclerosis (MS)	Prevalence: 83/100,000 in Europe [44].	10% of MS patients present with voiding dysfunction at disease onset, 75% of patients will develop it after 10 yrs of MS [45]. NDO: 65% [45], 43% [46]. DSD: 35% [45, 46]. DU: 25% [45].

3.2 Classification systems

3.2.1 Introduction

Relevant definitions can be found in the general ICS standardisation reports [2, 3, 47, 48]. Supplementary online Tables S1 and S2 list the definitions from these references, partly adapted, and other definitions considered useful for clinical practice: https://uroweb.org/guideline/neuro-urology/?type=appendices-publications. A classification system that also includes UUT dysfunction in neuro-urological patients has also been described [48].

3.3 Diagnostic evaluation

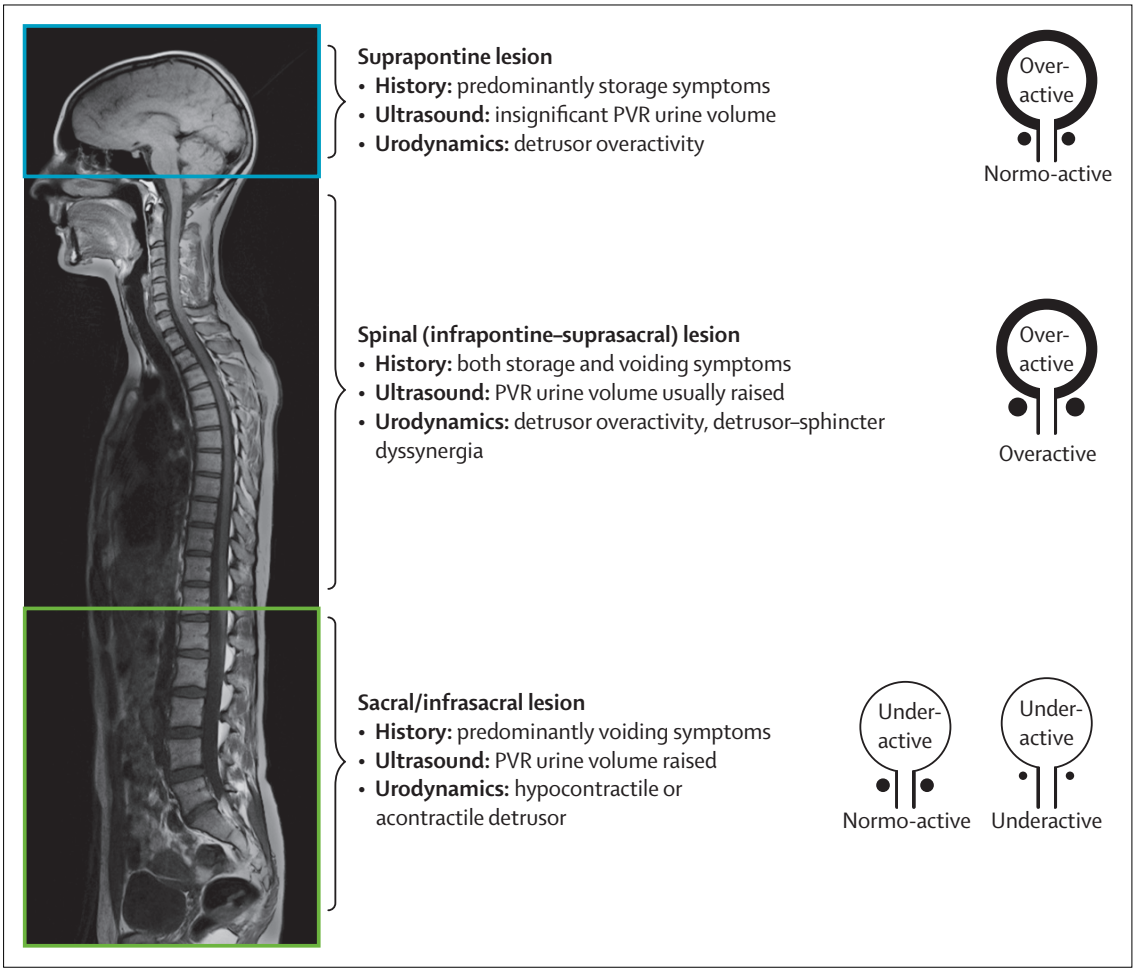
3.3.1 Introduction

The normal physiological function of the LUT depends on an intricate interplay between the sensory and motor nervous systems. When diagnosing neuro-urological symptoms, the aim is to describe the type of dysfunction involved. A thorough medical history, physical examination and bladder diary are mandatory before any additional diagnostic investigations can be planned. Results of the initial evaluation are used to decide the patient's long-term treatment and follow-up.

3.3.2 Classification systems

The pattern of LUT dysfunction following neurological disease is determined by the site and nature of the lesion. A very simple classification system for use in daily clinical practice to decide on the appropriate therapeutic approach is provided in Figure 1 [6].

Figure 1: Patterns of lower urinary tract dysfunction following neurological disease



The pattern of LUT dysfunction following neurological disease is determined by the site and nature of the lesion. Panel (A) denotes the region above the pons, panel (B) the region between the pons and the sacral cord and panel (C) the sacral cord and infrasacral region. Figures on the right show the expected dysfunctional states of the detrusor-sphincter system. Figure adapted from Panicker et al., [6] with permission from Elsevier.
PVR = post-void residual.

3.3.3 Timing of diagnosis and treatment

Early diagnosis and treatment are essential in both congenital and acquired neuro-urological disorders. This helps to prevent irreversible changes within the LUT, even in the presence of normal reflexes [49]. Furthermore, urological symptoms can be the presenting feature of neurological pathology [50, 51]. Early intervention can prevent irreversible deterioration of the LUT and UUT [51]. Long term follow-up (life-long) is mandatory to assess risk of UUT damage and renal failure [52, 53].

3.3.4 Patient history

History taking should include past and present symptoms and disorders (Table 4). It is the cornerstone of evaluation, as the answers will aid selection of diagnostic investigations and treatment options.

- In non-traumatic neuro-urological patients with an insidious onset, a detailed history may find that the condition started in childhood or adolescence [54].
- Urinary history consists of symptoms associated with both urine storage and voiding.
- Bowel history is important because patients with neuro-urological symptoms may also have related neurogenic bowel dysfunction [55].
- Sexual function may be impaired because of the neuro-urological condition [56].
- Special attention should be paid to possible warning signs and symptoms (e.g., pain, infection, haematuria, and fever) requiring further investigation.
- Patients with SCI usually find it difficult to report urinary tract infection (UTI)-related symptoms accurately [57, 58].
- The presence of urinary, bowel and sexual symptoms without neurological symptoms could be suggestive of an underlying neurological disease or condition.
- The severity of lesion after acute SCI does not predict the presence or absence of unfavourable urodynamic parameters [49].

Table 4: History taking in patients with suspected neuro-urological disorder

Past history
Childhood through to adolescence and into adulthood
Hereditary or familial risk factors
Specific female: menarche (age); this may suggest a metabolic disorder
Obstetric history
History of diabetes
Diseases, e.g., multiple sclerosis, parkinsonism, encephalitis, syphilis
Accidents and operations, especially those involving the spine and central nervous system
Present history
Present medication
Lifestyle (smoking, alcohol and drugs); may influence urinary, sexual and bowel function
Quality of life
Specific urinary history
Onset of urological history
Relief after voiding; to detect the extent of a neurological lesion in the absence of obstructive uropathy
Bladder sensation (painful, abnormal, absent or increased)
Initiation of micturition (normal, precipitate, reflex, strain, Credé)
Interruption of micturition (normal, paradoxical, passive)
Enuresis
Mode and type of voiding (catheterisation)
Frequency, voided volume, stress/urgency/mixed urinary incontinence, urgency episodes

Sexual history
Genital or sexual dysfunction symptoms
Sensation in genital area (absent, increased, abnormal, pain)
Specific male: libido, erection, (lack of) orgasm, ejaculation
Specific female: libido, dyspareunia, (lack of) orgasm
Bowel history
Type of bowel program
Frequency and faecal incontinence
Desire to defecate
Defecation pattern
Rectal sensation
Initiation of defecation (digital stimulation, enema, suppositories)
Neurological history
Acquired or congenital neurological condition
Mental status and comprehension
Neurological symptoms (somatic and sensory), with onset, evolution, and any treatment
Spasticity or autonomic dysreflexia (AD) (especially in lesions at or above level Th 6)
Mobility and hand function

3.3.4.1 Bladder diaries

Bladder diaries are considered a valuable diagnostic tool for the initial assessment of neurogenic LUT dysfunction. They provide data on the number of voids (spontaneous or intermittent catheter), voided volume, stress/urgency/mixed urinary incontinence episodes and contribute to the interpretation of urodynamic testing. Preferably, bladder diaries should be completed for three consecutive days [59].

3.3.5 ***Patient quality of life questionnaires***

Quality of life (QoL) is an essential aspect of the overall management of neuro-urological patients, for example when evaluating treatment related changes on a patient's QoL [60]. The type of bladder management has been shown to affect health-related QoL (HRQoL) mainly in patients with SCI [61, 62] and MS [63], as does the presence or absence of urinary, sexual and faecal incontinence [64]. Other research has also highlighted the importance of urological treatment and its impact on the urodynamic functionality of the neuro-urological patient in determining patient QoL [65].

In recent years a proliferation in the number of questionnaires to evaluate symptoms and QoL has been seen. Condition-specific questionnaires can be used to assess symptom severity and the impact of symptoms on QoL. A patient's overall QoL can be assessed using generic questionnaires. It is important that the questionnaire of choice has been validated in the neuro-urological population, and that it is available in the language that it is to be used in.

3.3.5.1 Available Questionnaires

Three condition-specific questionnaires for urinary or bowel dysfunction and QoL have been developed specifically for adult neuro-urological patients [63]. In MS and SCI patients the Qualiveen, also available in a short version, is validated and translated into various languages [66, 67]. Although several objective and subjective tools have been used to assess the influence of neurogenic lower urinary tract dysfunctions (N-LUTD) on QoL in SCI, the Quality life index-SCI and Qualiveen are the only validated condition-specific outcomes that have shown consistent sensitivity [68]. The Neurogenic Bladder Symptom Score (NBSS) and its short version has been validated in neurological patients to measure urinary symptoms and their consequences [69-71]. The QoL scoring tool related to Bowel Management (QoL-BM) [72] can be used to assess bowel dysfunction in MS and SCI patients. A new tool has recently been developed to understand the reasons for poor compliance in long-term management of neurogenic patients. [73, 74]. A variety of patient-reported outcome measures (PROMs) are available to evaluate sexual function in neuro-urological patients. However, only the Multiple Sclerosis Intimacy and Sexuality Questionnaire-15 (MSISQ-15) and -19 is supported by evidence [75-77].

In addition, several validated questionnaires that evaluate QoL and assess urinary symptoms as a subscale or question in neuro-urological patients have been identified [78] (Table 5). The condition-specific Incontinence-Quality of Life (I-QoL) questionnaire which was initially developed for the non-neurological population has now also been validated for neuro-urological patients [79].

A patient's overall QoL can be assessed by generic HRQoL questionnaires, the most commonly used being the I-QOL, King's Health Questionnaire (KHQ), or the Short Form 36-item and 12-item Health Survey Questionnaires (SF-36, SF-12) [80]. In addition, the quality-adjusted life year (QALY), quantifies outcomes, by weighing years of life spent in a specified health state, adjusted by a factor representing the value placed by society or patients on their specific health state [81].

No evidence was found for which validated questionnaires are the most appropriate for use, since no quality criteria for validated questionnaires have been assessed [80].

Table 5: Patient questionnaires

Questionnaire	Underlying neurological disorder	Bladder	Bowel	Sexual function
FAMS [82]	MS	X		X
FILMS [83]	MS	X	X	
HAQUAMS [84]	MS	X	X	X
I-QOL [79]	MS, SCI	X		X
LUTS-TCA [73]	MS, SCI, Parkinson	X

*3.3.6 **Physical examination and additional tests***

In addition to a detailed patient history, attention should be paid to possible physical and intellectual disabilities with respect to the planned investigations [92, 93]. Neuro-urological status should be described as completely as possible (Figure 2) [6]. Patients with a high spinal cord lesion or supraspinal neurological lesions may suffer from a significant drop in blood pressure when moved into a sitting or standing position. All sensations and reflexes in the urogenital area must be tested [6]. Furthermore, detailed testing of the anal sphincter and pelvic floor functions must be performed (Figure 2) [6, 94]. It is essential to have this clinical information to reliably interpret later diagnostic investigations (Table 6).

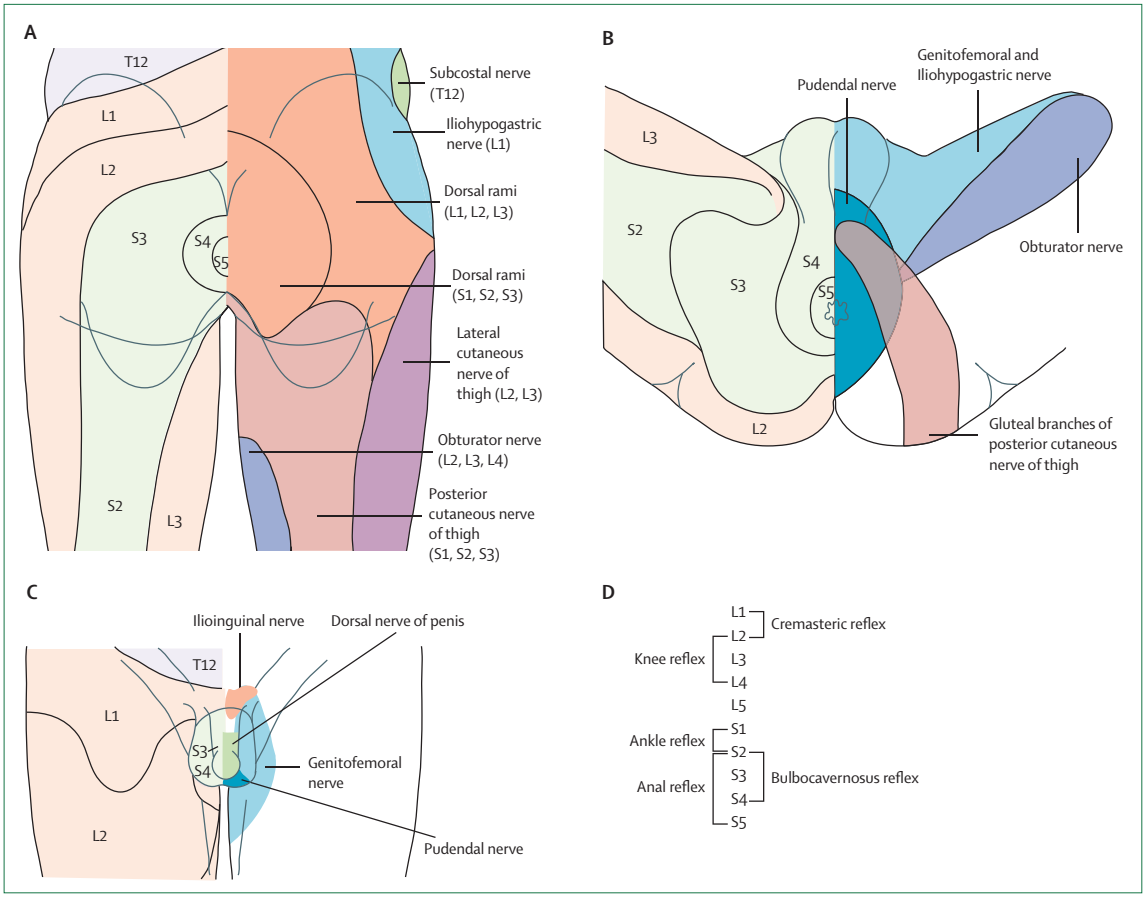
Additionally, urinalysis, blood chemistry, ultrasonography, post-void residual when indicated, incontinence quantification and were indicated free uroflowmetry, should be performed as part of the routine assessment of neuro-urological patients [6, 95].

3.3.6.1 Autonomic dysreflexia

Autonomic dysreflexia (AD) is a sudden and exaggerated autonomic response to various stimuli generally manifests in patients with SCI or spinal dysfunction at or above level Th 6. It is defined by an increase in systolic blood pressure > 20 mmHg from baseline and it is usually accompanied by a severe headache, blurred vision, feeling of anxiety, heart rate changes, as well as above the lesion, perspiration, piloerection, warm skin and flushing and below the lesion, pallor, cold skin, and sweating in the lower part of the body [96, 97]. Autonomic dysreflexia can have life-threatening consequences if not managed adequately. The stimulus can be distended

bladder or bowel (e.g., iatrogenic stimuli during cystoscopy or urodynamics) [98], but it can also be secondary to any noxious stimulus (e.g., infected toenail or pressure sore) or after sexual stimulation.

Figure 2: Lumbosacral dermatomes, cutaneous nerves, and reflexes



The physical examination includes testing sensations and reflexes mediated through the lower spinal cord. Abnormal findings would suggest a lesion affecting the lumbosacral segments; mapping out distinct areas of sensory impairment helps to further localise the site of the lesion. Distribution of dermatomes (areas of skin mainly supplied by a single spinal nerve) and cutaneous nerves over the perianal region and back of the upper thigh (A), the perineum [99] (B), male external genitalia [100] (C) and root values of lower spinal cord reflexes (D). Figure adapted from Panicker et al., [6] with parts A-C adapted from Standring [101], both with permission from Elsevier.

Table 6: Neuro-urological items to be specified

Sensation S2-S5 (both sides)
Presence (increased/normal/reduced/absent)
Type (light touch/pin prick)
Affected dermatomes
Reflexes (increased/normal/reduced/absent)
Bulbocavernous reflex
Perianal/anal reflex
Knee and ankle reflexes
Plantar responses (Babinski)
Anal sphincter tone
Presence (increased/normal/reduced/absent)
Voluntary contractions of anal sphincter and pelvic muscles (increased/normal/reduced/absent)

General urogenital assessment
Prostate palpation
Skin lesions
Size and presence of penis
Descensus (prolapse) of pelvic organs

3.3.6.2 Summary of evidence and recommendations for history taking and physical examination

Summary of evidence	LE
Early diagnosis and treatment are essential in both congenital and acquired neuro-urological disorders to prevent irreversible changes within the LUT.	4
An extensive general history is the basis of evaluation focusing on past and present symptoms including urinary, sexual, bowel and neurological function.	4
Assessment of present and expected future QoL is an essential aspect of the overall management of neuro-urological patients and is important to evaluate the effect of any therapy.	2a
Quality of life assessment should be completed with validated QoL questionnaires for neuro-urological patients.	1a
Bladder diaries provide data on the number of voids, voided volume, urinary incontinence, and urgency episodes.	3

Recommendations	Strength rating
Take an extensive general history, concentrating on past and present symptoms.	Strong
Take a specific history for each of the four mentioned functions - urinary, bowel, sexual and neurological.	Strong
Pay special attention to the possible existence of alarm symptoms/signs (e.g. pain, infection, haematuria, fever) that warrant further specific diagnosis.	Strong
Assess quality of life when evaluating and treating neuro-urological patients.	Strong
Use available validated tools for urinary and bowel symptoms in neuro-urological patients.	Strong
Use MSISQ-15 or MSISQ-19 to evaluate sexual function in multiple sclerosis patients.	Strong
Acknowledge individual patient disabilities when planning further investigations.	Strong
Describe the neurological status as completely as possible, sensations and reflexes in the urogenital area must all be tested.	Strong
Test the anal sphincter and pelvic floor functions.	Strong
Perform urinalysis, blood chemistry, bladder diary, post-void residual, incontinence quantification and urinary tract imaging as initial and routinary evaluation.	Strong

MSISQ 15/19 = Multiple Sclerosis Intimacy and Sexuality Questionnaire 15/19 question version.

*3.3.7 **Urodynamics***

3.3.7.1 Introduction

Urodynamic investigation is the only method that can objectively assess the function and dysfunction of the LUT. In neuro-urological patients, invasive urodynamic investigation is even more challenging than in general patients. Any technical source of artefacts must be critically considered. It is essential to maintain the quality of the urodynamic recording and its interpretation [1]. Same session repeat urodynamic investigations are crucial in clinical decision making, since repeat measurements may yield completely different results [102].

In patients at risk of AD, blood pressure (BP) and heartrate monitoring during the urodynamic study and other invasive procedures is mandatory [97, 103]. The rectal ampulla should be empty of stool before the start of the investigation. All urodynamic findings must be reported in detail and performed, according to the ICS technical recommendations and standards [1, 104].

In patients with SCI, first urodynamic investigation should take place within 3 months after SCI to facilitate early diagnosis of unfavourable urodynamic parameters and timely treatment [105] but there is need for further research regarding the urodynamic follow-up schedule during the first year after SCI [106].

3.3.7.2 Urodynamic tests

Free uroflowmetry and assessment of residual urine: It is recommended prior to planning any invasive urodynamics that patients are able to void in the usual position. For reliable information, it should be repeated at least two to three times [1]. Possible pathological findings include a low flow rate, low voided volume, intermittent flow, hesitancy and PVR.

Filling cystometry: This test is the only method for quantifying the patient's filling function. The status of LUT function must be documented during the filling phase. However, this technique has limited use as a solitary procedure. It is much more effective combined with bladder pressure measurement during micturition and is even more effective in video-urodynamics.

The bladder should be empty at the start of filling. A physiological filling rate should be used with body-warm saline. Possible pathological findings include neurogenic detrusor overactivity (NDO), low bladder compliance, abnormal bladder sensations, low cystometric capacity and urinary incontinence.

Detrusor leak point pressure [107]: Appears to have no use as a diagnostic tool. Some positive findings have been reported [52, 108, 109], but sensitivity is too low to estimate the risk to the UUT or for secondary bladder damage [110, 111].

Pressure flow study (or voiding cystometry): Reflects the coordination between detrusor and urethra or pelvic floor during the voiding phase. It is even more effective if combined with filling cystometry and video-urodynamics. Possible pathological findings include detrusor underactivity, acontractility, bladder outlet obstruction (BOO), DSD, a high urethral resistance, and residual urine.

Most types of obstruction caused by neuro-urological disorders are due to DSD [112, 113], non-relaxing urethra, and/or non-relaxing bladder neck [114, 115]. Pressure-flow analysis mainly assesses the amount of mechanical obstruction caused by the urethra's inherent mechanical and anatomical properties.

Electromyography (EMG): Reflects the activity of the external urethral sphincter, the peri-urethral striated musculature, the anal sphincter, and the striated pelvic floor muscles. Correct interpretation may be difficult due to artefacts introduced by other equipment. In the urodynamic setting, an EMG is useful as a gross indication of the patient's ability to control the pelvic floor. Possible pathological findings include inadequate recruitment upon specific stimuli (e.g. bladder filling, involuntary detrusor contractions, onset of voiding, coughing, Valsalva manoeuvre) suggesting a diagnosis of DSD [116].

Urethral pressure measurement: Has a very limited role in neuro-urological disorders. There is no consensus on parameters indicating pathological findings [117].

Video-urodynamics: Is the combination of filling cystometry and pressure flow studies with imaging. It is the optimum procedure for urodynamic investigation in neuro-urological disorders [5]. Possible pathological findings include all those described in the filling cystometry and the pressure flow study sections, and any morphological pathology of the LUT and reflux to the UUT [118].

Ambulatory urodynamics: This is the functional investigation of the urinary tract, which predominantly uses the natural filling of the urinary tract to reproduce the patient's normal activity. Although this type of study might be considered when conventional urodynamics does not reproduce the patient's symptoms, its role in the neuro-urological patient still needs to be determined [119, 120].

Triggered tests during urodynamics: Lower urinary tract function can be provoked by coughing, triggered voiding, or anal stretch. Fast-filling cystometry with cooled saline (the 'ice water test') was initially described to discriminate between upper and lower motor neuron lesions [121, 122]. Patients with upper motor neuron lesions develop a detrusor contraction if the detrusor is intact, while patients with lower motor neuron lesions do not. However, the test does not seem to be fully discriminative since also non neurological and lower motor SCI have shown positive test [123, 124].

Previously, a positive bethanechol test [125] (detrusor contraction > 25 cm H2O) was thought to indicate detrusor denervation hypersensitivity and the muscular integrity of an acontractile detrusor. However, in practice, the test has given equivocal results. A variation of this method was reported using intravesical electromotive administration of the bethanechol [126], but there was no published follow-up. Currently, there is no indication for this test.

3.3.7.3 Specialist uro-neurophysiological tests

The following tests are advised as part of the neurological work-up [127]:

- electromyography (in a neurophysiological setting) of pelvic floor muscles, urethral sphincter and/or anal sphincter;
- nerve conduction studies of pudendal nerve;
- reflex latency measurements of bulbocavernosus and anal reflex arcs;
- evoked responses from clitoris or glans penis;
- sensory testing on bladder and urethra.

Other elective tests, for specific conditions, may become obvious during the work-up and urodynamic investigations.

3.3.7.4 Summary of evidence and recommendations for urodynamics and uro-neurophysiological tests

Summary of evidence	**LE**
Urodynamic investigation is the only method that can objectively assess the (dys-)function of the LUT.	2a
Video-urodynamics is the optimum procedure for urodynamic investigation in neuro-urological disorders.	4
Specific uro-neurophysiological tests are elective procedures and should only be carried out in specialised settings.	4

Recommendations	**Strength rating**
Perform a urodynamic investigation to detect and specify lower urinary tract (dys-)function, use same session repeat measurement as it is crucial in clinical decision making.	Strong
Non-invasive testing is mandatory before invasive urodynamics is planned.	Strong
Use video-urodynamics for invasive urodynamics in neuro-urological patients. If this is not available, then perform a filling cystometry continuing into a pressure flow study.	Strong
Use a physiological filling rate and body-warm saline.	Strong
Perform blood pressure and heartrate monitoring during urodynamic investigation and other invasive procedures in patients at risk for autonomic dysreflexia.	Strong

3.3.8 ***Renal function***

In many patients with neuro-urological disorders, the UUT is at risk, particularly in patients who develop high detrusor pressure during the filling phase. Although effective treatment can reduce this risk, there is still a relatively high incidence of renal morbidity [128, 129]. Patients with SCI or SB have a higher risk of developing renal failure compared with patients with slowly progressive non-traumatic neurological disorders, such as MS and Parkinson's disease (PD) [130].

Caregivers must be informed of this risk and instructed to watch carefully for any signs or symptoms of a possible deterioration in the patient's renal function. In patients with poor muscle mass cystatin C based glomerular filtration rate (GFR) seems to be more accurate in detecting chronic kidney disease than serum creatinine estimated GFR [131]. There are no high-level evidence publications available which show the optimal management to preserve renal function in these patients [132].

3.4 Disease management

3.4.1 ***Introduction***

The primary aims for treatment of neuro-urological symptoms, and their priorities, are [129, 130]:

- protection of the UUT;
- achievement (or maintenance) of urinary continence;
- restoration of LUT function;
- improvement of the patient's QoL.

Further considerations are the patient's disability, cognition, social support, caregiver support, cost-effectiveness, technical complexity and possible complications [134].

Historically, renal failure was the main mortality factor in SCI patients who survived the trauma [135, 136]. Keeping the detrusor pressure during both the filling and voiding phases within safe limits significantly reduces the mortality from urological causes in these patients [137-139] and has consequently become the top priority in the treatment of patients with neuro-urological symptoms [133, 134].

In patients with high detrusor pressure during the filling phase (NDO, low bladder compliance), treatment is aimed primarily at conversion of an overactive, high-pressure bladder into a low-pressure reservoir despite the resulting residual urine [133]. Reduction of the detrusor pressure contributes to urinary continence, and consequently to social rehabilitation and QoL. It is also critical for preventing UTIs [140, 141]. However, complete continence cannot always be obtained.

*3.4.2 **Non-invasive conservative treatment***

3.4.2.1 Assisted bladder emptying - Credé manoeuvre, Valsalva manoeuvre, triggered reflex voiding

Incomplete bladder emptying is a serious risk factor for UTI, high intravesical pressure and incontinence. Methods to improve the voiding process should therefore be practiced.

Bladder expression: The downwards movement of the lower abdomen by suprapubic compression (Credé) or by abdominal straining (Valsalva) leads to an increase in intravesical pressure, and generally also causes a reflex sphincter contraction [142, 143]. The latter may increase bladder outlet resistance and lead to inefficient emptying. The high pressures created during these procedures are hazardous for the urinary tract [144, 145]. Therefore, their use should be discouraged unless urodynamics show that the intravesical pressure remains within safe limits [134].

Long-term complications are unavoidable for both methods of bladder emptying [143]. The already weak pelvic floor function may be further impaired, thus introducing or exacerbating already existing SUI [145].

Triggered reflex voiding: Stimulation of the sacral or lumbar dermatomes in patients with a upper motor neuron lesion can elicit a reflex detrusor contraction [145]. The risk of high pressure voiding is present and interventions to decrease outlet resistance may be necessary [146]. Triggering can induce AD, especially in patients with high level SCI (at or above Th 6) [147]. All assisted bladder emptying techniques require low outlet resistance. Even then, high detrusor pressures may still be present. Hence, patients need dedicated education and close urodynamic and urological surveillance [145, 148, 149].

Note: In the literature, including some of the references cited here, the concept "reflex voiding" is sometimes used to cover all three assisted voiding techniques described in this section.

External appliances: Social continence may be achieved by collecting urine during incontinence, for instance using pads. Condom catheters with urine collection devices are a practical method for men [134]. The penile clamp is absolutely contraindicated in case of NDO or low bladder compliance due to the risk of developing high intravesical pressure and pressure sores/necrosis in cases of altered/absent sensations.

3.4.2.2 Neuro-urological rehabilitation

3.4.2.2.1 Bladder rehabilitation including electrical stimulation

The term bladder rehabilitation summarises treatment options that aim to re-establish bladder function in patients with neuro-urological symptoms. Strong contraction of the urethral sphincter and/or pelvic floor, as well as anal dilatation, manipulation of the genital region, and physical activity inhibit micturition in a reflex manner [134, 150]. The first mechanism is affected by activation of efferent nerve fibres, and the latter ones are produced by activation of afferent fibres [110]. Electrical stimulation of the pudendal nerve afferents, strongly inhibits the micturition reflex and detrusor contraction [151]. This stimulation might then support the restoration of the balance between excitatory and inhibitory inputs at the spinal or supraspinal level [134, 152]. Evidence for bladder rehabilitation using electrical stimulation in neurological patients is mainly based on small non-comparative studies with a high risk of bias.

Behavioural therapy and bladder training: In patients with PD, behavioural therapy and bladder training may be considered based on randomised controlled trials (RCTs) with very limited number of patients [153, 154].

Pelvic floor muscle training (PFMT): In patients with MS and stroke, PFMT may have positive effects on LUTS, daytime urinary frequency and urinary incontinence but the evidence is still limited [155, 156].

Peripheral temporary electrostimulation: Tibial nerve stimulation and transcutaneous electrical nerve stimulation (TENS) might be effective and safe for treating neurogenic LUT dysfunction, but more reliable evidence from well-designed RCTs is required to reach definitive conclusions [152, 157, 158]. In post-stroke patients TENS has been shown to effectively improve urodynamic and bladder diary findings as well as QoL [159-161]. In an RCT, transcutaneous tibial nerve home stimulation has proven to significantly improve bladder diary parameters in patients with MS as well as in women with PD [162, 163]. In acute SCI, TENS is able to achieve bladder neuromodulation via modulation of the autonomous nervous system functions [164]. Greater volumes until full sensation, less detrusor-sphincter dyssynergia and an increased bladder capacity can be found when compared to sham-treated patients [165].

A SR on dorsal genital nerve stimulation showed higher relative and absolute bladder capacities and inhibition of detrusor hyperactivity in SCI people, although these therapeutic effects may be dependent on the current, amplitude and longer periods of stimulation [166].

Interferential medium frequency current electrical stimulation for SCI patients with American spinal cord injury association impairment scale (AIS) levels B, C and D demonstrated a significant decrease in PVR and volume of urine leakage between catheterisation [167]. Neuromuscular electrical stimulation applied in the sacral area has also improved the performance in symptoms scores in highly selected patients with UI after stroke [160]; however, new RCTs with more patients and longer follow-up are required.

Peripheral temporary electrostimulation combined with pelvic floor muscle training and biofeedback: In MS patients, combining active neuromuscular electrical stimulation with Pelvic Floor Muscle Training (PFMT) and EMG biofeedback can achieve a substantial reduction of neuro-urological symptoms [168, 169]. This treatment combination seems to be more effective than either therapy alone [170, 171]. However, the combination of intravaginal electrostimulation and PFMT was not superior to PFMT alone in reducing UI in women with incomplete SCI [172].

Intravesical electrostimulation: Intravesical electrostimulation can increase bladder capacity and improve bladder filling sensation in patients with incomplete SCI or myelomeningocele (MMC) [173]. In patients with neurogenic detrusor underactivity, intravesical electrostimulation may also improve voiding and reduce residual volume [174, 175].

Repetitive transcranial magnetic stimulation: Although improvement of neuro-urological symptoms has been described in PD, SCI and MS patients, this technique is still under investigation [176]. The role of cortical as well as sacral magnetic stimulation in MS patients with underactive bladder needs to be better defined [177].

Summary: To date, bladder rehabilitation techniques are mainly based on electrical or magnetic stimulation; however, there is a lack of well-designed studies.

3.4.2.3 Drug treatment

A single, optimal, medical therapy for neuro-urological symptoms is not always available. Commonly, a combination of different therapies (e.g. intermittent catheterisation and antimuscarinic drugs) is advised to prevent urinary tract damage and improve long-term outcomes, particularly in patients with a suprasacral SCI or MS [145, 178-180]. Drug treatments are categorised depending on their mechanism of action and focus on storage or voiding symptoms.

3.4.2.3.1 Drugs for storage symptoms

Antimuscarinic drugs: are the first-line choice for treating NDO, increasing bladder capacity and reducing episodes of UI secondary to NDO by the inhibition of parasympathetic pathways [134, 181-187]. Antimuscarinic drugs have been used for many years to treat patients with NDO [185, 186, 188], and the responses of individual patients to antimuscarinic treatment are variable. Despite a meta-analysis confirming the clinical and urodynamic efficacy of antimuscarinic therapy compared to placebo in adult NDO, a more recent integrative review has indicated that the information provided is still too limited for clinicians to be able to match trial data to the needs of individual patients with SCI, mainly due to the lack of use of standardised clinical evaluation tools such as the American Spinal Injury Association bladder diary and validated symptoms score [186, 189].

Higher doses or a combination of antimuscarinic agents may be an option to maximise outcomes in neurological patients [182, 183, 190-193]. However, these drugs have a high incidence of adverse events, which may lead to early discontinuation of therapy. Despite this, NDO patients have generally shown better treatment adherence compared to idiopathic DO patients [194].

Choice of antimuscarinic agent: Oxybutynin [134, 182, 183, 185, 186, 195], trospium [186, 192, 196], tolterodine [197] and propiverine [186, 198] are established, effective and well-tolerated treatments even in long-term use [185, 186, 199, 200]. Darifenacin [201, 202] and solifenacin [203] have been evaluated in NDO secondary to SCI and MS [186, 201-203] with results similar to other antimuscarinic drugs. A pilot study using solifenacin in NDO due to PD showed an improvement in UI [204]. Fesoterodine, an active metabolite of tolterodine, has also been introduced; improving urodynamic variables in SCI, MS and PD patients [205, 206]. Fesoterodine for SCI patients can diminish the magnitude and frequency of AD episodes [207]. Favourable results with the new drug imidafenacin have been reported in suprapontine as well as SCI patients [208, 209].

Side effects: Controlled-release antimuscarinics have some minor side effects, e.g. dry mouth [210]. It has been suggested that different ways of administration may help to reduce side effects [211]. Imidafenacine has been safely used in neurological patients with no worsening of cognitive function [208]. Nevertheless, the potential risk of developing dementia should be taken into account [212]; consider switching to beta-3 agonists or other therapies if cognition is affected [213].

Beta-3-adrenergic receptor agonists
Despite the increasing use of mirabegron in neuro urological patients, its role in these patients is still unclear [214, 215]. In MS and SCI patients, with very short follow-up, mirabegron has not demonstrated any significant effect on detrusor pressure or cystometric capacity [69, 216, 217], despite the reported improvement in LUT symptoms and quality of life similar to antimuscarinics [215]. Cardiovascular safety in NDO population has been suggested in a placebo-controlled RCT [218]. A significant subjective improvement in NDO symptoms has also been reported using lower dosages of mirabegron in patients affected by CNS lesions without any negative effects on voiding function [219]. A standard dosage of 50 mg has been found effective with no worsening of cognitive function in patients with PD [220].

Vibegron treatments significantly improved maximum cystometric capacity, bladder compliance, and NDO in a retrospective cohort study [221], but more studies are needed to do a recommendation.

Other drugs
A SR found that desmopressin may be effective for treating nocturnal polyuria in MS patients; however, adverse events were common, with the included studies being heterogeneous and of low quality [222].

Combination therapy with mirabegron and desmopressin in MS patients has shown promising results; however, clinical experience is still very limited in neuro-urological populations [223, 224].

In preliminary studies, improvements in daily incontinence rates, nocturia, daytime and 24-hour voids, as well as the low risk of adverse events, suggest that cannabinoids may be effective and safe in MS patients [225, 226]. A concomitant improvement in NDO symptoms has been reported in male MS patients using daily tadalafil to treat neurogenic erectile dysfunction (ED) [227].

3.4.2.3.2 Drugs for voiding symptoms
Detrusor underactivity: Cholinergic drugs, such as bethanechol and distigmine, have been considered to enhance detrusor contractility and promote bladder emptying, but are not frequently used in clinical practice [228]. Only preclinical studies have documented the potential benefits of cannabinoid agonists for improving detrusor contractility when administered intravesically [229, 230].

Decreasing bladder outlet resistance: α-blockers (e.g. tamsulosin, naftopidil and silodosin) seem to be effective for decreasing bladder outlet resistance, PVR and AD [231-235].

Increasing bladder outlet resistance: Several drugs have shown efficacy in selected cases of mild SUI, but there are no high-level evidence studies in neurological patients [134].

3.4.2.4 Summary of evidence and recommendations for drug treatments

Summary of evidence	**LE**
Long-term efficacy and safety of antimuscarinic therapy for NDO is well documented.	1a
Mirabegron has shown similar symptom related clinical effects compared to antimuscarinics.	1b
Mirabegron does not improve urodynamic parameters in NDO patients.	1a
Maximise outcomes for NDO by considering combination therapy	3

Recommendations	Strength rating
Use antimuscarinic therapy as the first-line medical treatment for neurogenic detrusor overactivity.	Strong
Do not use mirabegron with the intention of reducing urodynamically proven neurogenic detrusor overactivity.	Strong
Prescribe α-blockers to decrease bladder outlet resistance.	Strong
Do not prescribe parasympathomimetics for underactive detrusor.	Strong

3.4.2.5 Minimally invasive treatment

3.4.2.5.1 Catheterisation

Intermittent self- or third-party catheterisation [236, 237] is the preferred management for neuro-urological patients who cannot effectively empty their bladders [134]. An adequate hand function is an independent risk factor for cessation of intermittent catheterisation (IC) [238].

It has not yet been established whether or not the incidence of UTI, other complications and user satisfaction are affected by either sterile, aseptic or clean IC, coated or uncoated catheters or by any other catheter type [239].

Sterile IC cannot be considered a routine procedure [134, 240] and careful counselling should be employed before commencing IC. In those with MS, commencing IC increases UTI rate over one year by seven fold, without improvement in QoL or symptom score [241]. In addition, in those with SCI, dissatisfaction (and discontinuation) is associated with increased UTI frequency, as well as being of the female sex [242]. It is worth considering patient satisfaction and subsequent compliance when instigating and continuing IC. Shared decision making is imperative, as although IC has better medical outcomes than indwelling catheterisation, in the SCI population it is associated with worse reported QoL compared to indwelling catheters, especially if recurrent (> 4 per year) UTIs complicate management [61, 243]. The use of hydrophilic catheters is associated with a lower rate of UTI [244]. An observational study found that of the 56.9% of patients who used IC 42.1% of patients discontinued IC within 12 months with inconvenience (36%), leakage (20%) and increased infections (19%) listed as the main reasons for the discontinuation [243].

To minimise the risk of UTI in neuro-urological patients, it is important that patient should be adequately taught to self-catheterise [134, 245-249]. The average frequency of catheterisations per day is four to six times [250] and the catheter size most often used is between 12-16 Fr. In aseptic IC, an optimum frequency of five times showed a reduction of UTI [250]. Ideally, bladder volume at catheterisation should, as a rule, not exceed 400-500 mL.

Indwelling transurethral catheterisation and, to a lesser extent, suprapubic cystostomy are associated with a range of complications as well as an enhanced risk for UTI [134, 251-258]; therefore, both procedures should be avoided, when possible. Silicone catheters are preferred as they are less susceptible to encrustation and because of the high incidence of latex allergy in the neuro-urological patient population [259].

Bladder cancer might be an increased risk in the general population with an indwelling catheter including neuro-urological patients, and clinicians should promptly investigate patients with the standard red flags for bladder cancer [258, 260].

3.4.2.5.2 Summary of evidence and recommendations for catheterisation

Summary of evidence	LE
Intermittent catheterisation is the standard treatment for patients who are unable to empty their bladder.	3
Indwelling transurethral catheterisation and suprapubic cystostomy are associated with a range of complications as well as an enhanced risk for UTI.	3

Recommendations	Strength rating
Use intermittent catheterisation as a standard treatment for patients who are unable to empty their bladder.	Strong
Thoroughly instruct patients in the technique and risks of intermittent catheterisation.	Strong
Avoid indwelling transurethral and suprapubic catheterisation whenever possible.	Strong

3.4.2.5.3 Intravesical drug treatment

To reduce NDO, antimuscarinics can also be administered intravesically [261]. The efficacy and tolerability of intravesical administration of oxybutynin hydrochloride for treatment of NDO has been demonstrated in a recent randomised controlled study [211]. This approach may reduce adverse effects due to the fact that the antimuscarinic drug is metabolised differently [262] and a greater amount is sequestered in the bladder, even more than with electromotive administration [263].

The vanilloids, capsaicin and resiniferatoxin, desensitise the C-fibres for a period of a few months [264, 265]. Clinical studies have shown that resiniferatoxin has limited clinical efficacy compared to botulinum toxin A injections in the detrusor [264].

Although preliminary data suggest that intravesical vanilloids might be effective for treating neurological LUT dysfunction, their safety profile appears to be unfavourable [222]. Currently, there is no indication for the use of these substances, which are not licensed for intravesical treatment.

3.4.2.5.4 Summary of evidence and recommendations for intravesical drug treatment

Summary of evidence	**LE**
A significant reduction in adverse events was observed for intravesical administration of oxybutynin compared to oral administration.	1a

Recommendation	**Strength rating**
Offer intravesical oxybutynin to neurogenic detrusor overactivity patients with poor tolerance to the oral route.	Strong

3.4.2.5.5 Botulinum toxin injections in the bladder

Botulinum toxin A causes a long-lasting but reversible chemical denervation that lasts for about nine months [266, 267]. The toxin injections are mapped over the detrusor in a dosage that depends on the preparation used. Botulinum toxin A has been proven effective in patients with neuro-urological disorders due to MS, SCI and PD in multiple RCTs and meta-analyses [268-271]. In mid- to long-term follow-up, 50%-70% of the patients continue botulinum toxin treatment [272-274]. Urodynamic studies might be necessary after treatment in order to monitor the effect of the injections on bladder pressure [275]. Repeated injections seem to be possible without loss of efficacy, even after initial low response rates, based on years of follow-up [266, 276-279]. The clinical efficacy of botulinum toxin A injection in patients with low morbidity after failure of augmentation enterocystoplasty has been demonstrated [280, 281]. The effectiveness of the different toxin variations seems to be comparable [282, 283]. A switch between different toxin variations may improve responsiveness [284]. The most frequent side effects are UTIs, urinary retention and haematuria [285]. Intermittent catheterisation may become necessary, this is especially relevant in MS patients as they do not often perform IC prior to intravesical botulinum toxin injections. However, a lower dose of botulinum toxin A (100 U) may reduce the rate of IC in MS patients [286]. Rare complications include generalised muscle weakness and AD [285]. Including the trigone has been suggested to be more effective than trigone-sparing injection [287]. Current research focuses on different delivery approaches to injection such as liposome encapsulated botulinum toxin to decrease side effects [288]. Neuro-urological patients with an indwelling catheter and concomitant bladder pain and/or catheter bypass leakage could benefit from intravesical botulinum injections [289].

3.4.2.5.6 Bladder neck and urethral procedures

Reduction of the bladder outlet resistance: This may be necessary to protect the UUT. This can be achieved by chemical denervation of the sphincter or by surgical interventions (bladder neck or sphincter incision or urethral stent – Section 3.4.3.1). However, high rates of long-term complications are still noted after the procedures. Patients should be fully aware about the high risk of urinary incontinence which can be the main reason of dissatisfaction although its management with external devices [290] (Section 3.4.2.1).

- *Botulinum toxin A:* This can be used to treat DSD effectively by injecting the sphincter at a dose that depends on the preparation used. An improvement of patient reported outcomes has been described in DSD patients with cervical, incomplete SCI, detrusor overactivity and partial hand function [291]. Detrusor sphincter dyssynergia is abolished only for a few months, necessitating repeat injections. The benefit of this treatment has been reported to be limited with mild AEs [292]. However, a recent SR concluded that, because of limited evidence, future RCTs assessing the effectiveness of botulinum toxin A injections also need to address the uncertainty about the optimal dose and mode of injection [293]. In addition, this therapy is not licensed.

- *Increasing bladder outlet resistance:* This can improve the continence condition. However, despite early positive results with urethral bulking agents, a relative early loss of continence is reported in patients with neuro-urological disorders [134, 294, 295].

- *Urethral inserts:* Urethral plugs or valves for the management of (female) stress incontinence have not been applied in neuro-urological patients. The experience with active pumping urethral prosthesis for treatment of the underactive or acontractile detrusor were disappointing [296].

3.4.2.5.7 Summary of evidence and recommendations for botulinum toxin A injections

Summary of evidence	**LE**
Botulinum toxin A has been proven effective in patients with neuro-urological disorders due to MS or SCI in multiple RCTs and meta-analyses.	1a

Recommendations	**Strength rating**
Use botulinum toxin injection in the detrusor to reduce neurogenic detrusor overactivity in multiple sclerosis or spinal cord injury patients if antimuscarinic therapy is ineffective.	Strong

*3.4.3 **Surgical treatment***

There is considerable heterogeneity in outcome parameters and definitions of cure used to report on outcomes of surgical interventions for SUI in neuro-urological patients [297]. The heterogeneity of outcome reporting makes it difficult to interpret and compare different studies and therapies. A consistent comparison of the outcomes of therapy can only be made after standardisation of outcome parameters and definitions of cure or success; therefore, it would seem prudent to develop a core outcome set (COS) for use in UI research in neuro-urological patients [297]. Until such a COS is developed it would seem feasible to use both a subjective and objective outcome parameter and the combination of both to define cure [297]. Due to the importance of QoL for neuro-urological patients a disease-specific QoL questionnaire or a validated bother questionnaire validated for neuro-urological patients should be used as the subjective outcome parameter [297].

3.4.3.1 Bladder neck and urethral procedures to improve neurogenic stress urinary incontinence

Procedures to treat neurogenic stress urinary incontinence (N-SUI) are suitable only when the risk for upper urinary tract deterioration and detrusor pressures can be controlled. A simultaneous therapy of bladder management may be necessary [298].

- *Urethral sling:* Various materials have been used for this procedure with enduring positive results. The procedure is established in women with the ability to self-catheterise [298-303]. There is growing evidence that female synthetic mid-urethral slings (MUS) can be used effectively with acceptable medium to long-term results and minimal morbidity in neuro-urological patients [300, 301]. Autologous pubovaginal sling has been considered the procedure of choice for treating female N-SUI and it should be preferred when concomitant bladder augmentation is also indicated [300]. Compared to transobturator, the retropubic route has been suggested to be more effective in women with N-SUI [301]. However, either for both synthetic MUS as well as autologous sling additional bladder management may become necessary due to the risk of "*de novo*" LUTS [300-302]. Complications include the need to perform IC especially after retropubic approach, mesh erosion or extrusion requiring partial or total removal, and retropubic haematoma and the 5-year failure rate is relevant [300, 301]. In men, both autologous and synthetic slings have been investigated less frequently compared to women and mainly in patients already on IC regimen before surgery [300]. The cure rate ranged from 29% to 71% at a follow-up of 12 to 36 months. Complications included haematoma, tape infection or erosion into urethra and difficulty to perform IC [300].

- *Artificial urinary sphincter (AUS):* This device was introduced by Light and Scott for male patients with N-SUI [304]. It has stood the test of time and acceptable long-term outcomes can be obtained [305]. Implantation of AUS is the most often performed procedure for N-SUI especially in men with a high success/improvement rate [300]. However, the complication and re-operation rates are higher than in non-neurogenic SUI (up to 60%), so it is advisable that patients are conscientiously informed about the success rates as well as the possible need for re-intervention [306, 307]. In a case series with 25 years follow-up only 7.1% of patients were revision free at twenty years [308]. Re-interventions are commonly due to mechanical failure, urethral atrophy or erosion and infection. There is growing interest in the use of this device with development of laparoscopic and robot-assisted approaches via an anterior or a posterior access to the bladder neck [309, 310]. Nonetheless, careful patient selection and appropriate preoperative investigation are crucial [310]. Although from a single institution series, long-term surgical results are now available and support the potentially prominent role of AUS placement in female patients with N-SUI [300, 311-313]. Long-term surgical and patient-reported outcomes are needed to determine the role of AUS placement in female patients with N-SUI [311].

- *Adjustable continence device – (inflatable balloons):* The efficacy of this device has been reported mainly in post-prostatectomy incontinence (non-neurogenic male lower urinary tract symptoms EAU guidelines – Section 5.6.5.3.2). A similar cure and improvement rate has been reported in neurological patients when compared to non-neurological patients [314, 315]. However, it is associated with a low safety profile due to the high complication and limited device survival rate [316].

- *Bladder neck and urethra reconstruction:* The classical Young-Dees-Leadbetter procedure [317] for bladder neck reconstruction in children with bladder exstrophy, and Kropp urethra lengthening [318] improved by Salle [319], are established methods to restore continence provided that IC is practiced and/or bladder augmentation is performed [134, 320].

Endoscopic techniques for treating anatomic bladder outlet obstruction [321]:

- *Transurethral resection of the prostate* is indicated in male patients with refractory LUT symptoms due to benign prostatic obstruction. Special consideration should be given to pre-operative abnormal sphincter function and the type of neurological disease, which can lead to persistent or "*de novo*" LUTS [322, 323].

- *Urethrotomy* is indicated in patients with urethral strictures. Cold knife or neodymium:YAG contact laser urethrotomy at the twelve o'clock position can be performed [324, 325].

- *Urethroplasty* should be performed on an individual basis depending on the urethral lesion (erosion, stricture, diverticula, fistula), length and location. However urethral surgery in neurological patients has a high failure rate and in recurrent strictures, urinary diversion should be considered [326].

- *Sphincterotomy* has been shown to be an efficient technique for the resolution of AD, hydronephrosis and recurrent UTI, and for decreasing detrusor pressure, PVR and vesicoureteral reflux. It is irreversible and should be limited to men who are able to wear a condom catheter. By staged incision, bladder outlet resistance can be reduced without completely losing the closure function of the urethra [133, 134, 327]. The incision with less complications, is the twelve o'clock sphincterotomy with cold knife [328] or neodymium:YAG laser [329]. Sphincterotomy needs to be repeated at regular intervals in many patients [330], but it is efficient and does not cause severe adverse effects [133, 331]. Secondary narrowing of the bladder neck may occur, for which combined bladder neck incision might be considered [332].

- *Bladder neck incision:* This may be indicated for anatomical or functional bladder neck obstruction [290, 293, 321, 323].

- *Stents:* Implantation of urethral stents results in continence being dependent on adequate closure of the bladder neck [134]. The results are comparable with sphincterotomy and the stenting procedure has a shorter duration of surgery and hospital stay [333, 334]. However, the costs [133], possible complications and re-interventions [335, 336] are limiting factors in their use [337-340].

3.4.3.2 Denervation, deafferentation, sacral neuromodulation

Sacral anterior root stimulation (SARS) is aimed at producing detrusor contraction. The technique was developed by Brindley [341] and is only applicable to complete lesions above the implant location, as its stimulation amplitude is over the pain threshold. The urethral sphincter efferents are also stimulated, but because the striated muscle relaxes faster than the smooth muscle of the detrusor, so-called "post-stimulus voiding" occurs. This approach has been successful in highly selected patients [342-345]. Although it has been shown that detrusor pressure during SARS decreases over time, the changes do not seem to be clinically relevant during the first decade after surgery [346]. By changing the stimulation parameters, this method can also induce defecation or erection. A recent study reported that Charcot spinal arthropathy should be considered as a potential long-term complication of SARS, leading to spinal instability and to SARS dysfunction [347].

Sacral rhizotomy, also known as sacral deafferentation, has achieved some success in reducing NDO [348-350], but nowadays, it is used mostly as an adjuvant to SARS [342, 351-354]. Alternatives to rhizotomy are sought in this treatment combination [355-357].

There is growing evidence, including one RCT [358], on the use of sacral neuromodulation for treating neuro-urological symptoms, but due to the paucity of disease specific studies it remains unclear which neurological patients are most suitable [359-361]. MS patients with NDO have been often reported as good responders to several types of neuromodulations [361-363]. The neuromodulation effect on urodynamic parameters is still unclear [364]. With the development of MRI-compatible pulse generators and leads, the avoidance of this procedure in patients needing this imaging technique for their follow-up is no longer required.

Other neuromodulation techniques like the deep brain stimulation in PD patients may have beneficial effects in the LUT but these depend on the site of stimulation and although prospective, specifically designed studies are needed in neuro-urological patients [365, 366].

3.4.3.3 Bladder covering by striated muscle

When the bladder is covered by striated muscle, that can be stimulated electrically, or ideally that can be contracted voluntarily, voiding function can be restored to an acontractile bladder. The rectus abdominis [367] and latissimus dorsi [368] have been used successfully in neuro-urological patients [369, 370].

3.4.3.4 Bladder augmentation

The aim of auto-augmentation (detrusor myectomy) is to reduce NDO or improve bladder compliance. The advantages are low surgical burden, low rate of long-term adverse effects, positive effect on patient QoL, and it does not preclude further interventions [133, 298, 371-374].

Replacing or expanding the bladder by intestine ensures a low-pressure reservoir improving bladder compliance and abolishing or at least reducing NDO [375, 376]. Improved QoL and stable renal function has been reported during long-term follow-up in SCI and SB patients [377-379]. It is not clear whether augmented cystoplasty should be combined with simultaneous ureter reimplantation when high grade VUR is present [379, 380]. Patients performing IC with augmented cystoplasty had better urinary function and satisfaction with their urinary symptoms compared to patients performing IC with or without botulinum toxin treatment [381]. Long-term complications includes bladder perforation (1.9%), mucus production (12.5%), metabolic abnormalities (3.35%), bowel dysfunction (15%), and stone formation (10%) [377].

The procedure should be used with caution in neuro-urological patients but may become necessary if all less-invasive treatment methods have failed. Special attention should be paid to patients with pre-operative renal scars since metabolic acidosis can develop [382]. Supratrigonal cystectomy [376, 383], is indicated in patients with a severely thick and fibrotic bladder wall. Intermittent catheterisation may become necessary after this procedure. The long-term scientific evidence shows that bladder augmentation is a highly successful procedure that stabilises renal function and prevents anatomical deterioration; however, lifelong follow-up is essential in this patient group given the significant morbidity associated with this procedure [377, 384, 385].

3.4.3.5 Urinary diversion

When no other therapy is successful, urinary diversion must be considered for the protection of the UUT [298].

Continent diversion: This should be the first choice for urinary diversion. Patients with limited dexterity or anatomical barriers (e.g., urethral strictures, women with poor mobility and/or obesity) may prefer a stoma instead of using the urethra for catheterisation. For cosmetic reasons, the umbilicus is often used for the stoma site [386-392]. A SR of the literature concluded that continent catheterisable tubes/stomas are an effective treatment option in neuro-urological patients unable to perform intermittent self-catheterisation through the urethra [393]. The positive impact on QoL comprised sexual life improvement, better body image, high satisfaction rates in urologic management, independence, time saved on catheterisation, and better capacity to perform daily activity and work [394]. However, the complication rates were significant with 85/213 post-

operative events requiring re-operation [393]. Tube stenosis occurred in 4-32% of the cases. Complications related to concomitant procedures (augmentation cystoplasty, pouch) included neovesicocutaneous fistulae (3.4%), bladder stones (20-25%), and bladder perforations (up to 40% in one case series) [393].

Incontinent diversion: If catheterisation is impossible, incontinent diversion with a urine-collecting device is indicated. Ultimately, it could be considered in selected patients with intractable and untreatable incontinence, in patients with LUT destruction, when the UUT is severely compromised, and in patients who refuse other therapy [134]. An ileal segment is used for the diversion in most cases [134, 395-398]. Patients gain better functional status and QoL after surgery [399]. Moreover, to achieve a high satisfaction rate, it is necessary to involve relatives and caregivers with stoma management. Concomitant cystectomy to avoid pyocystitis may be advisable [400]. All procedures can be done open, laparoscopically as well as robotically [401-403]. However, prospective comparative studies are lacking [402, 404].

Undiversion: Long-standing diversions may be successfully undiverted or an incontinent diversion changed to a continent one with the emergence of new and better techniques for control of detrusor pressure and incontinence [134]. The patient must be carefully counselled and must comply meticulously with the instructions [134]. Successful undiversion can then be performed [405].

In a prospective observational study (n=1,479), QoL was investigated in neuro-urological patients using four different bladder management options. It is the first study to focus on PROMS and noted that surgery was associated with fewer bladder management difficulties and a better QoL [61].

3.4.3.6 Summary of evidence and recommendations for surgical treatment

Summary of evidence	**LE**
Bladder augmentation is an effective option to decrease detrusor pressure and increase bladder capacity, when all less-invasive treatment methods have failed.	3
Urethral sling placement is an established procedure, with acceptable mid- to long-term results, in women with the ability to self-catheterise.	3
Artificial urinary sphincter insertion is the most frequently offered option to treat neurogenic SUI with acceptable long-term outcomes, in males. The complication and re-operation rates are higher in neuro-urological patients; therefore, patients must be adequately informed regarding the success rates as well as the complications that may occur following the procedure.	3
Sacral neuromodulation is an effective and safe option in the treatment of selective neurogenic LUT dysfunction.	1b

Recommendations	**Strength rating**
Offer bladder augmentation in low bladder compliance and/or refractory neurogenic detrusor overactivity.	Strong
Place an autologous urethral sling as first-line treatment in female patients with neurogenic stress urinary incontinence (SUI) who are able to self-catheterise.	Strong
Place a synthetic urethral sling, as an alternative to autologous urethral slings, in selected female patients with neurogenic SUI who are able to self-catheterise.	Weak
Insert an artificial urinary sphincter in selected female patients with neurogenic SUI; however, patients should be referred to experienced centres for the procedure.	Weak
Insert an artificial urinary sphincter in male patients with neurogenic SUI.	Strong
Consider sacral neuromodulation in selected neuro-urological patients.	Strong

3.5 Urinary tract infection in neuro-urological patients

3.5.1 Epidemiology, aetiology and pathophysiology

Urinary tract infection is the onset of signs and/or symptoms accompanied by laboratory findings of a UTI (bacteriuria, leukocyturia and positive urine culture) [387]. There are no evidence-based cut-off values for the quantification of these findings [406]. The published consensus is that a significant bacteriuria in persons performing IC is present with > 102 cfu/mL, > 104 cfu/mL in clean-void specimens and any detectable concentration in suprapubic aspirates. Regarding leukocyturia, ten or more leukocytes in centrifuged urine samples per microscopic field (400x) are regarded as significant [387].

The pathogenesis of UTI in neuro-urological patients is multifactorial. Male gender seems to be a risk factor for febrile and recurrent UTIs [407, 408]. Several etiological factors have been described: altered intrinsic defence mechanisms, impaired washout and catheterisation [409-412]. Poor glycemic control has also been established as a risk factor for UTI in women with type 1 diabetes [413]. However, the exact working mechanisms remain unknown. The presence of asymptomatic bacteriuria in SCI patients is higher than in the general population and varies depending on bladder management. Prevalence of bacteriuria in those performing clean IC varies from 23%-89% [414]. Sphincterotomy and condom catheter drainage has a 57% prevalence [415]. Asymptomatic bacteria should not be routinely screened for in this population [416] but a nomogram can be a helpful tool for early prediction of UTIs [417].

Individuals with neuro-urological symptoms, especially those with SCI, may have other signs and symptoms in addition to or instead of traditional signs and symptoms of a UTI in able-bodied individuals [418]. Other problems, such as AD, may develop or worsen due to a UTI [244]. The most common signs and symptoms suspicious of a UTI in those with neuro-urological disorders are fever, new onset or increase in incontinence, including leaking around an indwelling catheter, increased spasticity, malaise, lethargy or sense of unease, cloudy urine with increased urine odour, discomfort or pain over the kidney or bladder, dysuria, or AD [244, 419]. New incontinence is the most specific symptom, whereas cloudy and foul-smelling urine has the highest positive predictive value for UTI diagnosis [420].

*3.5.2 **Diagnostic evaluation***

Urine culture and urinalysis are the optimum tests for the diagnosis of UTI in neuro-urological patients. A dipstick test is more useful to exclude rather than to prove UTI [421, 422] and is not recommended. As bacterial strains and resistance patterns in persons with neuro-urological disorders may differ from those of able-bodied patients, microbiologic testing is mandatory [423].ro-urological disorders may differ from those of able-bodied patients, microbiologic testing is mandatory [400].

*3.5.3 **Disease management***

Bacteriuria in patients with neuro-urological disorders should not be treated. Treatment of asymptomatic bacteriuria results in significantly more resistant bacterial strains without improving the outcome [424]. Urinary tract infections in persons with neuro-urological disorders are by definition a complicated UTI; therefore, single-dose treatment is not advised. There is no consensus in the literature about the duration of treatment as it depends on the severity of the UTI and the involvement of the kidneys and the prostate. Generally, a five to seven day course of antibiotic treatment is advised, which can be extended up to fourteen days according to the extent of the infection [424]. The choice of antibiotic therapy should be based on the results of the microbiologic testing. If immediate treatment is mandatory (e.g., fever, septicaemia, intolerable clinical symptoms, extensive AD), the choice of treatment should be based on local and individual resistance profiles, as well as on results from previous urine cultures [425]. In patients with afebrile UTI, an initial non-antibiotic treatment may be justified [426, 427].

3.5.3.1 Recurrent UTI

Recurrent UTI in patients with neuro-urological disorders may indicate suboptimal management of the underlying functional problem, e.g., high bladder pressure during storage and voiding, incomplete voiding or bladder stones. The improvement of bladder function, by treating NDO by botulinum toxin A injection in the detrusor [428], and the removal of bladder stones or other direct supporting factors, especially indwelling catheters, as early as possible, are mandatory [423].

3.5.3.2 Prevention

If the improvement of bladder function and removal of foreign bodies/stones is not successful, additional UTI prevention strategies should be utilised. In a meta-analysis the use of hydrophilic catheters was associated with a lower rate of UTI [244].

Various medical approaches have been tested for UTI prophylaxis in patients with neuro-urological disorders. The benefit of cranberry juice or probiotics for the prevention of UTI could not be demonstrated in RCTs [429, 430]. Methenamine hippurate is not effective in individuals with neuro-urological symptoms [431]. There is no sufficient evidence to support the use of L-methionine for urine acidification to prevent recurrent UTIs [432]. There is only weak evidence that oral immunotherapy reduces bacteriuria in patients with SCI [433] and that recurrent UTIs are reduced [434]. Low-dose, long-term, antibiotic prophylaxis can reduce UTI frequency, but increases bacterial resistance and is therefore not recommended [435].

Weekly cycling of antibiotic prophylaxis provided long-term positive results, but the results of this trial need to be confirmed in further studies [436]. Another possible future option, the inoculation of apathogenic Escherichia coli strains into the bladder, has provided positive results in initial studies, but because of the paucity of data [437], cannot be recommended as a treatment option. There is initial evidence that homeopathic treatment can decrease UTI frequency [438].

The use of daily intravesical iodine washouts shows promising results for reduction of symptomatic UTIs and hospitalisation without increase in multi drug resistance in patients with NLUTD who perform IC [439] Other intravesical agents have also been trialed for the reduction of UTIs, both antimicrobial and non. Intravesical gentamicin has been shown to reduce UTIs and oral antibiotic use, without increasing antimicrobial resistance [435, 440]. Intravesical hyaluronic acid was also reported in this metanalysis to reduce mean number of UTIs [441].

In summary, based on the criteria of evidence-based medicine, there is currently no preventive measure for recurrent UTI in patients with neuro-urological disorders that can be recommended without limitations. Therefore, individualised concepts should be taken into consideration, including immunostimulation, phytotherapy and complementary medicine [442]. Prevention of UTIs in patients with neuro-urological disorders is important to pursue, but since there are no data favouring one approach over another, prophylaxis is essentially a trial-and-error approach.

*3.5.4 **Summary of evidence and recommendations for the treatment of UTI***

Summary of evidence	**LE**
Treatment of asymptomatic bacteriuria results in significantly more resistant bacterial strains without improving patient outcome.	1a
Low-dose, long-term, antibiotic prophylaxis can reduce UTI frequency, but increases bacterial resistance.	2a
Recurrent UTIs in patients with neuro-urological disorders may indicate suboptimal management of the underlying functional problem. Improvement of bladder function as early as possible is mandatory.	3
There is currently no preventive measure for recurrent UTI in patients with neuro-urological disorders that can be recommended without limitations.	3

Recommendations	**Strength rating**
Do not use dipstick urine analysis to screen for urinary tract infection (UTI) in neuro-urological patients.	Strong
Do not screen for or treat asymptomatic bacteriuria in patients with neuro-urological disorders.	Strong
Avoid the use of long-term antibiotics for recurrent UTIs.	Strong
In patients with recurrent UTIs, optimise treatment of neuro-urological symptoms and remove foreign bodies (e.g., stones, indwelling catheters) from the urinary tract.	Strong
Individualise UTI prophylaxis in patients with neuro-urological disorders as there is no optimal prophylactic measure available.	Strong

3.6 Sexual function and fertility

This section specifically focuses on sexual dysfunction and infertility in patients with a neurological disease [443, 444]. Non-neurogenic, male sexual dysfunction and infertility are covered in separate EAU Guidelines [445, 446]. In neuro-urological patients sexual problems can be identified at three levels: primary (direct neurological damage), secondary (general physical disabilities) and tertiary (psychosocial and emotional issues) sexual dysfunction [447]. Adopting a systematic approach, such as the PLISSIT model (Permission, Limited Information, Specific Suggestions and Intensive Therapy) [448], provides a framework for counselling and treatment involving a stepwise approach to the management of neurogenic sexual dysfunction. Sexual dysfunction is associated with neurogenic LUT dysfunction in patients with MS [449] and SB [450]. Although various PROMs are available to evaluate sexual function, the evidence for good PROMs is limited and studies with high methodological quality are needed [77].

3.6.1 ***Erectile dysfunction***

3.6.1.1 Phosphodiesterase type 5 inhibitors (PDE5Is)

Phosphodiesterase type 5 inhibitors (PDE5Is) are recommended as first-line treatment in neurogenic ED [443, 444]. In SCI patients, tadalafil, vardenafil and sildenafil have all improved retrograde ejaculation and improved erectile function and satisfaction on IIEF-15. Tadalafil 10 mg was shown to be more effective than sildenafil 50 mg. All currently available PDE5Is appear to be effective and safe, although there are no high-level evidence studies in neuro-urological patients investigating the efficacy and side effects across different PDE5Is, dosages and formulations [451].

For MS patients two studies reported significant improvement in ED when using sildenafil and tadalafil [444, 452] however, another study showed no improvement in ED with sildenafil [453]. One study found a significant improvement in ED in SB patients when using sildenafil [454].

In PD normal erectile function was described in over half of the patients using sildenafil 100 mg and a significant improvement in IIEF-15 score was found compared to placebo. While most neuro-urological patients require long-term therapy for ED some have a low compliance rate or stop therapy because of side effects [455, 456], most commonly headache and flushing [444]. In addition, PDE5Is may induce relevant hypotension in patients with tetraplegia/high-level paraplegia and multiple system atrophy [455, 456]. As a prerequisite for successful PDE5I-therapy, some residual nerve function is required to induce erection. Since many patients with SCI use on-demand nitrates for the treatment of AD, they must be counselled that PDE5Is are contraindicated when using nitrate medication.

3.6.1.2 Drug therapy other than PDE5Is

Fampridine to treat neurogenic spasticity has been shown to be beneficial in improving ED in two domains of the IIEF-15 in SCI and MS patients, however, with a significant discontinuation rate due to severe adverse events [457]. Sublingual apomorfine was shown to have poor results on ED in SCI patients and side-effects in half of the patients [458]. In PD, pergolide mesylate showed a significant improvement in IIEF-15 scores up to twelve months follow-up [459].

3.6.1.3 Mechanical devices

Mechanical devices (vacuum tumescence devices and penile rings) may be effective but are less popular [460-464].

3.6.1.4 Intracavernous injections and intraurethral application

Patients not responding to oral drugs may be offered intracavernous injections (alprostadil, papaverine and phentolamine) that have been shown to be effective in a number of neurological conditions, including SCI, MS, and diabetes mellitus [465-471], but their use requires careful dose titration and some precautions. Complications of intracavernous drugs include pain, priapism and corpora cavernosa fibrosis.

Intracavernous vasoactive drug injection is the first-line therapeutic option in patients taking nitrate medications, as well as those with concerns about drug interactions with PDE5Is, or in whom PDE5Is are ineffective. The impact of intracavernous injections on ejaculation and orgasmic function, their early use for increasing the recovery rate of a spontaneous erection, and their effectiveness and tolerability in the long-term are unclear [455]. Intra-urethral alprostadil application is an alternative, but less effective, route of administration [467, 472].

3.6.1.5 Sacral neuromodulation

Sacral neuromodulation for LUT dysfunction may improve sexual function; however, high level evidence studies are lacking.

3.6.1.6 Penile prostheses

Penile prostheses may be considered for treatment of neurogenic ED when all conservative treatments have failed. At a mean follow-up of seven years, 83.7% of patients with SCI were able to have sexual intercourse [444]. Serious complications, including infection and prosthesis perforation, may occur in about 10% of patients, depending on implant type [473-475].

3.6.1.7 Summary of evidence and recommendations for erectile dysfunction

Summary of evidence	LE
The long-term efficacy and safety of oral PDE5Is for the treatment of ED is well documented.	1b
Intracavernous vasoactive drug injections have been shown to be effective in a number of neurological conditions, including SCI and MS; however, their use requires careful dose titration and precautions.	3
Mechanical devices (vacuum tumescence devices and penile rings) may be effective but are less popular.	3
Reserve penile prostheses for selected patients, those in which all conservative treatments have failed, with neurogenic ED.	4

Recommendations	Strength rating
Prescribe oral phosphodiesterase type 5 inhibitors as first-line medical treatment in neurogenic erectile dysfunction (ED).	Strong
Give intracavernous injections of vasoactive drugs (alone or in combination) as second-line medical treatment in neurogenic ED.	Strong
Offer mechanical devices such as vacuum devices and rings to patients with neurogenic ED.	Strong

*3.6.2 **Male fertility***

Male fertility can be compromised in the neurological patient by ED, ejaculation disorder, impaired sperm quality or various combinations of these three disorders. Among the major conditions contributing to neurogenic infertility are pelvic and retroperitoneal surgery, diabetes mellitus, SB, MS and SCI [476]. Erectile dysfunction is managed as described previously. Retrograde ejaculation may be reversed by sympathomimetic agents contracting the bladder neck, including imipramine, ephedrine, pseudoephedrine, and phenylpropanolamine [476]. The use of a balloon catheter to obstruct the bladder neck may be effective in obtaining antegrade ejaculation [477]. If antegrade ejaculation is not achieved, the harvest of semen from the urine may be considered [478].

Prostatic massage is safe and easy to use for obtaining semen in men with lesions above Th 10 [479]. In several patients, vibrostimulation or transrectal electroejaculation are needed for sperm retrieval [476, 480, 481]. Semen retrieval is more likely with vibrostimulation in men with lesions above Th 10 [482-484]. In men with SCI, especially at or above Th 6, AD might occur during sexual activity and ejaculation [485, 486]; patients at risk and fertility clinics must be informed and aware of this potentially life-threatening condition. In SCI patients the use of oral midodrine can improve sperm retrieval at vibrostimulation [487].

In men with MS, use of disease modifying drugs during the conception phase, has not been associated with altered pregnancy outcomes [488]. Surgical procedures, such as, microsurgical epididymal sperm aspiration or testicular sperm extraction, may be used if vibrostimulation and electroejaculation are not successful [489, 490]. Pregnancy rates in patients with SCI are lower than in the general population, but since the introduction of intracytoplasmic sperm injection, men with SCI now have a good chance of becoming biological fathers [491-493].

3.6.2.1 Sperm quality and motility

The following has been reported on sperm quality and motility:

- bladder management with clean IC may improve semen quality compared to indwelling catheterisation, reflex voiding or bladder expression [494];
- in SCI patients sperm quality decreases at the early post-traumatic phase demonstrating lower spermatozoid vitality (necrospermia), reduced motility (asthenospermia) and leucospermia [489];
- long-term valproate treatment for epilepsy negatively influences sperm count and motility [495];
- vibrostimulation produces samples with better sperm motility than electrostimulation [496, 497];
- electro-ejaculation with interrupted current produces better sperm motility than continuous current [498];
- freezing of sperm is unlikely to improve fertility rates in men with SCI [499].

3.6.2.2 Summary of evidence and recommendations for male fertility

Summary of evidence	LE
Vibrostimulation and transrectal electroejaculation have been shown to be effective for sperm retrieval in neuro-urological patients.	1b
Surgical procedures, such as, microsurgical epididymal sperm aspiration or testicular sperm extraction, may be used if vibrostimulation and electroejaculation are not successful.	3
In men with SCI at or above Th 6, AD might occur during sexual activity and ejaculation.	3

Recommendations	Strength rating
Perform vibrostimulation and transrectal electroejaculation for sperm retrieval in men with spinal cord injury.	Strong
Perform microsurgical epididymal sperm aspiration, testicular sperm extraction and intracytoplasmic sperm injection after failed vibrostimulation and/or transrectal electroejaculation in men with spinal cord injury.	Strong
Counsel men with spinal cord injury at or above Th 6 and fertility clinics about the potentially life-threatening condition of autonomic dysreflexia.	Strong

3.6.3 Female sexuality

The most relevant publications on neurogenic female sexual dysfunction are in women with SCI and MS, while there is only limited evidence for women with stroke and SB. After SCI, about 65-80% of women continue to be sexually active, but to a much lesser extent than before the injury, and about 25% report a decreased satisfaction with their sexual life [500-502]. Although sexual dysfunction is very common in women with MS, it is still often overlooked by medical professionals [503, 504]. A vast majority of female SB patients showed sexual dysfunction [505] and considered information about sexuality from their physicians insufficient [506]. Women with SCI reported dissatisfaction with the quality and quantity of sexuality-related rehabilitation services and were less likely to receive sexual information than men [507-509]. Similarly, majority of female stroke patients are not sexually satisfied [510].

The greatest physical barrier to sexual activity is UI. A correlation has been found between the urodynamic outcomes of low bladder capacity, compliance and high maximum detrusor pressure and sexual dysfunction in MS patients. Problems with positioning and spasticity affect mainly tetraplegic patients. Peer support may help to optimise the sexual adjustment of women with SCI in achieving a more positive self-image, self-esteem and feelings of being attractive to themselves and others [500, 511-513].

The use of specific drugs for sexual dysfunction is indicated to treat inadequate lubrication. Data on sildenafil for treating female sexual dysfunction are poor and controversial [444]. Although good evidence exists that psychological interventions are effective in the treatment of female hypoactive sexual desire disorder and female orgasmic disorder [514], there is a lack of high-level evidence studies in the neurological population.

Neurophysiological studies have shown that women with the ability to perceive Th 11-L2 pin-prick sensations may have psychogenic genital vasocongestion. Reflex lubrication and orgasm are more prevalent in women with SCI who have preserved the sacral reflex arc (S2-S5), even when it has not been shown in an individual woman that a specific level and degree of lesion is the cause of a particular sexual dysfunction. In SCI women with a complete lesion of the sacral reflex, arousal and orgasm may be evoked through stimulation of other erogenous zones above the level of lesions [507, 515, 516].

Sacral neuromodulation for LUT dysfunction may improve sexual function but high-evidence studies are lacking [444].

3.6.4 Female fertility

There are few studies on female fertility in neurological patients. More than a third (38%) of women with epilepsy had infertility and the relevant predictors were exposure to multiple (three or more) antiepileptic drugs, older age and lower education [517].

Although it seems that the reproductive capacity of women with SCI is only temporarily affected by SCI with cessation of menstruation for approximately six months after SCI [518], there are no high-level evidence studies. About 70% of sexually active women use some form of contraception after injury, but fewer women use the birth control pill compared to before their injury [519].

Women with SCI are more likely to suffer complications during pregnancy, labour and delivery compared to able-bodied women. Complications of labour and delivery include bladder problems, spasticity, pressure sores, anaemia, and AD [520-524]. Obstetric outcomes include higher rates of Caesarean sections and an increased incidence of low birth-weight babies [519, 522-524].

Epidural anaesthesia is chosen and effective for most patients with AD during labour and delivery [525, 526].

There is very little published data on women's experience of the menopause following SCI [527]. Women with MS who plan a pregnancy should evaluate their current drug treatment with their treating physician [528-530]. Clinical management should be individualised to optimise both the mother's reproductive outcomes and MS course [528, 529, 531].

3.6.4.1 Summary of evidence and recommendation for female sexuality and fertility

Summary of evidence	**LE**
Data on specific drugs for treating female sexual dysfunction are poor and controversial.	4
There are limited numbers of studies on female fertility in neurological patients, clinical management should be individualised to optimise both the mother's reproductive outcomes and medical condition.	4

Recommendations	**Strength rating**
Do not offer medical therapy for the treatment of neurogenic sexual dysfunction in women.	Strong
Take a multidisciplinary approach, tailored to individual patient's needs and preferences, in the management of fertility, pregnancy and delivery in women with neurological diseases.	Strong

3.7 Follow-up

*3.7.1 **Introduction***

Neuro-urological disorders are often unstable, and the symptoms may vary considerably, even within a relatively short period. Regular follow-up is therefore necessary to assess the UUT [132].

Depending on the type of the underlying neurological pathology and the current stability of the neuro-urological symptoms, the interval between initial investigations and control diagnostics may vary and, in many cases, should not exceed one to two years. high-risk neuro-urological this interval should be much shorter. The UUT should be checked by ultrasonography at regular intervals in high-risk patients; about once every six months [6, 532]. In these patients, physical examination and urine laboratory should take place every year [6, 532]. In MS patients higher scores on the Expanded Disability Status Scale (EDSS) are associated with risk factors for UUT deterioration [533]. A urodynamic investigation should be performed as a diagnostic baseline, and repeated during follow-up, more frequently in high-risk patients [6, 532]. The bladder diary can aid in detecting MS patients that require urodynamic investigations [534]. In addition, bladder wall thickness can be measured on ultrasonography as an additional risk assessment for upper tract damage [535], although a 'safe' cut-off threshold for this has not been agreed [536]. The utility of DMSA (dimercaptosuccinic acid) for follow-up of neuro-urological patients has not been fully evaluated [537]. Any significant clinical change warrants further, specialised, investigation [6, 532]. However, there is a lack of high level evidence studies on this topic and every recommendation must be viewed critically in each individual neuro-urological patient [132].

The increased prevalence of muscle invasive bladder cancer in neuro-urological patients also warrants long-term follow-up [260]. The exact frequency of cystoscopy with or without cytology remains unknown, but presence of risk factors similar to the general population should trigger further investigation [538].

Adolescent patients with neurological pathology are at risk of being lost to follow-up during the transition to adulthood. It is important that a standardised approach during this transition is adopted to improve follow-up and specific treatment during adult life [539].

3.7.2 Summary of evidence and recommendations for follow-up

Summary of evidence	LE
Neuro-urological disorders are often unstable, and the symptoms may vary considerably; therefore, regular follow-up is necessary.	4

Recommendations	Strength rating
Assess the upper urinary tract at regular intervals in high-risk patients.	Strong
Any significant clinical changes should instigate further, specialised, investigation.	Strong
Perform urodynamic investigation as a mandatory baseline diagnostic intervention in high-risk patients at regular intervals.	Strong

3.8 Conclusions

Neuro-urological disorders have a multifaceted pathology. They require an extensive and specific diagnosis before one can embark on an individualised therapy, which takes into account the medical and physical condition of the patient and the patient's expectations about their future. The urologist can select from a wealth of therapeutic options, each with its own pros and cons. Notwithstanding the success of any therapy embarked upon, close surveillance is necessary for the patient's entire life.

These Guidelines offer you expert advice on how to define the patient's neuro-urological symptoms as precisely as possible and how to select, together with the patient, the appropriate therapy. This last choice, as always, is governed by the golden rule: as effective as needed, as non-invasive as possible.

5. CONFLICT OF INTEREST

All members of the Neuro-urology working group have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website: http://uroweb.org/guideline. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative and travel and meeting expenses. No honoraria or other reimbursements have been provided.

6. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:
EAU Guidelines. Edn. presented at the EAU Annual Congress Paris 2024. ISBN 978-94-92671-23-3.

If a publisher and/or location is required, include:
EAU Guidelines Office, Arnhem, The Netherlands. http://uroweb.org/guidelines/compilations-of-all-guidelines/

References to individual guidelines should be structured in the following way:
Contributors' names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

TABLE OF CONTENTS PAGE

1. INTRODUCTION

1.1 Aims and Objectives

The European Association of Urology (EAU) Sexual and Reproductive Health Guidelines aim to provide a comprehensive overview of the medical aspects relating to sexual and reproductive health in adult men. These Guidelines cover the former EAU Guidelines on Male Sexual Dysfunction, Male Infertility and Male Hypogonadism.

It must be emphasised that guidelines present the best evidence available to the experts. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - while taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel Composition

The EAU Sexual and Reproductive Health Guidelines Panel consists of an international multi-disciplinary group of urologists, endocrinologists and a psychologist. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guideline/sexual-and-reproductive-health/.

1.3 Available Publications

A quick reference document, the Pocket Guidelines, is available. This is an abridged versions that may require consultation together with the full-text version. A number of scientific publications are also available. All documents can be viewed through the EAU website: http://www.uroweb.org/guideline/sexual-and-reproductive-health/.

1.4 Publication History

The EAU Sexual and Reproductive Health Guidelines were first published in 2020. This 2024 document presents a limited update of the 2023 publication.

1.5 Changes in the Guideline for 2024

The 2024 Sexual and Reproductive Health Guidelines have undergone a major revision and restructuring of the full text as well as a review of all recommendations.

2. METHODOLOGY

2.1 Methods

Recommendation within the Guidelines are developed by the panels to prioritise clinically important care decisions. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and the nature and variability of patient values and preferences. This decision process, which can be reviewed in the strength rating forms which accompany each guideline statement, addresses a number of key elements:

1. the overall quality of the evidence which exists for the recommendation [1];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact and certainty of patient values and preferences on the intervention

Strong recommendations typically indicate a high degree of evidence quality and / or a favourable balance of benefit to harm and patient preference. Weak recommendations typically indicate availability of lower quality evidence, and/or equivocal balance between benefit and harm, and uncertainty or variability of patient preference [2].

Additional information can be found in the general Methodology section of this print, and online at the EAU website: http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at this address.

2.2 Review

The EAU Sexual and Reproductive Health Guidelines were peer-reviewed prior to publication in 2020. The new priapism section was reviewed prior to publication in 2021. In 2023 the newly added section on penile size abnormalities and dysmorphophobia was reviewed prior to publication. The Panel would like to acknowledge the contribution of Dr. Miguel Ricou from the Department of Community Medicine, Information and Health Decision Sciences at the Faculty of Medicine, University of Porto, Portugal, for his expertise and time in reviewing the penile size abnormalities and dysmorphophobia section from a bioethics perspective.

3. MALE HYPOGONADISM

3.1 Definition, epidemiology and classification of male hypogonadism

3.1.1 ***Definition***

Male hypogonadism is a clinical syndrome which comprises of symptoms with or without signs and biochemical evidence of testosterone deficiency. Hypogonadism is associated with decreased testicular function and production of androgens and/or impaired sperm production [3]. This may be caused by impaired testicular function (hypergonadotropic hypogonadism or primary hypogonadism) or as a result of inadequate stimulation of the testes by the hypothalamic-pituitary axis (hypogonadotropic hypogonadism or secondary hypogonadism) (Table 1) or uncommonly by reduced ability of testosterone to stimulate the androgen receptor at the cellular level. Hypogonadism can adversely affect multiple organ functions and quality of life (QoL) [3, 4]. This chapter specifically addresses the management of adult male hypogonadism also called late-onset hypogonadism (LOH). Some insights related to congenital or pre-pubertal hypogonadism are also provided.

3.1.2 ***Epidemiology***

The prevalence of LOH increases with age, with the major causes being obesity, other comorbidities (e.g., diabetes) and overall poor health [5]. The incidence of hypogonadism has been reported to be between 12.3 and 11.7 cases per 1,000 people per year [6, 7]. Aging accounts for a low percentage of hypogonadism, as there is only a small gradual decline in testosterone, up to the age of 80 years, in healthy ageing men [5]. In men aged 40-79 years, the incidence of symptomatic hypogonadism varies between 2.1 and 5.7% [6, 8, 9].

There is a high prevalence of LOH within specific populations, including patients with obesity, type 2 diabetes (T2DM), metabolic syndrome (MetS), cardiovascular diseases (CVD), chronic obstructive pulmonary disease (COPD), renal disease and cancer [9]. In particular low testosterone levels are relatively common in men with T2DM [10, 11] and in those with metabolic derangements.

Klinefelter syndrome, a trisomy associated with a 47, XXY karyotype, is the most prevalent genetic cause of primary hypogonadism, with a global prevalence of 1/500-1,000 live male births [12-15]. However, < 50% of individuals with Klinefelter syndrome are diagnosed during their lifetime [16].

3.1.3 ***Classification***

Male hypogonadism can be classified according to the aetiology into primary hypogonadism or secondary hypogonadism (Table 1) [3, 17]. A compensated or subclinical form of hypogonadism, characterised by normal testosterone serum levels and elevated luteinising hormone (LH) production, has also been reported [18]; the clinical significance of this condition is unclear [18-21].

The classification of hypogonadism has also been divided into two broad categories: 'Classical/Organic' and 'Functional, often but not correctly identified as LOH [58]. The clinical effects of testosterone deficiency are however common to all patients independent of the cause of the hypogonadism; although, they may vary in severity or as a result of age of onset (see below). Classical hypogonadism includes: congenital or acquired diseases causing structural and/or irreversible impairment of the pituitary and/or testes. Functional hypogonadism is diagnosed on the absence of any recognised organic alterations in the HPG axis and it is mainly a consequence of comorbidities, affecting the Hypothalamic-Pituitary-Testicular (HPT) axis and should be treated first by resolving or improving any underlying conditions (e.g., anorexia in younger male subjects). Late onset hypogonadism, conversely represents even a broader clinical entity including adulthood onset forms which can have either organic or functional origin and can be primary or secondary [22] (see below). Late onset hypogonadism is frequently diagnosed in the absence of an identifiable classical cause of hypogonadism, which becomes more prevalent with age, usually occurring, but not exclusively, in men aged > 40 years. By definition LOH must comprise both persistent specific symptoms and biochemical evidence of testosterone deficiency [3, 23].

Finally, hypogonadism can also result from several conditions leading to reduced sensitivity/insensitivity to testosterone and its metabolites [3].

The current guidelines maintain a classification of Primary and Secondary Hypogonadism, with special reference to LOH.

The classification, based on the aetiology of hypogonadism, allows clinicians to adequately select appropriate treatment. In patients with secondary hypogonadism, both fertility and testosterone normalisation can be theoretically achieved with adequate treatment, whereas in primary hypogonadism only testosterone therapy can be considered [3, 17] (Table 1). However, it should also be recognised that symptoms and signs of hypogonadism can be similarly independent of the site of origin of the disease. Conversely, the age of onset of hypogonadism can influence the clinical phenotype [24]. Accordingly, early onset, such as that occurring during foetal life, the clinical phenotype can span from an almost complete female phenotype (e.g., complete androgen insensitivity or enzymatic defects blocking androgen synthesis) to various defects in virilisation. In the case of a pre- or peri-pubertal appearance of hypogonadism due to a milder central (isolated hypogonadotropic hypogonadism [IHH]) or a peripheral defect (such as in Klinefelter syndrome), there may be delayed puberty with an overall eunuchoid phenotype. Finally, when hypogonadism arises post-puberty, particularly with advancing age, symptoms may manifest subtly and frequently overlap with the natural ageing process, leading to confusion [24].

Table 1: Classification of male hypogonadism

PRIMARY HYPOGONADISM (hypergonadotropic hypogonadism)	
Congenital or developmental disorders	
Common causes	*Uncommon causes*
• Klinefelter syndrome	• Rare chromosomal abnormalities - (XX male, 47 XYY and 48 XXYY syndrome • 21 Trisomy (Down syndrome) • Noonan syndrome • Autosomal translocations1 • Defects of testosterone biosynthesis • CAH (testicular adrenal rest tumours) • Disorders of sex development (gonadal • dysgenesis) • LHR gene mutations • Myotonic dystrophy (including type I and II) • Uncorrected cryptorchidism (including INSL3 • and LGR8 mutations) • Bilateral congenital anorchia • Sickle cell disease • Adreno-leukodystrophy
Acquired disorders	
Drug-induced	*Localised problems*
• Chemotherapy agents • Alkylating agents • Methotrexate • Testosterone synthesis inhibitors - Ketoconazole, Aminoglutethimide, Mitotane and Metyrapon	• Bilateral surgical castration or trauma • Testicular irradiation • Orchitis (including mumps orchitis) • Autoimmune testicular failure • Testicular Torsion • Alcohol/Cirrhosis • Environmental Toxins
Systemic diseases/conditions with hypothalamus/pituitary impact	
• Chronic systemic diseases* • Chronic organ failure* • Glucocorticoid excess (Cushing syndrome)* • Ageing* • HIV	• Malignancies – Lymphoma and Testis cancer • Spinal cord injury • Vasculitis • Infiltrative diseases (amyloidosis; leukaemia)

SECONDARY HYPOGONADISM (hypogonadotropic hypogonadism)	
Congenital or developmental disorders	
Common causes	*Uncommon causes*
• Haemochromatosis*	• Combined hormone pituitary deficiency • Idiopathic hypogonadotropic hypogonadism • IHH with variants: Normosmic IHH, Kallmann syndrome, isolated LH β gene mutations and Prader-Willi syndrome
Acquired disorders	
Drug-induced	*Localised problems*
• Oestrogens • Testosterone or androgenic anabolic steroids • Progestogens (including cyproterone acetate) • Hyperprolactinemia-induced drugs • Opiates - GnRH agonist or antagonist and glucocorticoids	• Traumatic brain injury • Pituitary neoplasm (micro/macro-adenomas) • Hypothalamus tumours • Pituitary stalk diseases • Iatrogenic - surgical hypophysectomy and pituitary or cranial irradiation • Inflammatory and infectious diseases -lymphocytic hypophysitis; pituitary infections; granulomatous lesions; sarcoidosis; Wegener's granulomatosis; other granulomatosis and encephalitis • Langerhans' histiocytosis • Hyperprolactinaemia, as a consequence of localised problems (hypothalamus-pituitary mass)
Systemic diseases/conditions impacting the hypothalamus/pituitary	
• Chronic systemic diseases* - Type 2 diabetes mellitus/Metabolic Syndrome/metabolic diseases; HIV infection; chronic organ failure; and chronic Inflammatory Arthritis • Glucocorticoid excess (Cushing syndrome)* • Eating disorders* • Endurance exercise • Acute and critical illness • Ageing*	• Spinal cord injury • Transfusion-related iron overload (β-thalassemia)
ANDROGEN RESISTANCE/DECREASED TESTOSTERONE BIOACTIVITY	
Congenital or developmental disorders	
• Aromatase deficiency • Kennedy diseases (spinal and bulbar muscular atrophy) and other extensions of CAG repeats • Partial or complete androgen insensitivity • 5α reductase type II (5aR) deficiency	
Acquired disorders	
Drug-induced	*Localised problems*
• Drug-induced AR blockage - steroidal antiandrogen, cyproterone acetate and spironolactone • Non-steroidal antiandrogen – flutamide, bicalutamide and nilutamide • Drug-induced 5α reductase (5aR) activity blockade – finasteride and dutasteride • Drug-induced ER blockade – clomiphene, tamoxifen and raloxifene • Drug-induced aromatase activity blockade – letrozole, anastrozole and exemestane • Increased Sex Hormone Binding Globulin (SHBG)	• Coeliac disease

** Conditions acting at central and peripheral levels resulting in either primary and secondary hypogonadism.*

[1] Different autosomal translocations can cause rare cases of hypogonadism and infertility.

A brief discussion on the physiology of testosterone production can be found in Appendix 1, online supplementary evidence.

3.2 Comorbidities associated with male hypogonadism

3.2.1 ***Obesity***

Low testosterone levels are common in men with obesity. Male hypogonadism is associated with a greater percentage of fat mass and a lower lean mass compared to men with adequate testosterone levels [25, 26]. Low levels of testosterone are strongly linked to heightened visceral adiposity. Additionally, they result in lipid accumulation in the liver and muscle, correlating with atherosclerosis [25, 26].

3.2.2 ***Metabolic Syndrome/Type 2 Diabetes***

Hypogonadism is frequently associated with MetS or its related components, including central obesity, hyperglycaemia, insulin resistance and dyslipidaemia and arterial hypertension [27].

Several randomised controlled trials (RCTs) have demonstrated that testosterone therapy may improve insulin resistance and hyperglycaemia and lower total and low-density protein
(LDL) cholesterol [28-33]. Testosterone therapy in hypogonadal T2DM improved glycaemic control in some RCTs and registry trials; however, there is no conclusive evidence [29, 34, 35]. A large placebo-controlled RCT, including 1,007 patients with impaired glucose tolerance or newly-diagnosed T2DM and total testosterone < 14 nmol/L showed that testosterone therapy for two years reduced the proportion of patients with T2DM regardless of a lifestyle programme [33]. Similarly, a registry study reported that testosterone therapy was associated in time with remission of T2DM [34]. High-density lipoprotein (HDL)-cholesterol may decrease, remain unchanged or increase with testosterone therapy.

Testosterone therapy in men with MetS and low testosterone has been shown to reduce mortality compared to untreated men [36, 37], although no conclusive evidence is available.

Erectile dysfunction (ED) is common in men with MetS and T2DM (up to 70% of patients). The causes of ED are multi-factorial and 30% of men with ED have co-existing testosterone-deficiency/hypogonadism. Some evidence has suggested that ED is only found in men with T2DM and clearly reduced testosterone levels (< 8 nmol/L or 2.31 ng/mL) [38]. From a pathophysiological perspective, it has been reported that this is because ED is predominantly caused by vascular and neuropathic disease, and therefore not likely in men who do not have established vascular disease. Therefore, men presenting with ED should be screened for MetS. Likewise, patients with ED and diabetes may be offered testosterone measurement.

Placebo-controlled RCTs of testosterone therapy in T2DM have demonstrated improved sexual desire and satisfaction, although data on erectile function were limited [29, 38]. Similar results were derived from a meta-analysis of published trials [39]. Accordingly, a large two-year RCT of testosterone undecanoate vs. placebo showed that testosterone therapy significantly improved sexual function and ED in men with impaired glucose tolerance or newly-diagnosed T2DM low testosterone (< 14 nmol/L) [33].

Testosterone therapy has been associated with a reduced percentage of body fat and increase in lean body mass [40]. Data from a registry study have suggested that testosterone therapy with long-acting intramuscular testosterone undecanoate over eleven years was associated with a substantial but gradual loss of weight, along with a reduction in waist circumference [41]

3.2.3 ***Sars-CoV-2 / COVID-19***

Data seem to suggest that low circulating testosterone levels are more frequently associated with worse clinical outcomes in men with COVID-19 [42-49]. Accordingly, a cohort study, analysing two large academic health systems databases, including 723 men with a history of COVID-19 reported that hypogonadal men had a higher risk of being hospitalised [50]. In addition, a meta-analysis suggested that reduced testosterone levels detected at hospital admission for COVID-19 are associated with a four- five-fold increased risk of being admitted to the Intensive Care Unit (ICU) or dying, after adjustment for potential confounders [51].

Although no information on the role of testosterone therapy in the acute phase of the disease is available currently, data also showed that the hypogonadal patients under testosterone therapy had a reduced risk to be hospitalised after SARS-CoV-2 infection [50]. However, whether or not low testosterone can directly contribute to worse COVID-19 outcomes is still under investigation. The possibility that low testosterone in the acute phase of COVID-19 infection represents an adaptive response mechanism to dampen non-essential activities non

conducive to recovery (physical and sexual activities) by turning off testosterone-dependent functions, cannot be excluded [52, 53]. Accordingly, a meta-analysis showed that secondary or mixed hypogonadism is more frequently observed in the acute phase of the infection [51].

Studies evaluating patients in the recovery phase of COVID-19 have documented either restored [54, 55] or persistently low testosterone levels in the majority of cases [56]. A longitudinal evaluation study showed that during the recovery phase a further improvement of testosterone levels can be observed up to twelve months after COVID-19. Male subjects who have recovered from COVID-19 should be accurately followed-up to exclude any long-term andrological consequences including impairment in sperm and testosterone production [51].

Table 2: Main factors associated with an increase or reduction of SHBG circulating levels

SHBG increase	SHBG decrease
• Drugs: anticonvulsants, oestrogens, thyroid hormone • Hyperthyroidism • Hepatic disease • Ageing • Smoking • AIDS/HIV	• Drugs: growth hormone (GH), glucocorticoids, testosterone, anabolic androgenic steroids • Hypothyroidism • Obesity • Acromegaly • Cushing's disease • Insulin resistance (MetS/T2DM) • Non-alcoholic fatty liver disease (NAFLD), • Nephrotic syndrome

3.3 Late-onset hypogonadism

Testosterone production declines with ageing. The European Male Aging Study (EMAS) reported a 0.4% per annum (log hormone-age) decrease in total testosterone and a 1.3% per annum decline in free testosterone (fT) [5]. Late onset hypogonadism is the term frequently used to describe this phenomenon and the detection of hypogonadism in adulthood. Evidence indicates that several associated diseases and chronic comorbidities can interfere with the HPG axis leading to the development of primary hypogonadism or, more frequently, secondary hypogonadism in adulthood, thus significantly influencing the physiological age-dependent decline of testosterone. Combining the data from three different waves of the Massachusetts Male Aging Study (MMAS), demonstrated that associated comorbidity and obesity significantly decreased, whereas smoking tended to increase total, free and bio-available testosterone concentrations [57]. Data derived from the EMAS confirmed these findings [5, 19]. Based upon these data and other evidence, as previously reported the concept of *functional and organic hypogonadism* has been more recently introduced (see above) [58]. Considering that suppression of HPG axis activity is functional, and potentially reversible by empiric measures, such as weight loss, the need for testosterone therapy has been questioned [58].

3.3.1 Clinical Diagnosis and Evaluation

The mainstay of LOH diagnosis includes signs and symptoms consistent with hypogonadism, coupled with biochemical evidence of low morning serum total testosterone levels on two or more occasions, measured with a reliable assay and in fasting conditions.

3.3.2 History taking

Specific symptoms associated with hypogonadism, including LOH, are shown in Table 3. These symptoms are non-specific and need to be recorded and taken in context with the clinical and biochemical state. Several self-reported questionnaires or structural interviews have been developed for screening of hypogonadism. Although these case-history tools have demonstrated clinical utility in supporting the biochemical diagnosis of hypogonadism, or in the assessment of testosterone therapy outcomes, their specificity remains poor and they should not be used for a systematic screening of hypogonadal men [59]. Headache and/or visual disturbance may indicate a pituitary-related disorder. History of surgical intervention for cryptorchidism or hypospadias must be taken into account as possible signs of congenital defects. Chronic and systemic comorbidities must be comprehensively investigated in every patient. Use of drugs that potentially interfere with the HPG axis should be excluded (Table 1). Acute diseases are associated with development of functional hypogonadism and determination of serum total testosterone levels should be avoided in these conditions; however, the role of testosterone in the case of acute illness remains to be clarified [42, 46, 51, 60]. Fertility issues should be always discussed.

Table 3: Specific symptoms associated with LOH

	Sexual symptoms	Physical symptoms	Psychological symptoms
More specific	• Reduced libido • Erectile dysfunction • Decreased spontaneous/morning erections	• Decreased vigorous activity • Difficulty walking > 1 km • Decreased bending	• Low mood/mood deflection • Decreased motivation • Fatigue
Less specific	• Reduced frequency of sexual intercourse • Reduced frequency of masturbation • Delayed ejaculation	• Hot flushes • Decreased energy • Decreased physical strength/function/ activity	• Concentration difficulties • Sleep disturbances

3.3.3 ***Physical examination***

Since obesity is frequently associated with hypogonadism (mostly functional), the determination of body mass index (BMI) and the measurement of waist circumference are strongly recommended in all individuals. Testicular and penile size, as well as the presence of sexual secondary characteristics can provide useful information regarding overall androgen status. In addition, upper segment/lower segment ratio (n.v. > 0.92) and arm-span to height ratio (n.v. < 1.0) can be useful to identify a eunuchoid body shape, especially in subjects with pre-pubertal hypogonadism or delayed puberty. Finally, digital rectal examination (DRE) should be performed in all subjects to exclude prostate abnormalities before testosterone therapy (any type) or to support suspicion of hypogonadism (in case of reduced volume) [61].

3.3.4 ***Laboratory Diagnostics***

Testosterone levels are produced in a circadian variation, which may persist in ageing men [62, 63]. Testosterone levels are also potentially influenced by food intake [64]; therefore, serum total testosterone should be measured in fasting conditions in the morning (between 07.00 and 11.00 hours). A confirmatory measurement should always be undertaken in the case of a primary pathological value, and before starting any testosterone therapy.

Liquid Chromatography-Tandem Mass Spectrometry (LC-MS/MS) represents the most accurate method for sex steroid evaluation; however, standardised automated platform immuno-assays for total testosterone assessment demonstrate a good correlation with LC-MS/MS [65]. Available immuno-assays are not able to provide an accurate estimation of fT; therefore, direct fT evaluation with these methods is not recommended and should be avoided [66]. Equilibrium dialysis is the most accurate method for total testosterone measurement and FT calculation [67]. Alternatively, fT can be derived from specific mathematical calculations using total testosterone as derived by common immunoassays and taking into account serum sex hormone binding globulin (SHBG) and albumin levels [68] (http://www.issam.ch/freetesto.htm).

Data from meta-analyses have shown that testosterone therapy is ineffective when baseline levels are > 12 nmol/L (3.5 ng/mL). Positive outcomes are documented when testosterone levels are < 12 nmol/L, being higher in symptomatic patients with more severe forms of hypogonadism (< 8 nmol/L). Hence, 12 nmol/L should be considered as a possible threshold for starting testosterone therapy in the presence of hypogonadal symptoms [40, 69].

In clinical conditions that may interfere with SHBG levels, evaluation of fT should be considered to better estimate actual androgen levels (Figure 1). Unfortunately, despite its potential clinical value [70], no validated thresholds for fT are available from clinical studies and this represents an area of uncertainty; however, data from the EMAS indicated that fT levels < 220 pmol/L (6.4 ng/dL) increased the likelihood to correct identify hypogonadism as compared with total testosterone level alone, particularly when total testosterone levels are between 8.0 and 11 nmol per litre [8, 71, 72].

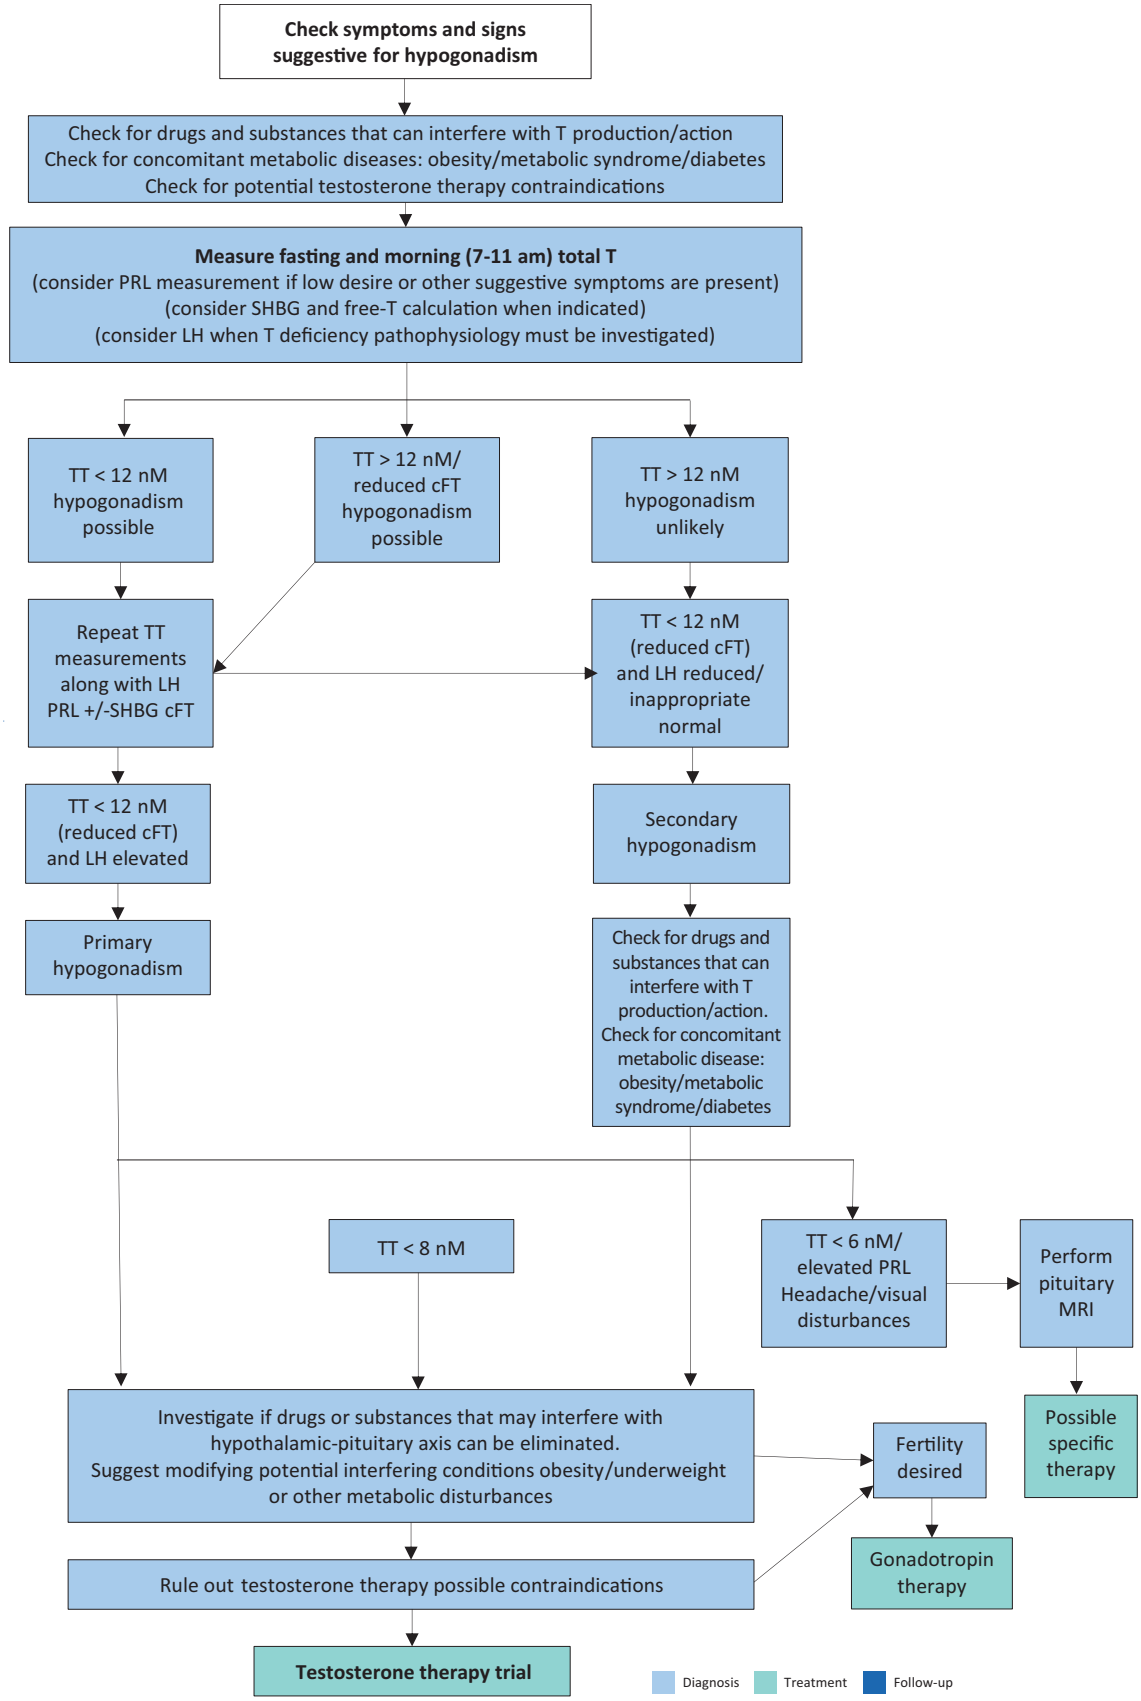
The determination of LH must be performed along with prolactin (PRL) when pathological total testosterone levels are detected, in order to correctly define the underlying conditions and exclude possible organic causes (Figure 1). Follicle-stimulating hormone determination can further support the diagnosis of primary or secondary hypogonadism [21, 73]. Due to its negative influence on libido, PRL can also be considered as first-line screening in patients with reduced sexual desire. In addition, contrast-enhanced pituitary magnetic resonance imaging (MRI) scanning, as well as other pituitary hormone evaluations, is required in the presence of specific symptoms such as visual disturbances, headache and when hyperprolactinemia is confirmed [74, 75]. Limited evidence suggests also performing pituitary MRI in the case of severe hypogonadism (< 6 nmol/L, 1.75 ng/mL) with inadequate gonadotropin levels (Figure 1) [74-76].

3.3.5 *Summary of evidence and recommendations for the diagnostic evaluation and screening of LOH*

Summary of evidence	LE
Sexual symptoms are the most specific symptoms associated with late-onset hypogonadism (LOH).	1a
Diagnosis of LOH should be based on specific signs and symptoms of androgen deficiency, together with consistently low serum testosterone levels.	1a
Total testosterone 12 nmol/L (3.5 ng/mL) represents a reliable threshold to diagnose LOH.	1a
Functional hypogonadism is a consequence of comorbidity/concomitant drugs, which can impair testosterone production in adulthood. The diagnosis of functional hypogonadism is a diagnosis of exclusion, after ruling out organic causes of hypogonadism.	4
Calculated free-testosterone of < 220 pmol/L has been suggested as a possible cut-off to diagnose LOH.	3
Self-reported questionnaires and structural interviews have been developed for screening of hypogonadism but their specificity remains poor.	2a

Recommendations	Strength rating
Diagnostic evaluation	
Check for concomitant diseases, drugs and substances that can interfere with testosterone production/action.	Strong
Measure total testosterone in the morning (between 07.00 and 11.00 hours) and in the fasting state, with a reliable laboratory assay.	Strong
Repeat total testosterone on at least two separate occasions when < 12 nmol/L and before starting testosterone therapy.	Strong
Use 12 nmol/L total testosterone (3.5 ng/mL) as a reliable threshold to diagnose late onset hypogonadism (LOH).	Strong
Measure sex hormone-binding globulin and free-testosterone calculation when indicated	Strong
Analyse luteinising hormone and follicle-stimulating hormone serum levels to differentiate between the different types of hypogonadism.	Strong
Measure prolactin (PRL) levels if evidence of low sexual desire (or other suggestive signs/symptoms) and secondary hypogonadism is present.	Strong
Perform pituitary magnetic resonance imaging (MRI) in secondary hypogonadism, with elevated PRL or symptoms specific of a pituitary mass and/or presence of other anterior pituitary hormone deficiency.	Strong
Perform pituitary MRI in secondary severe hypogonadism (total testosterone < 6 nmol/L).	Weak
Screening	
Screen for late onset hypogonadism (LOH) only in symptomatic men.	Strong
Do not use structured interviews and self-reported questionnaires for systematic screening for LOH as they have a low specificity.	Strong

Figure 1: Diagnostic evaluation of Late-Onset Hypogonadism



TT = total testosterone; cFT = calculated free testosterone; PRL = prolactin; SHBG = sex hormone-binding globulin; LH = luteinising hormone; MRI = Magnetic resonance imaging.

3.4 Treatment of Classical and LOH

3.4.1 Indications and contraindications for treatment of hypogonadism

Patients with symptomatic hypogonadism (total testosterone < 12 nmol/L) without specific contraindications are suitable candidates to receive testosterone therapy (Table 4).

Absolute contraindications are untreated breast and prostate cancer (PCa). Similarly, conditions such as cardiovascular events as well as uncontrolled or poorly controlled congestive heart failure should be considered when prescribing testosterone therapy [77]. Conversely, severe lower urinary tract symptoms (LUTS) [International Prostate Symptom Score (IPSS) score > 19] represent a relative contraindication, as there is insufficient data on the long-term effects of testosterone therapy in these patients [66]. A positive family history for venous thromboembolism requires further analysis to exclude a condition of undiagnosed thrombophilia-hypofibrinolysis [78]. These patients need to be carefully counselled prior to testosterone therapy initiation. A haematocrit (HCT) > 54% should require testosterone therapy withdrawal, reduction in dose, change of formulation and venesection depending on the clinical situation to avoid any potential cardiovascular complications. Lower baseline HTC (48-50%) should be carefully evaluated before testosterone therapy initiation, to avoid pathological increases during treatment, especially in high-risk men such as those with COPD or Obstructive Sleep Apnoea Syndrome (OSAS). Accordingly, the Framingham Heart Study showed that HCT > 48% represented a condition associated with increased risk of coronary artery disease (CAD) and mortality and was associated with cardiovascular disorders [79]. Testosterone therapy suppresses gonadotropin and endogenous testosterone secretion as well as spermatogenesis [80]; therefore, testosterone therapy is contraindicated in individuals who desire fertility [81]. Secondary hypogonadism is characterised by low or inappropriately normal gonadotropin levels; therefore, the rationale is to substitute the gonadotropin deficiency with simultaneously FSH and LH analogues, if fertility is desired [82].

Table 4: Main contraindications of testosterone therapy

Absolute contraindications	Locally advanced or metastatic prostate cancer (PCa) Male breast cancer Men with an active desire to have children Haematocrit ≥ 54% Uncontrolled or poorly controlled congestive heart failure
Relative contraindication	IPSS score > 19 Baseline haematocrit 48-50% Familial history of venous thromboembolism

3.4.2 Testosterone therapy outcomes

3.4.2.1 Sexual dysfunction

Sexual concerns are the main symptoms of hypogonadal patients [3, 8, 83, 84]. A consistent body of evidence shows that testosterone therapy in hypogonadal men (total testosterone < 12 nmol/L) may have a beneficial effect on several aspects of sexual life; in contrast, there is no evidence of benefits in using testosterone therapy for treating sexual dysfunction in eugonadal men [69, 85-87]. The beneficial effect on sexual function seems to be more related to testosterone level normalisation than the specific testosterone formulations used [87, 88].

A meta-analysis of placebo-controlled RCTs showed that testosterone therapy significantly improves erectile function (as measured by IIEF-Erectile Function domain score) and that patients with more severe hypogonadism (i.e., total testosterone < 8 nmol/L) are more likely to achieve better improvement than patients with milder hypogonadism (i.e., total testosterone < 12 nmol/L) [69]. Similar results were observed for sexual desire; however, the presence of metabolic comorbidity (such as diabetes and obesity) decreased the magnitude of these improvements. In particular, testosterone therapy alone resulted in a clinically effective outcome only in patients with milder ED [69]. Similar results have also been confirmed in an update analysis [89] and in a recently published Cochrane review [1970]. In line with these data, report from the non-inferiority "Testosterone Replacement Therapy for Assessment of Long-term Vascular Events and Efficacy Response in Hypogonadal Men (TRAVERSE)" study, showed in middle-aged and older hypogonadal (total testosterone < 10.4 nmol/L) men with pre-existing or a high risk of CVD, testosterone therapy with gel for two years improved sexual activity, hypogonadal symptoms, and sexual desire, but not erectile function [90].

Other sexual function parameters, such as intercourse, orgasm and overall satisfaction, were all improved compared with placebo [69, 89]. Men with a comorbidity, such as T2DM, usually show modest improvements in terms of sexual function after testosterone therapy and may potentially require concomitant phosphodiesterase type 5 inhibitors (PDE5Is) to improve effectiveness [3, 87]. A meta-analysis including 913 patients derived from eight RCTs suggested that combination therapy (testosterone and PDE5Is) was superior when compared

to PDE5Is alone in improving erectile function [92]. The specific beneficial effect derived from the combined use of testosterone therapy and PDE5Is is unclear [85]. Similarly, information related to the combined use of testosterone therapy with other ED drug therapies is lacking [3, 87].

The Sexual Function Trial of the Testosterone Trials (TTrials) (one of the largest placebo-controlled trials on testosterone therapy) documented consistent improvements in 10 of 12 measures of sexual activities in older (≥ 65 years) hypogonadal men, particularly in frequency of intercourse, masturbation and nocturnal erections (as measured by PDQ-Q4) [93, 1973]. The magnitude in improvement was shown to be proportional to the increase in serum total testosterone, fT and E2 levels, it was not possible to demonstrate a threshold level [94]. A study of 220 men with MetS with or without T2DM also found that sexual function improved in men who reported sexual problems with improvement in IIEF scores, with specific increases in libido and sexual satisfaction [29].

3.4.2.2 Vitality and physical strength

The role of testosterone in stimulating muscle growth and strength is well established. Accordingly, androgenic-anabolic steroids (AAS) have been used as performance-enhancing agents to increase physical performance in competitive sport [95]. In this regard, testosterone therapy in hypogonadal men has been shown to increase muscle mass and reduce fat mass, with limited effects on final weight [40]. Despite this evidence, the role of testosterone therapy in older men with mobility limitations remains unclear. The National Health and Nutrition Examination Survey 1999-2004 [96] was unable to detect any association between overall circulating testosterone levels and the amount of physical activity. However, among non-obese men, those in the highest physical activity tertile were significantly less likely to have low or low-normal testosterone than those in the lowest tertile. Data from TTrials indicated that testosterone therapy did not substantially increase the fraction of men whose six-minute walking distance increased > 50 m or the absolute increase in the distance walked by those enrolled in the physical function trial [93]. However, when the whole population of the TTrials was considered, a significant, although modest, positive effect on these two parameters was reported [93]. Similar data were derived from the Vitality Trial [93]. As support of the aforementioned considerations, a recent meta-analysis including 2043 subjects older than 60 years failed to show a significant improvement of muscle strength of testosterone therapy when compared to placebo [97].

3.4.2.3 Mood and cognition

Several observational studies have documented a relationship between depressive symptoms, reduced QoL and hypogonadism [98, 99]. However, the specific relationship between hypogonadism and the incidence of depression is still unclear [99]. Only a few placebo-controlled RCTs have investigated the role of testosterone therapy in improving depressive symptoms. Data derived from TTrials showed that testosterone therapy improved mood, and depressive symptoms as continuous measures using several instruments [93]. However, the final effect was small in magnitude. In line with this data, the largest meta-analysis of available studies, including 1,890 hypogonadal men (baseline total testosterone < 12 nmol/L or fT < 225 pmol/L) men from 27 RCTs, documented that the positive effect of testosterone therapy was particularly evident in patients with milder symptoms [100]. The BLAST study of testosterone therapy in T2DM reported that those men with depression were less likely to respond with regards to symptoms of sexual dysfunction compared to men without depression [35].

Robust data on the effect of testosterone therapy on QoL are limited. Although recent meta-analyses suggest a significant effect of testosterone therapy over placebo, the magnitude is low and the heterogeneity high, therefore reducing the scientific value of the effect [88, 101].

The role of testosterone therapy in patients with cognitive impairment is even more uncertain. The TTrials evaluated the effect of testosterone therapy in 493 individuals with age-associated memory impairment to assess possible improvement of several aspects of cognitive function. However, results failed to demonstrate any beneficial effect of testosterone therapy in improving cognitive function [93]. Similarly, a meta-analysis involving 17 studies enrolling 1,438 patients with a mean age of 70.4 years and a mean follow-up of 45.6 weeks did not find any effect of testosterone therapy on cognitive domains [102].

3.4.2.4 Body composition and metabolic profile

Late onset hypogonadism is associated with a greater percentage of fat mass and a lesser lean mass compared to testosterone-repleted men [103]. The major effect of low testosterone is to increase visceral adiposity but it also leads to deposition of lipids in the liver and muscle and is associated with atherosclerosis [25]. Some published data have suggested that testosterone therapy reduces percentage body fat and increases lean mass [104]. Testosterone therapy has also been found to decrease waist circumference, body weight and BMI, with these effects more predominant after twelve months of treatment [104-106]. Over two years, the T4DM RCT reported that men on testosterone therapy and a lifestyle programme had a greater reduction in waist circumference, total and abdominal fat mass and an increase in total and arm muscle mass and an increased

strength in the non-dominant hand compared to a lifestyle programme alone [33]. There was a trend toward reduction in body weight although this approached significance but did not reach significance. The latter result is probably compounded by the increase in muscle mass as well as the decrease in fat mass. However, it should be recognised that the results of previous studies are mainly derived from registry and observational trials, which have important limitations due to the risk of selection bias for the non-random assignment of testosterone exposure. Accordingly, data derived from RCTs showed only an improvement of fat mass and lean mass of the same amount without any modifications in body weight [40]. A meta-analysis including seventeen RCTs specifically investigated the role of testosterone therapy on several metabolic parameters in patients with T2DM and/or MetS [39]. In line with what was reported in the general population, testosterone therapy was associated with an improvement in body composition either in T2DM or MetS without any effects on body weight. Similarly positive effects were also observed on fasting glycemia and insulin resistance (HOMA index) whilst more conflicting data were obtained for HbA1c and lipid profile [39].

3.4.2.5 Bone

Evidence suggests that bone mineralisation requires circulating sex steroids within the normal range [107]. The possible association between mild hypogonadism and osteopenia/osteoporosis is weak, whereas severe hypogonadism (total testosterone < 3.5 nM) is frequently associated with bone loss and osteoporosis, independent of patient age [107]. Three independent meta-analyses showed a positive effect of testosterone therapy on bone mineral density (BMD), with the highest effect at the lumber level [108-110]. Interestingly, the latter meta-analysis has provided novel evidence that the role of testosterone on BMD was even higher in patients with diabetes [110], who are at a higher risk of hypogonadism and bone fracture [39, 111, 112]. Similarly, data derived from TTrials and the T4DM studies confirmed that testosterone therapy increased BMD in hypogonadal ageing men [93, 113]. However, available data are insufficient to determine the effect of testosterone therapy alone on the risk of fractures [107]. Recent data from the aforementioned TRAVERSE trial quite surprisingly showed an increased incidence of overall bone fractures among men who have received testosterone therapy compared to those who received placebo [1971]. However, it should be recognized that no difference in major osteoporotic fractures (i.e., hip, wrist, humerus, clinical spine and hip) were observed between groups. Moreover, this observation was derived from patient reports and therefore it deserves to be more specifically adjudicated. In conclusion, it should be recognized that the use of testosterone therapy as an adjunct to anti-resorptive treatment in hypogonadal patients at high risk of fractures has not been established. Therefore, anti-resorptive therapy must be the first-choice treatment in hypogonadal men at high risk for bone fractures. The combination of anti-resorptive treatment and testosterone therapy should be offered only in conjunction with hypogonadism-related symptoms.

3.4.2.6 Summary of evidence and recommendations for testosterone therapy outcome

Summary of evidence	**LE**
Testosterone therapy can improve:	
• Milder forms of ED and libido in hypogonadal men;	1a
• Other sexual symptoms, including intercourse frequency, orgasm and overall satisfaction.	1b
• Body composition and insulin resistance.	1a
• Weight, waist circumference and lipid profile, but the evidence is conflicting.	3
• Mild depressive symptoms in hypogonadal men.	1a
• Bone mineral density, but information related to fracture risk is lacking.	1a

Recommendations	**Strength rating**
Do not use testosterone therapy in eugonadal men.	Strong
Use testosterone therapy as first-line treatment in hypogonadal patients with mild erectile dysfunction (ED).	Strong
Use a combination of phosphodiesterase type 5 inhibitors and testosterone therapy in more severe forms of ED.	Weak
Use conventional medical therapies for severe depressive symptoms and osteoporosis.	Strong
Do not use testosterone therapy to reduce weight and enhance cardio-metabolic status.	Weak
Do not use testosterone therapy to improve cognition vitality and physical strength in ageing men.	Strong

3.4.3 Choice of treatment

3.4.3.1 Lifestyle factors

As reported above, functional hypogonadism is frequently associated with obesity and metabolic disorders [114]. Therefore, weight loss and lifestyle changes should be the first approach for all overweight and obese men with hypogonadism. A previous meta-analysis documented that a low-calorie diet can to revert obesity-associated secondary hypogonadism by increasing total testosterone and fT, reducing oestrogens and restoring normal gonadotropin circulating levels [115]. This was confirmed in an updated meta-analysis showing that the increase in testosterone is significantly associated with weight reduction [116]. Similar results can be obtained through physical activity, which is associated with the duration of scheduled exercise and weight loss obtained [116]. However, it should be recognised that the increase in testosterone levels observed after a low-calorie diet and physical activity is small (1-2 nmol) [115, 116]. In addition, 60-86% of weight lost is regained after three years and 75-121% after five years [117]. Lifestyle changes represent an essential part of the management of obesity; however, some evidence suggests that when compared to lifestyle modifications alone, testosterone therapy-treated obese men benefit most from relief of their symptoms associated with testosterone deficiency, whereas those not treated did not benefit [82]. There is limited evidence to suggest that combination of life-style interventions and testosterone therapy in symptomatic hypogonadal men might result in better outcomes [103]. As described above, the T4DM study has demonstrated that over two-years testosterone therapy with lifestyle intervention was superior to lifestyle intervention alone in reducing waist circumference and total and abdominal fat content. There was no significant reduction in body weight when compared to lifestyle intervention alone [33]. Interestingly, recent data also showed that weight loss obtained thought the use of Glucagon-like peptide-1 analogues analogues can result in better testosterone increases as compared with diet programs alone [1972].

3.4.3.2 Medical preparations

Several testosterone formulations are available (Table 5). Direct comparisons among different testosterone products are still lacking. Candidates for testosterone therapy should be adequately informed about the possible risks and benefits of all available testosterone preparations. The final choice should be based on the clinical situation, testosterone formulation availability, and patient needs and expectations [22, 118].

3.4.3.2.1 Oral formulations

An oral formulation has been available in oleic acid since the 1970s, and has been recently reformulated in a mixture of castor oil and propylene glycol laureate (testosterone undecanoate [TU] caps), to allow the drug to be maintained at room temperature without degradation [22, 118]. The main limitation is related to poor bioavailability, which is strongly dependent on dietary fat content [22, 118]. The US Food and Drug Administration (FDA) approved a new formulation of oral TU in a liquid-filled soft gel capsule, which improved oral availability [119]. Available evidence showed that TU capsule formulations can reach steady 24-hour average serum testosterone levels in more than 80% of hypogonadal men, thus resulting in a significant improvement of all sexual function domains at all time points when compared to baseline along with an excellent safety profile [119]. More recently, the FDA has approved a new oral formulation which contains as carriers Vitamin E, phytosterol esters, polyoxyl 40 hydrogenated castor oil and propylene glycol monolaurate [119]. For all new oral TU formulations a mild increase in arterial blood pressure has been reported. Hence, the FDA has required a black box warning that these drugs can induce a blood pressure increase [119].

Mesterolone is a 5α-dihydrotestosterone (DHT) derivate available for oral administration. Along with DHT, mesterolone cannot be converted to oestrogens and can only be used for a limited period and for specific indications, such as the presence of painful gynaecomastia. However, the lack of a full spectrum of testosterone bioactivity strongly limits its long-term use [22].

3.4.3.2.2 Parenteral formulations

Injectable testosterone preparations can be classified according to their half-lives (Table 5). Testosterone propionate is a short-term ester formulation requiring multiple fractionated doses (usually 50-100 mg, every two to three days), thus representing a major limitation for its use [22, 118]. Cypionate and enanthate-T esters are short-term formulations, requiring administration every two to four weeks. A formulation containing mixed testosterone esters (TU, isocaproate, phenyl propionate, propionate) which has the benefit of a steady release of testosterone into the circulation, is available in some countries. The use of these older formulations is associated with wide fluctuations in plasma testosterone concentrations and is often reported as unpleasant by patients potentially resulting in adverse effects, such as polycythaemia [22, 118, 120]. A longer-lasting TU injectable formulation is widely available [22, 118], with a good safety/benefit profile allowing the maintenance of normal stable testosterone levels at a dose of 1,000 mg initially every twelve weeks, following a six-week loading dose, but can be adjusted to a frequency of ten to fourteen weeks dependent on the trough (pre-injection level) after three to five injections to maintain levels in the therapeutic range (usually > 12 and < 18 nmol/L) [22, 118, 121].

3.4.3.2.3 Transdermal testosterone preparations

Among the available transdermal formulations, testosterone gels represent the most frequently used preparations. The gel is quickly absorbed by the stratum corneum, creating a reservoir within the subcutaneous tissues from where testosterone is continuously delivered for 24 hours, after a single daily application. These formulations have been shown to normalise serum testosterone levels with an excellent safety profile [22, 118]. The introduction of specific devices and skin enhancers has resulted in better skin penetration of the drugs, thus reducing potential adverse effects. Local skin adverse effects are limited when compared to those with traditional testosterone patches, but they potentially allow transference of testosterone during close contact with the skin surface. The risk can be reduced by wearing clothing or by applying the gel on skin surfaces not usually touched (e.g., the inner thigh surface) [22, 118]. To reduce the total amount of gel applied and residual quantities remaining on the skin, new formulations of testosterone gel have been introduced with a testosterone concentration of 1.62-2% [22, 118]. Another transdermal testosterone formulation includes a topical, alcohol-based testosterone (2%) solution, which must be applied to the underarm once daily, using a metered dose applicator [22, 118]. This testosterone formulation is not available in Europe. Testosterone levels should be monitored to optimise the testosterone dose. Blood collection is best taken two to four hours after gel application to use the peak level of testosterone absorbed as a reference for adequate therapeutic levels. Levels of testosterone after application can vary and a repeat measurement may be indicated especially as sometimes, inadvertently, the skin over the venipuncture site can be contaminated by the gel, leading to falsely elevated results.

In some European countries, DHT is available as a hydroalcoholic 2.5% gel. It is rapidly absorbed, reaching a steady state in two to three days [22, 118]. Similar to that reported for mesterolone, DHT is not aromatised but can be useful for treating particular conditions, such as gynaecomastia and microphallus [22, 118].

3.4.3.2.4 Transmucosal formulations

A testosterone buccal system is still available in several countries. It consists of a sustained-release muco-adhesive buccal-testosterone-tablet requiring twice-daily application to the upper gums. The tablet does not dissolve completely in the mouth and must be removed after twelve hours. This formulation has been proven to restore testosterone levels within the physiological range with minimal or transient local problems, including gum oedema, blistering and gingivitis [22, 118].

A gel for intranasal administration is available in some countries, including the USA and Canada. It requires administration two or three times daily using a specific metered-dose pump. The application is rapid, non-invasive, and convenient, and avoids secondary transference observed with other topical products [22, 118]. Preliminary results suggest that intranasal testosterone is associated with lower suppression of Gn levels and with a lower risk of haematocrit increases [122].

3.4.3.2.5 Subdermal depots

The implantation of testosterone pellets, available in a limited number of countries, represents the longest available testosterone formulation lasting from four to seven months. The procedure is invasive and may be unattractive to patients [22, 118].

3.4.3.2.6 Anti-oestrogens

Anti-oestrogens, including selective oestrogen receptor (ER) modulators (SERMs) and aromatase inhibitors (AI) have been suggested as off-label treatments to restore testosterone levels and fertility in men with functional secondary hypogonadism or idiopathic infertility. They work by preventing down-regulation of the HPG axis by oestrogens and for this reason are particularly useful in men with obesity and metabolic disorders [116, 123]. In the latter case, the hypothesis is that the excess of adipose tissue leads to increased aromatase activity and oestrogens levels resulting in impairment of the HPG [114]. Due to their putative mechanism of action, they require an intact HPG axis and cannot work in primary hypogonadism or secondary hypogonadism due to organic damage of the HPG axis. Both types of SERMs, which bind ERs with an agonist or antagonist effect depending upon the target tissue, and AIs, which prevent androgens from being converted into oestrogens by aromatase, have been used in clinical practice [22, 118]. The evidence published so far is poor; all these products are off-label treatments and SERMs, due to their agonistic effect on venous vessels, could predispose men to the development of venous thromboembolism [22, 118]. In this context patients should be warned of the potential increased risk of venous thromboembolism, although data are lacking. Long-term use of these agents can lead to reduced bone density and the development of osteoporosis, potentially increasing fracture risk.

3.4.3.2.7 Gonadotropins

Gonadotropin therapy should be considered the standard in men with secondary hypogonadism who desire paternity (Table 5) [22, 118]. Recombinant hCG (rhCG) and LH (rLH) formulations offer comparable effects to urinary-derived preparations [118]. According to a meta-analysis of the available evidence, hCG should be administered with FSH since combined therapy results in better outcomes. Similar to recombinant hCG, recombinant FSH (rFSH) offers comparable effects to urinary-derived preparations [121].

Table 5: Available preparations for hypogonadism treatment

Formulation	Chemical structure	t ½	Standard dosage	Advantages	Disadvantages
GONADOTROPINS					
Human chorionic gonadotrophin (HCG)					
Extractive	HCG purified from the urine of pregnant women	NA	1,000-2,000 IU 3 times/week	Low cost	Multiple weekly administration
Recombinant	Human recombinant HCG	NA	No data on men	NA	NA
Luteotropic hormone (LH)					
Recombinant	Human recombinant LH	NA	No data on men	NA	NA
Follicle-stimulating hormone (FSH)					
Extractive	FSH purified from urine of pregnant women	NA	75-150 IU 3 times/week	Low cost	Multiple weekly administration
Recombinant	Human recombinant FSH	NA	75-150 IU 3 times/week	NA	Multiple weekly administration
TESTOSTERONE PREPARATIONS					
Oral					
Testosterone undecanoate	17-α-hydroxylester	4 hours	120-240 mg 2-3 times daily	- Reduction of liver involvement - Oral convenience - Modifiable dosage	- Unpredictable absorption depending on dietary fat content - Must be taken with meals
Testosterone undecanoate self-emulsifying delivery system	17-α-hydroxylester	2-5 hours	100-237 mg 2 times daily	- Oral convenience - Modifiable dosage - Quick reversal	- Gastrointestinal side effects - increase in blood pressure
Mesterolone	1α-methyl-4, 5α-dihydro-testosterone	12 hours	50-100 mg 2-3 times daily	- Oral convenience - Modifiable dosage - Useful in gynaecomastia	- Not aromatisable
Parental					
Testosterone enanthate	17-α-hydroxylester	4-5 days	250 mg every 2-3 weeks	- Low cost - Short-acting preparation allowing drug withdrawal in case of adverse effects	- Fluctuations in circulating testosterone levels - Multiple injections - Relative risk of polycythemia
Testosterone cypionate	17-α-hydroxylester	8 days	200 mg every 2-3 weeks		
Testosterone propionate	17-α-hydroxylester	20 hours	100 mg every 2 days		
Testosterone ester mixture*	4-androsten-3-one-17 beta-hydroxy-androst-4-en-3-one	4-5 days	250 mg every 3 weeks		
Testosterone undecanoate in castor oil	17-α-hydroxylester	34 days	1,000 mg every 10-14 weeks *750 mg every 10 weeks	- Steady-state testosterone level without fluctuation - Long-lasting - Less frequent administration	- Pain at the injection site - Long-acting preparation not allowing rapid drug withdrawal in case of adverse effects

Surgical implants	Native testosterone	N/A	4-6 200 mg implants lasting up to 6 months	- Long duration and constant serum testosterone level	- Placement is invasive - Risk of extrusion and site infections
TRANSDERMAL					
Testosterone patches	Native testosterone	10 hours	50-100 mg/ day	Steady-state testosterone level without fluctuation	- Skin irritation - Daily administration
Testosterone gel 1-2%	Native testosterone	6 hours	50-100 mg/ day		- Possible transfer during intimate contact - Daily administration
Underarm testosterone (testosterone solution 2%)	Native testosterone	NA	60-120 mg/ day		
Dihydro-testosterone gel 2.5%	Native dihydro-testosterone	NA	34-70 mg/day	- Steady-state testosterone level without fluctuation - Useful in gynaecomastia	- Possible transfer during intimate contact - Daily administration - Not aromatisable
TRANSMUCOSAL					
Testosterone buccal system	Native testosterone	12 hours	60 mg 3 times daily	Steady-state testosterone level without fluctuation	- Possible oral irritation - Twice-daily dosing - Unpleasant taste
Testosterone nasal	Native testosterone	6 hours	33 mg 3 times daily		- Nasal irritation - Multiple daily administrations

NA = not applicable.
** Testosterone ester mixture - propionate (30mg), phenylpropionate (60mg), isocaproate (60mg), decanoate (100mg)*

3.4.3.2.8 Summary of evidence and recommendations for choice of treatment for LOH

Summary of evidence	**LE**
Weight loss obtained through a low-calorie diet and regular physical activity results in a small improvement in testosterone levels.	1a
Testosterone gels and long-acting injectable testosterone undecanoate preparations provide optimal safety profiles.	1a
Gonadotropin treatment can be used to restore fertility in men with secondary hypogonadism.	1a

Recommendations	**Strength rating**
Treat, when indicated, organic causes of hypogonadism (e.g., pituitary masses, hyperprolactinemia, etc).	Strong
Improve lifestyle and reduce weight (e.g., obesity); withdraw, when possible, concomitant drugs that can impair testosterone production; treat other co-morbidities, when possible, before starting testosterone therapy.	Strong
Fully inform patients about the expected benefits and adverse effects of any treatment option. Select the testosterone preparation in a joint decision process, and fully inform patients of the risks and benefits.	Strong
Use testosterone gels rather than long-acting depot administration when starting initial treatment in high-risk men.	Weak

3.5 Safety and follow-up in hypogonadism management

3.5.1 Hypogonadism and fertility issues

Pharmacological management of hypogonadism aims to increase testosterone levels to normal levels which resolve or improve symptoms of hypogonadism. The first choice is to administer exogenous testosterone. However, while exogenous testosterone has a beneficial effect on the clinical symptoms of hypogonadism, it temporarily inhibits gonadotropin secretion by the pituitary gland, resulting in impaired spermatogenesis and sperm cell maturation [124]. Therefore, testosterone therapy is contraindicated in hypogonadal men seeking fertility treatment [81]. When secondary hypogonadism is present, gonadotropin therapy may maintain normal testosterone levels and restore sperm production [3].

3.5.2 Male breast cancer

Studies have documented that breast cancer growth is significantly influenced by testosterone and/or by its conversion to oestradiol (E_2) through different mechanisms and pathways [125]. Accordingly, the use of SERMs still represents an important therapeutic option in the management of this cancer [125]. No information is available on the role of testosterone therapy in patients successfully treated for male breast cancer; therefore, treated and active male breast cancer should be recognised as absolute contraindications for testosterone therapy.

3.5.3 Lower urinary tract symptoms/benign prostatic hyperplasia (BPH)

A trial of 60 patients undergoing testosterone therapy for six months showed no significant differences on post-void residual urine and prostate volume, while storage symptoms as measured by IPSS significantly improved, despite an increase in prostate-specific antigen (PSA) level [126]. A larger pre-treatment prostate volume was a predictive factor of improvement in LUTS. Similarly, a placebo-controlled RCT including 120 hypogonadal (total testosterone < 12 nmol/L) men with MetS and listed for BPH surgery, showed that testosterone therapy did not result in a difference in LUTS severity compared to placebo. Conversely, an improvement in ultrasound markers of inflammation in the expression of several pro-inflammatory genes was found in the treatment active arm [127]. A long-term study of 428 men undergoing testosterone therapy for eight years demonstrated significant improvements in IPSS, no changes in max flow rate (Q_{max}) and residual urine volume, but also a significant increase in prostate volume [128]. Similar data from the Registry of Hypogonadism in Men (RHYME), including 999 patients with a follow-up of three years, did not demonstrate any significant difference in PSA levels or total IPSS in men undergoing testosterone therapy, compared to untreated patients [129]. Similar results were reported in an Italian registry (SIAMO-NOI), collecting data from 432 hypogonadal men from fifteen centres [130]. Meta-analyses have not found significant changes in LUTS between patients treated with testosterone or placebo [131-137]. According to the most recent literature, there are no grounds to discourage testosterone therapy in hypogonadal patients with BPH/LUTS and there is evidence of limited benefit from androgen administration. The only concern is related to patients with severe LUTS (IPSS > 19), as they are usually excluded from RCTs; therefore, limiting the long-term safety data of testosterone therapy in this specific setting [61].

3.5.4 Prostate cancer (PCa)

A considerable number of observational studies have failed to demonstrate any association between circulating higher testosterone levels and PCa [138]. In contrast, studies investigating the relationship between low levels of testosterone and risk of PCa have found that men with very low levels of fT have a reduced risk of developing low-to-intermediate-grade PCa, but have a non-significantly increased chance of developing high-grade PCa [138]. This peculiar pattern was also reported in trials such as the Health Professionals Follow-up Study, the Prostate Cancer Prevention Trial (PCPT) and the Reduction by Dutasteride of Prostate Cancer Events (REDUCE), with varying magnitudes of significance [139].

A meta-analysis, including 27 placebo-controlled, RCTs, found no evidence of increased PSA levels following testosterone therapy for one-year. When considering eleven studies reporting on the occurrence of PCa, the meta-analysis found no evidence of increased risk of PCa. However, a one year follow-up may be considered too short to draw firm conclusions on the risks of developing PCa. Furthermore, the analysis was restricted to studies with > 1-year follow-up, but no significant changes in PSA levels nor increased risk of PCa were found [132]. After five-year of median follow-up in three independent registry studies with > 1,000 patients undergoing testosterone therapy, PCa occurrence always remained below the reported incidence rate in the general population [140]. Similar results were reported by a large observational study including 10,311 men treated with testosterone therapy and 28,029 controls with a median follow-up of 5.3 years [141]. The same study, also showed that the risk of PCa was decreased for men in the highest tertile of testosterone therapy cumulative dose exposure as compared with controls [141].

Recently, the TRAVERSE study, a multicenter, randomized, double-blind, placebo-controlled, noninferiority trial involving 5246 men aged 45 to 80 years, who had pre-existing or a high risk of CVD and who have been

treated because of low testosterone levels (i.e., total T < 10.4 nmol/L) associated with reported symptoms of hypogonadism, did not show any difference in terms of PCa incidence or high-grade PCa rate between arms (testosterone therapy vs. placebo) at a mean follow-up, was 33.0± (SD) 12.1 months. Conversely, the same trial showed a significantly greater increase from baseline of total PSA in the treatment group as compared with the placebo arm [77].

With regards to PCa survivors, safety in terms of the risk of recurrence and progression has not yet been established. Limited data are available in the literature, with most case series not providing sufficient data to draw definitive conclusions (e.g., insufficient follow-up, small samples, lack of control arms, heterogeneity in study population and treatment regimen, etc.) [142]. A meta-analysis derived from thirteen studies including 608 patients, of whom 109 had a history of high-risk PCa, with follow-up of 1-189.3 months [143], suggested that testosterone therapy did not increase the risk of biochemical recurrence, but the available evidence is poor, limiting data interpretation [143]. Similar considerations can be derived from another, larger meta-analysis of 21 studies [144]. However, it is important to recognise both meta-analyses demonstrated high heterogeneity among the different studies and included a limited number of subjects. An RCT assessing the safety/benefit ratio of testosterone therapy in hypogonadal men successfully treated with prostatectomy for non-aggressive prostate PCa is currently ongoing [145].

In conclusion, recent literature does not support an increased risk of PCa in hypogonadal men undergoing testosterone therapy. Although it is mandatory to avoid testosterone administration in men with advanced PCa, insufficient long-term prospective data on the safety of testosterone therapy in PCa survivors [144], should prompt caution in choosing to treat symptomatic hypogonadal men in this setting. In particular, patients should receive comprehensive counselling regarding the uncertain long-term effects of testosterone therapy in this context, which necessitates further investigation. Due to the lack of strong evidence-based data on safety, the possible use of testosterone therapy in symptomatic hypogonadal men previously treated for PCa should be fully discussed with patients and limited to low-risk individuals.

3.5.5 ***Cardiovascular Disease***

Evidence suggests that hypogonadal men have an increased risk of CVD [146, 147]. Whether or not LOH is a cause or a consequence of atherosclerosis has not been clearly determined. Late-onset hypogonadism is associated with CV risk factors, including central obesity, insulin resistance and hyperglycaemia, dyslipidaemia, pro-thrombotic tendency and chronic inflammatory state [147]. Atherosclerosis is a chronic inflammatory disease, that releases pro-inflammatory cytokines into the circulation, which are known to suppress testosterone release from the HPG axis. Evidence from RCTs of testosterone therapy in men with MetS and/or T2DM demonstrates some benefit in CV risk, including reduced central adiposity, insulin resistance, total cholesterol and LDL-cholesterol and suppression of circulating cytokines [28-30, 35, 147, 148]. However, due to the equivocal nature of these studies, testosterone therapy cannot be recommended for use outside of treatment of specific symptoms.

Published data show that LOH is associated with an increase in all-cause and CVD-related mortality [7, 149-152]. These studies are supported by a meta-analysis that concluded that hypogonadism is a risk factor for cardiovascular morbidity [136] and mortality [153]. Importantly, men with low testosterone when compared to eugonadal men with angiographically proven coronary disease have twice the risk of earlier death [147]. Longitudinal population studies have reported that men with testosterone in the upper quartile of the normal range have a reduced number of CV events compared to men with testosterone in the lower three quartiles [149]. Androgen deprivation therapy for PCa is linked to an increased risk of CVD and sudden death [154]. Conversely, two long-term epidemiological studies have reported reduced CV events in men with high normal serum testosterone levels [155, 156]. Erectile dysfunction is independently associated with CVD and may be the first clinical presentation in men with atherosclerosis.

The knowledge that men with hypogonadism and/or ED may have underlying CVD should prompt individual assessment of their CV risk profile. Individual risk factors (e.g., lifestyle, diet, exercise, smoking, hypertension, diabetes and dyslipidaemia) should be assessed and treated in men with pre-existing CVD and in patients receiving androgen deprivation therapy. Cardiovascular risk reduction can be managed by primary care clinicians, but patients should be appropriately counselled by clinicians active in prescribing testosterone therapy [83]. If appropriate, patients should be referred to cardiologists for risk stratification and treatment of comorbidity.

No RCTs have provided a clear answer on whether testosterone therapy affects CV outcomes. The TTrial (n=790) conducted in older men [157], the TIMES2 study (n=220) [29], along with the BLAST studies involving men with Metabolic Syndrome (MetS) and Type 2 Diabetes Mellitus (T2DM), as well as the study involving pre-frail and frail

elderly men - all of which lasted for one year, and the T4DM study spanning two years - did not show any increase in Major Adverse Cardiovascular Events (MACE) increase in Major Adverse Cardiovascular Events (MACE) [29, 32, 33, 157, 158]. Randomised controlled trials, between three and twelve months, in men with known heart disease treated with testosterone have not found an increase in MACE, but have reported improvement in cardiac ischaemia, angina and functional exercise capacity [159-161]. A large cohort study (n=20,4857 men) found that neither transdermal gel or intramuscular testosterone was associated with an increased risk of composite cardiovascular outcome in men with or without prevalent CVD (mean follow-up 4.3 years) [162]. The European Medicines Agency (EMA) has stated that 'The Co-ordination Group for Mutual recognition and Decentralisation Procedures-Human (CMDh), a regulatory body representing EU Member States, has agreed by consensus that there is no consistent evidence of an increased risk of heart problems with testosterone in men. However, the product information is to be updated in line with the most current available evidence on safety, and with warnings that the lack of testosterone should be confirmed by signs and symptoms and laboratory tests before treating men with these drugs [163].

Data recently released from the TRAVERSE study confirm the findings of the EMA [77]. The latter is the first double-blind, placebo-controlled, non-inferiority RCT with primary CV safety as an end point. The results showed that testosterone therapy was noninferior to placebo with respect to the incidence of MACE. However, a mild higher incidence of atrial fibrillation, acute kidney injury, and pulmonary embolism was observed in the testosterone group [77]. The latter observations, however, need to be confirmed since previous available data do not support an increased risk of venous thromboembolism [78, 164] or major arrhythmias [165] after testosterone therapy. Similarly, the long-term follow-up (median of 5.1 years since last injection) of the T4DM study showed no differences in self-reported rates of new diagnosis of CVD [166].

In conclusion, current available data from interventional studies suggest that there is no increased risk up to three years of testosterone therapy [167-171]. The currently published evidence has reported that testosterone therapy in men with diagnosed hypogonadism has neutral or beneficial actions on MACE in patients with normalised testosterone levels. The findings could be considered sufficiently reliable for at least a three year course of testosterone therapy, after which no available study can exclude further or long-term CV events [172, 173].

3.5.5.1 Cardiac Failure

Testosterone therapy is contraindicated in men with severe chronic cardiac failure because fluid retention may lead to exacerbation of the condition. Some studies have shown that men with moderate chronic cardiac failure may benefit from low doses of testosterone, which achieve mid-normal range testosterone levels [160, 174, 175]. An interesting observation is that untreated hypogonadism increased the re-admission and mortality rate in men with heart failure [176]. If a decision is made to treat hypogonadism in men with chronic cardiac failure, it is essential that the patient is followed up carefully with clinical assessment and both testosterone and haematocrit measurements on a regular basis.

*3.5.6 **Erythrocytosis***

An elevated haematocrit level is the most common adverse effect of testosterone therapy. Stimulation of erythropoiesis is a normal biological action that enhances the delivery of oxygen to testosterone-sensitive tissues (e.g., striated, smooth and cardiac muscle). Any elevation above the normal range for haematocrit usually becomes evident between three and twelve months after testosterone therapy initiation. However, polycythaemia can also occur after any subsequent increase in testosterone dose, switching from topical to parenteral administration and, development of comorbidity, which can be linked to an increase in haematocrit (e.g., respiratory or haematological diseases).

There is no evidence that an increase of haematocrit up to and including 54% causes any adverse effects. If the haematocrit exceeds 54% there is a testosterone independent, but weak associated rise in CV events and mortality [79, 177-179]. Any relationship is complex as these studies were based on patients with any cause of secondary polycythaemia, which included smoking and respiratory diseases. There have been no specific studies in men with only testosterone-induced erythrocytosis.

As detailed, the TRAVERSE study, which had included symptomatic hypogonadal men aged 45-80 years who had pre-existing or a high risk of CVD, showed a mild higher incidence of pulmonary embolism, a component of the adjudicated tertiary end point of venous thromboembolic events, in the testosterone therapy than in the placebo group (0.9% vs. 0.5%) [77]. However, three previous large studies have not shown any evidence that testosterone therapy is associated with an increased risk of venous thromboembolism [180, 181]. Of those, one study showed that an increased risk peaked at six months after initiation of testosterone therapy, and then declined over the subsequent period [182]. In one study venous thromboembolism was reported in 42 cases

and 40 of these had a diagnosis of an underlying congenital thrombophilia (including factor V Leiden deficiency, prothrombin mutations and homocysteinuria) [183]. A meta-analysis of RCTs of testosterone therapy reported that venous thromboembolism was frequently related to underlying undiagnosed thrombophilia-hypofibrinolysis disorders [78]. In an RCT of testosterone therapy in men with chronic stable angina there were no adverse effects on coagulation, by assessment of tissue plasminogen activator or plasminogen activator inhibitor-1 enzyme activity or fibrinogen levels [184]. Similary, another meta-analysis and systematic review of RCTs found that testosterone therapy was not associated with an increased risk of venous thromboembolism [164]. With testosterone therapy elevated haematocrit levels are more likely to occur if the baseline level is toward the upper limit of normal prior to initiation. Added risks for raised haematocrit on testosterone therapy include smoking or respiratory conditions at baseline. Higher haematocrit is more common with parenteral rather than topical formulations. Accordingly, a large retrospective two-arm open registry, comparing the effects of long-acting testosterone undecanoate and testosterone gels showed that the former preparation was associated with a higher risk of haematocrit levels > 50%, when compared to testosterone gels [185]. In men with pre-existing CVD extra caution is advised with a definitive diagnosis of hypogonadism before initiating testosterone therapy and monitoring of testosterone as well as haematocrit during treatment.

Elevated haematocrit in the absence of comorbidity or acute CV or venous thromboembolism can be managed by a reduction in testosterone dose, change in formulation or if the elevated haematocrit is very high by venesection (500 mL), even repeated if necessary, with usually no need to stop the testosterone therapy.

*3.5.7 **Obstructive Sleep Apnoea***

There is no evidence that testosterone therapy can result in the onset or worsening of sleep apnoea. Combined therapy with Continuous Positive Airway Pressure (CPAP) and testosterone gel was more effective than CPAP alone in the treatment of obstructive sleep apnoea [186]. In one RCT, testosterone therapy in men with severe sleep apnoea reported a reduction in oxygen saturation index and nocturnal hypoxaemia after seven weeks of therapy compared to placebo, but this change was not evident after eighteen weeks' treatment and there was no association with baseline testosterone levels [187].

*3.5.8 **Follow-up***

Testosterone therapy alleviates symptoms and signs of hypogonadism in men in a specific time-dependent manner. The TTrials clearly showed that testosterone therapy improved sexual symptoms as early as three months after initiation [93]. Similar results have been derived from meta-analyses [78, 85]. Hence, the first evaluation should be planned after three months of treatment. Further evaluation may be scheduled at six months or twelve months, according to patient characteristics, as well as results of biochemical testing (see below). Patients at high risk of developing elevated haematocrit should be evaluated every three months during the first year of testosterone therapy and at least every six months thereafter. Accordingly, current guidelines suggest that haematocrit should be maintained below 45% in patients with polycythaemia vera to avoid thromboembolism risk [188]. Similarly, data derived using a multi-institutional database including a large cohort of hypogonadal (total testosterone < 12 nmol/L) men who received testosterone therapy and subsequently did (n=5,887) or did not (n=4,2784) develop polycythaemia (haematocrit > 52%) showed that men who had an increased haematocrit had a higher risk of MACE or venous thromboembolism mostly during the first year of therapy [189]. The risk was even higher when a haematocrit threshold of 54% was considered whilst no risk was observed when a 50% threshold was applied [189]. Table 6 summarises the clinical and biochemical parameters that should be monitored during testosterone therapy.

TTrials were designed to maintain the serum testosterone concentration within the normal range for young men (280–873 ng/dL or 9.6-30 nmol/L) [93]. This approach resulted in a good benefit/risk ratio. A similar approach could be considered during follow-up. The correct timing for the evaluation of testosterone levels varies according to the type of preparation used (Table 5). Testosterone is involved in the regulation of erythropoiesis [120] and prostate growth [61], hence evaluation of PSA and haematocrit should be mandatory before and during testosterone therapy. However, it is important to recognise that the risk of PCa in men aged < 40 years is low. Similarly, the mortality risk for PCa in men aged > 70 years has not been considered high enough to warrant monitoring in the general population [190]. Therefore, any screening for PCa through the determination of PSA and DRE in men aged < 40 or > 70 years during testosterone therapy should be discussed with the patients.

Baseline and, at least, annual glyco-metabolic profile evaluation may be a reasonable consideration, particularly in the management of functional hypogonadism. Testosterone therapy may be beneficial for hypogonadal men with low or moderate fracture risk [107]; therefore, dual energy X-ray absorptiometry (DEXA) bone scan may also be considered at baseline and 18-24 months following testosterone therapy, particularly in patients with more severe hypogonadism [107].

Digital rectal examination may detect prostate abnormalities that can be present even in men with normal PSA values. Hence, DRE is mandatory in all men at baseline and is recommended to be performed at least annually during testosterone therapy, as long as there is no significant increase in PSA velocity.

The decision to stop testosterone therapy or to perform a prostate biopsy due to PSA increase or prostate abnormalities should be based on local PCa guidelines. There is a large consensus that any increase of haematocrit > 54% during testosterone therapy requires therapy withdrawal and phlebotomy to avoid potential adverse effects including venous-thromboembolism and CVD, especially in high-risk individuals. In patients with lower risk of relevant clinical sequelae, the situation can be alternatively managed by reducing testosterone dose and switching formulation along with venesection. A positive family history of venous-thromboembolism should be carefully investigated and the patient counselled about testosterone therapy to avoid/prevent thrombophilia-hypofibrinolysis [78]. Finally, caution should be exercised in men with pre-existing CVD or at higher risk of CVD [77].

Table 6: Clinical and biochemical parameters to be checked during testosterone therapy

Parameters		Year 1 of treatment			After year 1 of treatment	
	Baseline	3 months	6 months	12 months	Annually	18-24 months

[1]Population with polycythaemia vera or at high risk of secondary polycythaemia (e.g., sleep apnea, morbid obesity, heavy smokers, chronic obstructive pulmonary disease); [2]Prostate cancer survivors.

3.5.9 Summary of evidence and recommendations on safety and monitoring in testosterone treatment

Summary of evidence	LE
Testosterone therapy is contraindicated in men with secondary hypogonadism who desire fertility.	1a
Testosterone therapy is contraindicated in men with active prostate cancer or breast cancer, as these patients are usually excluded from RCTs.	1a
Testosterone therapy does not increase the risk of prostate cancer, but long-term prospective follow-up data are required to validate this statement.	1a
The effect of testosterone therapy in men with severe lower-urinary tract symptoms is limited, as these patients are usually excluded from RCTs.	1a
There is no substantive evidence that testosterone therapy, when replaced to normal levels, results in the development of major adverse cardiovascular events.	1a
There is no evidence of a relationship between testosterone therapy and mild, moderate or CPAP-treated severe sleep apnoea.	1b

Recommendations	Strength rating
Fully counsel symptomatic hypogonadal men who have been surgically treated for localised prostate cancer (PCa) and who are currently without evidence of active disease considering testosterone therapy, emphasising the lack of sufficient safety data on long-term follow-up.	Weak
Restrict treatment to patients with a low risk of recurrent PCa*. Treatment should start after at least one year of follow-up with prostate-specific antigen (PSA) level < 0.01 ng/mL.	Weak
Advise patients that safety data on the use of testosterone therapy in men treated for breast cancer are unknown.	Strong
Assess cardiovascular risk factors before commencing testosterone therapy.	Strong
Assess men with known cardiovascular disease (CVD) for cardiovascular symptoms before initiating testosterone therapy and monitor these men with close clinical assessment and evaluation during treatment.	Strong
Treat men with hypogonadism and pre-existing CVD, venous-thromboembolism or chronic cardiac failure, who require testosterone therapy with caution, by careful clinical monitoring and regular measurement of haematocrit (not exceeding 54%) and testosterone levels.	Weak
Exclude a family history of venous-thromboembolism before starting testosterone therapy.	Strong
Monitor testosterone, and haematocrit at three, six and twelve months after testosterone therapy initiation, and thereafter annually. A haematocrit > 54% requires testosterone therapy adjustment or withdrawal and venesection if required. Re-introduce testosterone therapy at a lower dose once the haematocrit has normalised and consider switching to topical testosterone preparations.	Strong
Evaluate patients with polycythaemia vera and those with a higher risk of developing elevated haematocrit every three months during the first year of testosterone therapy, and at least every six months thereafter.	Strong
Evaluate total PSA in PCa survivors at three, six and twelve months during the first year of testosterone therapy, and annually thereafter.	Strong

**As for EAU risk groups for biochemical recurrence of localised or locally advanced prostate cancer (see EAU Prostate Cancer Guidelines, 2024)*

4. EPIDEMIOLOGY AND PREVALENCE OF SEXUAL DYSFUNCTION AND DISORDERS OF MALE REPRODUCTIVE HEALTH

4.1 Erectile dysfunction

Epidemiological data have shown a high prevalence and incidence of ED worldwide [191]. Among others, the Massachusetts Male Aging Study (MMAS) [192] reported an overall prevalence of 52% ED in non-institutionalised men aged 40-70 years in the Boston area; specific prevalence for minimal, moderate, and complete ED was 17.2%, 25.2%, and 9.6%, respectively. In the Cologne study of men aged 30-80 years, the prevalence of ED was 19.2%, with a steep age-related increase from 2.3% to 53.4% [193]. The incidence rate of ED (new cases per 1,000 men annually) was 26 in the long-term data from the MMAS study [194] and 19.2 (mean follow-up of 4.2 years) in a Dutch study [195]. In a cross-sectional real-life study among men seeking first medical help for new-onset ED, one in four patients were younger than 40 years, with almost 50% of the young men complaining of severe ED [196]. Differences among these studies can be explained by differences in methodology, ages, and socio-economic and cultural status of the populations studied. The prevalence rates of ED studies are reported in Table 1 online supplementary evidence: https://uroweb.org/guidelines/sexual-and-reproductive-health/publications-appendices.

4.2 Premature ejaculation

The highest prevalence rate of 31% (men aged 18-59 years) was found by the National Health and Social Life Survey (NHSLS), which determines adult sexual behaviour in the USA [197]. Prevalence rates were 30% (18-29 years), 32% (30-39 years), 28% (40-49 years) and 55% (50-59 years), respectively. However, it is unlikely that the premature ejaculation (PE) prevalence is as high as 20-30% based on the relatively low number of men

who seek medical help for PE. These high prevalence rates may be a result of the dichotomous scale (yes/no) in a single question asking if ejaculation occurred too early, as the prevalence rates in European studies have been significantly lower [198]. Two separate observational, cross-sectional surveys from different continents found that the overall prevalence of PE was 19.8 and 25.8%, respectively [199, 200]. Further stratifying these complaints into the classifications defined by Waldinger *et al.*, [201], rates of lifelong PE were 2.3 and 3.18%, acquired PE 3.9 and 4.48%, variable PE 8.5 and 11.38% and subjective PE 5.1 and 6.4%, respectively [199, 200]. Both studies showed that men with acquired PE were more likely to seek treatment compared to men with lifelong PE. The prevalence rates of premature ejaculation as evidenced by the highly discrepant prevalence rates reported in Appendix 2 online supplementary evidence: https://uroweb.org/guidelines/sexual-and-reproductive-health/publications-appendices.

4.3 Other ejaculatory disorders

4.3.1 ***Delayed ejaculation***

Due to its rarity and uncertain definitions, the epidemiology of delayed ejaculation (DE) is not clear [202]. However, several well-designed epidemiological studies have revealed that its prevalence is around 3% among sexually active men [197, 203]. According to data from the NHSLS, 7.78% of a national probability sample of 1,246 men aged 18-59 years reported an inability to achieve climax or ejaculation [197]. In a similar stratified national probability sample survey completed over six months among 11,161 men and women aged 16-44 years in Britain, 0.7% of men reported an inability to reach orgasm [204]. In an international survey of sexual problems among 13,618 men aged 40–80 years from 29 countries, 1.1-2.8% of men reported that they frequently experience inability to reach orgasm [205]. Another study conducted in the United States (USA), in a national probability sample of 1,455 men aged 57-85 years, 20% of men reported an inability to climax and 73% reported that they were bothered by this problem. [206]. Similar to PE, there are distinctions among lifelong, acquired and situational DE [207]. Although the evidence is limited, the prevalence of lifelong and acquired DE is estimated at 1 and 4%, respectively [208].

4.3.2 ***Anejaculation and Anorgasmia***

Establishing the exact prevalence of anejaculation and anorgasmia is difficult since many men cannot distinguish between ejaculation and orgasm. The rarity of these clinical conditions further hampers the attempts to conduct epidemiological studies. In a report from the USA, 8% of men reported unsuccessfully achieving orgasm during the past year [197].

According to Kinsey *et al.*, [209], 0.14% of the general population has anejaculation. The most common causes of anejaculation were spinal cord injury, diabetes mellitus and multiple sclerosis. Especially in most cases of spinal cord injury, medical assistance is the only way to ejaculate. While masturbation leads to the lowest rates of ejaculation, higher response rates can be obtained with penile vibratory stimulation or acetylcholine esterase inhibitors followed by masturbation in patients with spinal cord injury [210].

4.3.3 ***Retrograde ejaculation***

Similar to anejaculation, it is difficult to estimate the true incidence of retrograde ejaculation (RE). Although RE is generally reported in 0.3-2% of patients attending fertility clinics [211], diabetes may increase these rates by leading to autonomic neuropathy. Autonomic neuropathy results in ED and ejaculatory dysfunctions ranging from DE to RE and anejaculation, depending on the degree of sympathetic autonomic neuropathy involved [212]. In 54 diabetic patients with sexual dysfunction, RE was observed with a 6% incidence [213]. In a controlled trial, RE was observed in 34.6% of diabetic men [214]. A trial reported the rate of RE among 57 type-1-diabetes mellitus patients (aged 18-50 years) was at least 8.8% [215]. Retrograde ejaculation was also reported in studies of patients who had undergone transurethral resection of prostate (TURP) or open prostatectomy due to disrupted bladder neck integrity. A study of the effect of prostatectomy on QoL in 5,276 men after TURP, found that 68% reported post-surgical RE [216]. However, with the development of less invasive techniques, the incidence of RE decreases following the surgical treatment of LUTS [217-221].

4.3.4 ***Painful ejaculation***

Painful ejaculation is a common but poorly understood clinical phenomenon, which is associated with sexual dysfunction. Several studies demonstrated its prevalence to range between 1-10% in the general population [222-224]; however, it may increase to 30-75% among men with chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) [225-229]. It should be noted that the design of most of these studies was not scientifically sound and the condition was probably under-reported due to the lack of an evidence-based definition and well-defined prognostic criteria.

*4.3.5 **Haemospermia***

The exact incidence and prevalence of haemospermia is difficult to elucidate due to a number of factors including its covert presentation, usually self-limiting nature and patient embarrassment. The symptoms represent 1-1.5% of all urological referrals and occur in all age groups, with a mean age of 37 years [230, 231]. In a PCa screening study of 26,126 men, aged ≥ 50 years or older than 40 with a history of PCa or of black ethnicity, haemospermia was found in 0.5% on entry to the trial [232].

4.4 Low sexual desire

The global prevalence of low sexual desire in men is 3-28% [205, 233, 234]. Low solitary and dyadic sexual desires have been reported in 68% and 14% of men, respectively [235]. Also, low sexual desire has been observed as a common complaint in gay men, with a prevalence of 19-57% [236, 237]. Despite its relationship with age, low sexual desire has also been reported among young men (18-29 years), with a prevalence of 6-19% [197, 238, 239].

5. MANAGEMENT OF ERECTILE DYSFUNCTION

5.1 Definition and classification

Erectile dysfunction (ED) is defined as the persistent inability to attain and maintain an erection sufficient to permit satisfactory sexual performance [240]. Erectile dysfunction may affect psychosocial health and have a significant impact on the QoL of patients and their partner's [192, 241-243]. Erectile dysfunction is commonly classified into three groups based on aetiology: organic, psychogenic and mixed ED. However, this classification should be used, with caution as most cases are actually of mixed aetiology. It has therefore been suggested to use the terms "primary organic" or "primary psychogenic".

5.2 Risk factors

Erectile dysfunction is associated with numerous risk factors including age, diabetes mellitus, dyslipidaemia, hypertension, CVD, obesity, MetS, hyperhomocysteinemia, lack of exercise, smoking and drug use [242, 244-255]. In addition, several therapeutic agents for CVD have been shown to have a detrimental effect on erectile function (EF), whereas newer drugs have exhibited a neutral or even beneficial effect [247, 256, 257]. Other reported risk factors include atrial fibrillation, hyperthyroidism, vitamin D and folic acid deficiency, hyperuricemia, depression and anxiety disorders, chronic kidney and rheumatic disease, COPD, migraine, inflammatory bowel disease and osteoporosis [252, 258-270]. In addition, a growing body of evidence has demonstrated an association between the onset of new ED in men who have had COVID-19 [1974-1976].

Erectile dysfunction is also frequently associated with other urological conditions and procedures including LUTS/BPH and surgery for LUTS/BPH [275-277], chronic pelvic pain syndrome (CPPS) and chronic prostatitis [278], bladder pain syndrome/interstitial cystitis [279], premature ejaculation [280] and urethroplasty surgery for posterior urethral strictures [281].

5.3 Pathophysiology

The pathophysiology of ED may be vasculogenic, neurogenic, anatomical, hormonal, drug-induced and/or psychogenic (Table 7) [282]. In most cases, numerous pathophysiological pathways can co-exist and may all negatively impact EF.

Table 7: Urological conditions associated with ED [282]

Vasculogenic
Recreational habits (i.e., cigarette smoking)
Lack of regular physical exercise
Obesity
Cardiovascular diseases (e.g., hypertension, coronary artery disease, peripheral vasculopathy)
Type 1 and 2 diabetes mellitus; hyperlipidaemia; metabolic syndrome; hyperhomocysteinemia
Major pelvic surgery (e.g., radical prostatectomy) or radiotherapy (pelvis or retroperitoneum)

Neurogenic
Central causes
Degenerative disorders (e.g., multiple sclerosis, Parkinson's disease, multiple atrophy, etc.)
Spinal cord trauma or diseases
Stroke
Central nervous system tumours
Peripheral causes
Type 1 and 2 diabetes mellitus
Chronic renal failure, chronic liver failure
Polyneuropathy
Surgery (major surgery of pelvis/retroperitoneum) or radiotherapy (pelvis or retroperitoneum)
Surgery of the urethra (urethral stricture, open urethroplasty, etc.)
Anatomical or structural
Hypospadias, epispadias; micropenis
Phimosis
Peyronie's disease
Penile cancer (other tumours of the external genitalia)
Hormonal
Diabetes mellitus; Metabolic Syndrome (MeTS)
Hypogonadism (any type)
Hyperthyroidism
Hyper- and hypocortisolism (Cushing's disease, etc.)
Panhypopituitarism and multiple endocrine disorders
Mixed pathophysiological pathways
Chronic systemic diseases (e.g., diabetes mellitus, hypertension, MeTS, chronic kidney disease, chronic liver disorders, hyperhomocysteinemia, hyperuricemia, chronic obstructive pulmonary disease, rheumatic disease)
Psoriasis, gouty arthritis, ankylosing spondylitis, non-alcoholic fatty liver disease, chronic periodontitis, open-angle glaucoma, inflammatory bowel disease, chronic fatigue syndrome, allergic rhinitis, obstructive sleep apnoea, depression
Iatrogenic causes (e.g. TRUS-guided prostate biopsy)
Drug-induced
Antihypertensives (i.e., thiazidediuretics, beta-blockers)*
Antidepressants (e.g., selective serotonin reuptake inhibitors, tricyclics)
Antipsychotics
Antiandrogens (GnRH analogues and antagonists; 5-ARIs)
Recreational drugs (e.g., heroin, cocaine, marijuana, methadone, synthetic drugs, anabolic steroids, excessive alcohol intake)
Psychogenic
Generalised type (e.g., lack of arousal and disorders of sexual intimacy)
Situational type (e.g., partner-related, performance-related issues or due to distress)
Trauma
Penile fracture
Pelvic fracture

GnRH = gonadotropin-releasing hormone; 5-ARIs = 5α-reductase inhibitors.
**A symmetry analysis showed that cardiovascular drugs do not strongly affect the risk of subsequently being prescribed as an anti-erectogenic drug. The analysis only assessed the short-term risk [283].*

5.3.1 Pelvic surgery and prostate cancer treatment

Pelvic surgery, especially for oncological disease (e.g., radical prostatectomy (RP) [284], radical cystectomy [285] and colorectal surgery [286]), may have a negative impact on EF and overall sexual health. Surgery resulting in damage of the neurovascular bundles, that control the complex mechanism of the cavernous erectile response, may result in ED, although NS approaches have been adopted over the last few decades. To date only the surgical treatment of PCa has enough scientific evidence supporting its potential pathophysiological association with ED [287-289]. However, even non-surgical treatments of PCa (i.e., radiotherapy, or brachytherapy) can be associated with ED [287, 290, 291].

The ProtecT trial randomised 1,643 patients to active treatment (RP or RT) or active monitoring for localised PCa and assessed sexual function, including EF, using the EPIC-26 instrument [271]. At baseline, 67% of men reported erections firm enough for sexual intercourse. At the six year follow-up assessment this fell to 30% in the active monitoring group, 27%% in the RT group and 17% in the RP group, respectively.

Radical prostatectomy for the treatment of clinically localised intermediate- or high-risk PCa is a widely performed procedure. Research has shown that 25-75% of men experience post-RP ED [272, 273, 288]. Conversely, the rate of unassisted post-operative EF recovery ranges between 20 and 25% in most studies. These rates have not substantially improved or changed over the past seventeen years, despite growing attention to post-surgical rehabilitation protocols and refinement of surgical techniques [273, 274, 292]. Overall, patient age, baseline EF and surgical volume, with the subsequent ability to preserve the neurovascular bundles, are the main factors in promoting the highest rates of post-operative EF [272, 289, 293, 294]. Regardless of the surgical technique, surgeons' experience clearly impacts on post-operative EF outcome [295]. The surgical approach may also affect post-RP EF, but the current evidence conflicts with one systematic review reporting a significant advantage in favour of RARP compared to open retropubic RP for twelve-month potency rates [296] and two RCTs reporting only a small improvement in EF for RARP or no different in EF between techniques [297, 298].

Erectile dysfunction is also a common problem after both external beam radiation therapy (EBRT) and brachytherapy for PCa. A systematic review and meta-analysis including men treated with EBRT (65%), brachytherapy (31%) or both (4%) showed that the post-treatment prevalence of ED was 34% at one year and 57% at 5.5 years, respectively [299, 300]. Similar findings have been reported for stereotactic radiotherapy with 26-55% of previously sexually functioning patients reporting ED at five years [301].

Recently other modalities have emerged as potential therapeutic options in patients with clinically-localised PCa, including high-intensity focused US (HIFU), cryo-therapeutic ablation of the prostate (cryotherapy), focal padeliporfin-based vascular-targeted photodynamic therapy and focal RT by brachytherapy or CyberKnife®. All these approaches have been reported to have a less-negative impact on EF with many studies reporting a complete recovery at one-year follow-up [302].

5.3.2 Summary of evidence on the epidemiology/aetiology/pathophysiology of ED

Summary of evidence	LE
Erectile dysfunction is common worldwide.	2b
Erectile dysfunction shares common risk factors with cardiovascular disease.	2b
Lifestyle modification (regular exercise and decrease in BMI) can improve erectile function.	1b
Erectile dysfunction is a symptom, not a disease. Some patients may not be properly evaluated or receive treatment for an underlying disease or condition that may be causing ED.	4
Erectile dysfunction is common after RP, irrespective of the surgical technique used.	2b
Erectile dysfunction is common after external radiotherapy and brachytherapy.	2b
Erectile dysfunction is less common after cryotherapy and high-intensity focused US.	2b

5.4 Diagnostic evaluation (basic work-up)

5.4.1 Medical and sexual history

The first step in evaluating ED is always a detailed medical and sexual history of patients and, when available, their partners [303]. Figure 2 lists the minimal diagnostic evaluation (basic work-up) in patients with ED.

A detailed description should be made of the rigidity and duration of both sexually-stimulated and morning erections and problems with sexual desire, arousal, ejaculation, and orgasm [304-306]. Validated psychometric questionnaires, such as the IIEF [307] or its short version (i.e., Sexual Health Inventory for Men; SHIM) [308], help to assess the different sexual function domains (i.e. sexual desire, EF, orgasmic function, intercourse satisfaction, and overall satisfaction), as well as the potential impact of a specific treatment modality. Similarly, structured interviews allow the identification and quantification of the different underlying factors affecting EF [309].

Psychometric analyses also support the use of the Erectile Hardness Score (EHS) for the assessment of penile rigidity in practice and clinical trials research [310].

Patients should always be screened for symptoms of possible hypogonadism, including decreased libido and energy, and fatigue (see Table 3: Specific symptoms associated with LOH).

*5.4.2 **Physical examination***

Every patient must be given a physical examination focused on the genitourinary, endocrine, vascular and neurological systems [311, 312]. A physical examination may reveal unsuspected diagnoses, such as Peyronie's disease (PD), pre-malignant or malignant genital lesions, prostatic enlargement or irregularity/nodularity, or signs and symptoms suggestive of hypogonadism (see Table 3: Specific symptoms associated with LOH).

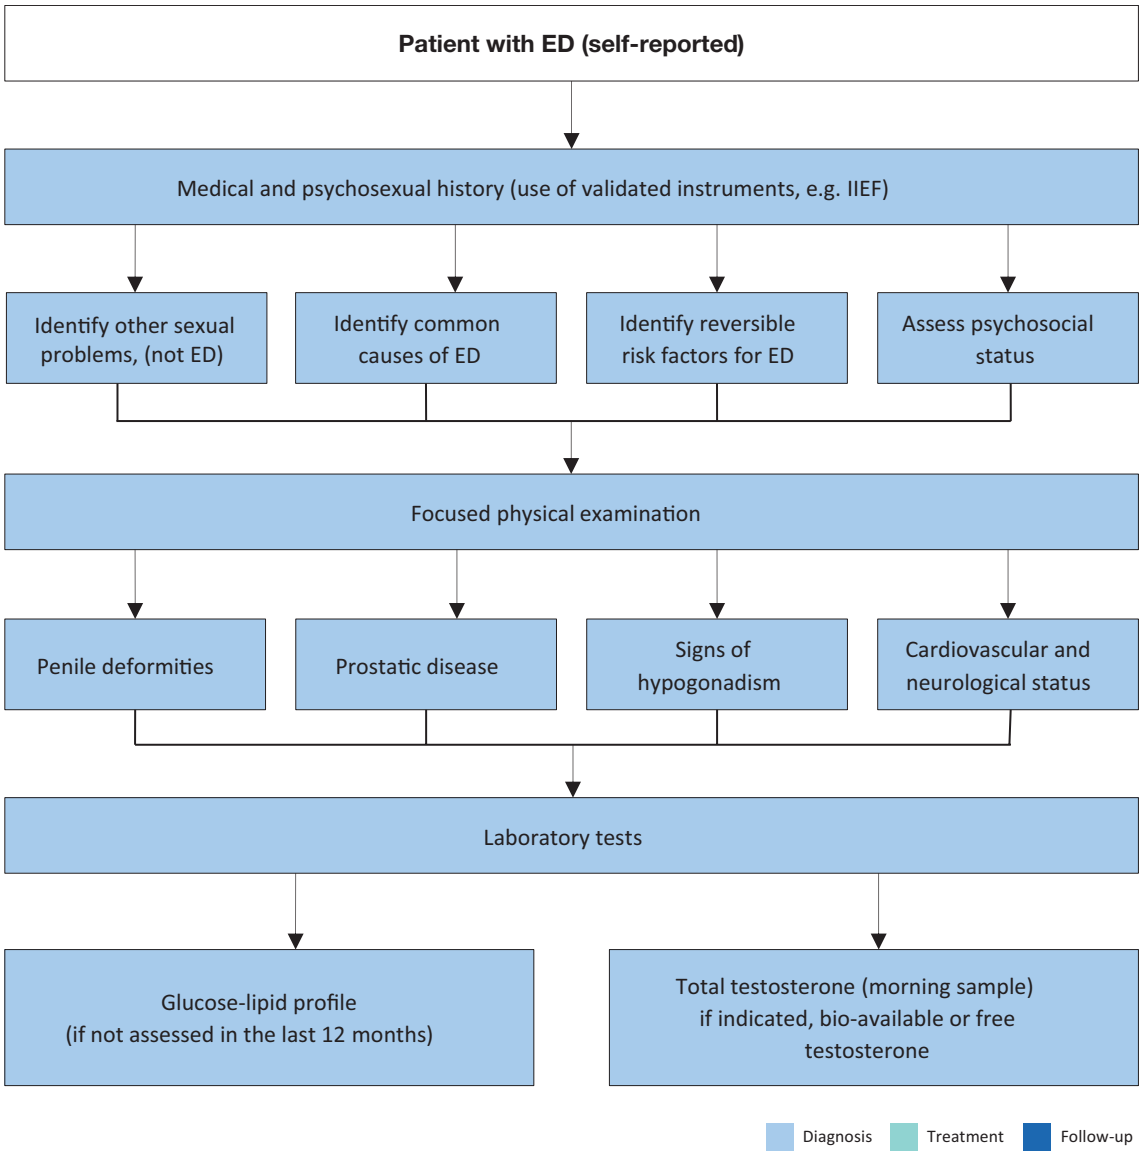
Blood pressure and heart rate should be measured if they have not been assessed in the previous three to six months. Likewise, either BMI calculation or waist circumference measurement should be undertaken to assess patients for comorbid conditions (e.g., MetS).

*5.4.3 **Laboratory testing***

Patients should undergo a fasting blood glucose or haemoglobin A1c and lipid profile measurement if they have not been assessed in the previous twelve months. Hormonal tests should include early morning total testosterone in a fasting state. The bio-available or calculated fT values may sometimes be needed to corroborate total testosterone measurements (see sections 3.2.1 and 3.4.1). Additional laboratory tests may be considered in selected patients with specific signs and associated symptoms (e.g., total PSA) [313], PRL and LH [314]). Although physical examination and laboratory evaluation of most men with ED may not reveal the exact diagnosis, clinical and biochemical evaluation presents an opportunity to identify comorbid conditions [312].

Figure 2: Minimal diagnostic evaluation (basic work-up) in patients with ED

ED = erectile dysfunction; IIEF = International Index of Erectile Function.



ED = erectile dysfunction; IIEF = International Index of Erectile Function.

5.4.4 Cardiovascular system and sexual activity: the patient at risk

Patients who seek treatment for sexual dysfunction have a high prevalence of CVDs. Overall, ED can improve the sensitivity of screening for asymptomatic CVD in men with diabetes [315, 316]. Erectile dysfunction significantly increases the risk of CVD, coronary heart disease, stroke and atrial fibrillation [317]. Longitudinal data from an observational population-based study of 965 men without CVD showed that younger men (especially those < 50 years) with transient and persistent ED have an increased Framingham CVD risk [318].

The current EAU Guidelines on the diagnosis and treatment of men with ED have been adapted from the recommendations from the Princeton Consensus conferences on sexual dysfunction and cardiac risk published in 2012 [319]. Over time, the Princeton Consensus (Expert Panel) Conference is dedicated to optimising sexual function and preserving cardiovascular health [319-322]. Accordingly, patients with ED have been stratified into three cardiovascular risk categories (Table 8), which can still be used as the basis for a treatment algorithm for initiating or resuming sexual activity (Figure 3): low-risk patients do not need cardiac testing or evaluation before initiation or resumption of sexual activity or therapy for sexual dysfunction; intermediate risk patients, according to the results of testing, may be moved to either the high- or low-risk group; high-risk individuals should be referred for cardiac assessment and treatment. Sexual activity should be stopped until the patient's cardiac condition has been stabilised by treatment.

Table 8: Cardiac risk stratification (based on 2nd and 3rd Princeton Consensus) [319, 322]

Low-risk category	Intermediate-risk category	High-risk category
Asymptomatic, < 3 risk factors for CAD (excluding sex)	≥ 3 risk factors for CAD (excluding sex)	High-risk arrhythmias
Mild, stable angina (evaluated and/or being treated)	Moderate, stable angina	Unstable or refractory angina
Uncomplicated previous MI	Recent MI (> 2, < 6 weeks)	Recent MI (< 2 weeks)
LVD/CHF (NYHA class I or II)	LVD/CHF (NYHA class III)	LVD/CHF (NYHA class IV)
Post-successful coronary revascularisation	Non-cardiac sequelae of atherosclerotic disease (e.g., stroke, peripheral vascular disease)	Hypertrophic obstructive and other cardiomyopathies
Controlled hypertension		Uncontrolled hypertension
Mild valvular disease		Moderate-to-severe valvular disease

CAD = coronary artery disease; CHF = congestive heart failure; LVD = left ventricular dysfunction; MI = myocardial infarction; NYHA = New York Heart Association.

Figure 3: Treatment algorithm for determining level of sexual activity according to cardiac risk in ED (based on 3rd Princeton Consensus) [319]

[a] *Sexual activity is equivalent to walking 1 mile on the flat in 20 minutes or briskly climbing two flights of stairs in 10 seconds.*

[b] *Sexual activity is equivalent to 4 minutes of the Bruce treadmill protocol.*

5.5 Diagnostic Evaluation (advanced work-up)

Most patients with ED can be managed based on their medical and sexual history; conversely, some patients may need specific diagnostic tests (Table 9).

*5.5.1 **Nocturnal penile tumescence and rigidity test***

The nocturnal penile tumescence and rigidity (NPTR) test applies nocturnal monitoring devices that measure the number of erectile episodes, tumescence (circumference change by strain gauges), maximal penile rigidity, and duration of nocturnal erections. The NPTR assessment should be performed on at least two separate nights. A functional erectile mechanism is indicated by an erectile event of at least 60% rigidity recorded on the tip of the penis that lasts for ≥ 10 minutes [323]. Nocturnal penile tumescence and rigidity monitoring is an approach for objectively differentiating between organic and psychogenic ED (patients with psychogenic ED usually have normal findings in the NPTR test). However, many potential confounding factors (e.g., situational) may limit its routine use for diagnostic purposes [324].

*5.5.2 **Intracavernous injection test***

The intracavernous injection test gives limited information about vascular status. A positive test is a rigid erectile response (unable to bend the penis) that appears within 10 minutes after the intracavernous injection and lasts for 30 minutes [325]. Overall, the test *per se* is inconclusive as a diagnostic procedure and a duplex Doppler study of the penis should be requested, if clinically warranted.

*5.5.3 **Dynamic duplex ultrasound of the penis***

Dynamic duplex ultrasound (US) of the penis is a second-level diagnostic test that specifically studies the haemodynamic pathophysiology of EF. Therefore, in clinical practice, it is usually applied in those conditions in which a potential vasculogenic aetiology of ED (e.g., diabetes mellitus, multiple concomitant CV risk factors and/or overt peripheral vascular disease, renal transplantation and poor responders to oral therapy) is suspected. Peak systolic blood flow > 30 cm/s, end-diastolic velocity < 3 cm/s and resistance index > 0.8 are considered normal [326, 327]. Recent data suggest that duplex scanning as a haemodynamic study may be better at tailoring therapy for ED, such as for low-intensity shock wave treatment (Li-SWT) in men with vasculogenic ED [328]. Further vascular investigation is unnecessary if a duplex US examination is normal.

*5.5.4 **Arteriography and dynamic infusion cavernosometry or cavernosography***

Pudendal arteriography should be performed only in patients who are being considered for penile revascularisation [329]. At present, dynamic infusion cavernosometry or cavernosography are rarely employed as diagnostic methods for evaluating venogenic ED, and there has been concern surrounding the concept of venogenic ED.

*5.5.5 **Psychopathological and psychosocial assessment***

Mental health issues and psychological distress are frequently comorbid with ED [330]. This is most evident for depression and anxiety-related disorders, but may also include transitory states of altered mood (i.e., dysfunctional affective states resulting from a specific life stressor or crisis) [264, 331, 332]. Relationship factors, including lack of satisfaction with the partner, poor sexual relationships, length of the relationship, or feeling emotionally disconnected from the partner during sex, have been related to erectile difficulties and dysfunction [331, 333, 334]. In contrast, intimacy was found to be a protective factor in ED [253, 335]. Additionally, the cognitive factors underpinning organic and non-organic ED (i.e., all dysfunctional thinking styles and expectations about sexuality, poor self-esteem and cognitive distraction from erotic cues) must also be assessed.

Psychosexual assessment in ED cases includes a clinical interview considering all the previous topics [336]. Also, self-reported measures are frequently used within the psychosocial context [337]. A growing amount of data suggests that men who have sex with men (MSM) present specific psychological risks associated with erectile capability regarding anal sex [338]. Therefore, professionals must tailor their assessment in the context of sexual minorities.

Figure 4: Psychopathological and psychosocial assessment

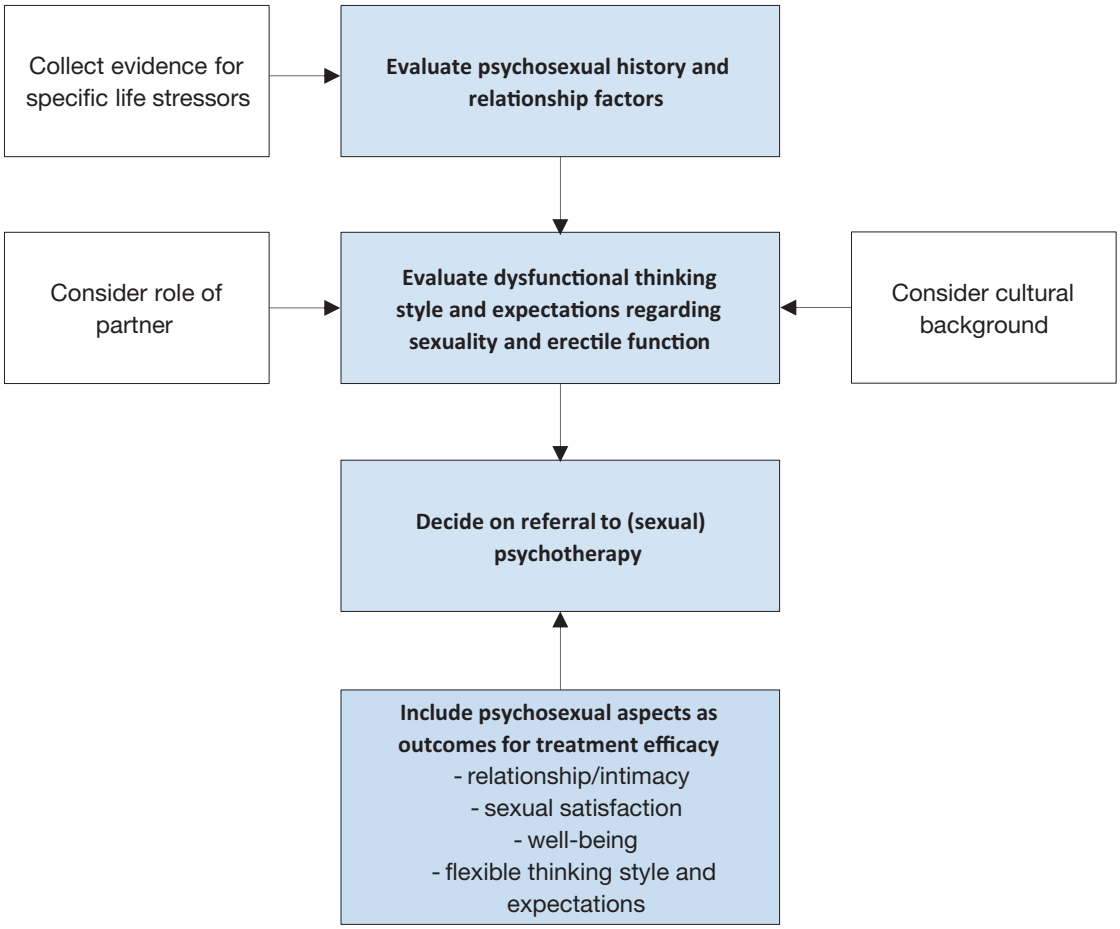


Table 9: Indications for specific diagnostic tests for ED and the specific diagnostic tests

Indications for specific diagnostic tests for ED
Primary ED (not caused by acquired organic disease or psychogenic disorder).
Young patients with a history of pelvic or perineal trauma, who could benefit from potentially curative revascularisation surgery or angioplasty.
Patients with penile deformities that might require surgical correction (e.g., Peyronie's disease and congenital penile curvature).
Patients with complex psychiatric or psychosexual disorders.
Patients with complex endocrine disorders.
Specific tests may be indicated at the request of the patient or their partner.
Medico-legal reasons (e.g., implantation of penile prosthesis to document end-stage ED, and sexual abuse).
Specific diagnostic tests for ED
Nocturnal Penile Tumescence and Rigidity (NTPR) using Rigiscan®
Vascular studies • Intracavernous vasoactive drug injection • Penile dynamic duplex ultrasonography • Penile dynamic infusion cavernosometry and cavernosography • Internal pudendal arteriography
Specialised endocrinological studies
Specialised psycho-diagnostic evaluation

5.5.6 Summary of evidence and recommendations for diagnostic evaluation of ED

Summary of evidence	LE
Medical and sexual history, physical examination and laboratory testing including metabolic and hormonal profile may identify risk factors for ED and may help in defining the ED aetiology.	3
Validated psychometric questionnaires (e.g. IIEF; EHS) are reliable tools to assess ED severity.	3
Specific diagnostic tests could be of help in discerning between vasculogenic, hormonal or psychogenic causes of ED	3

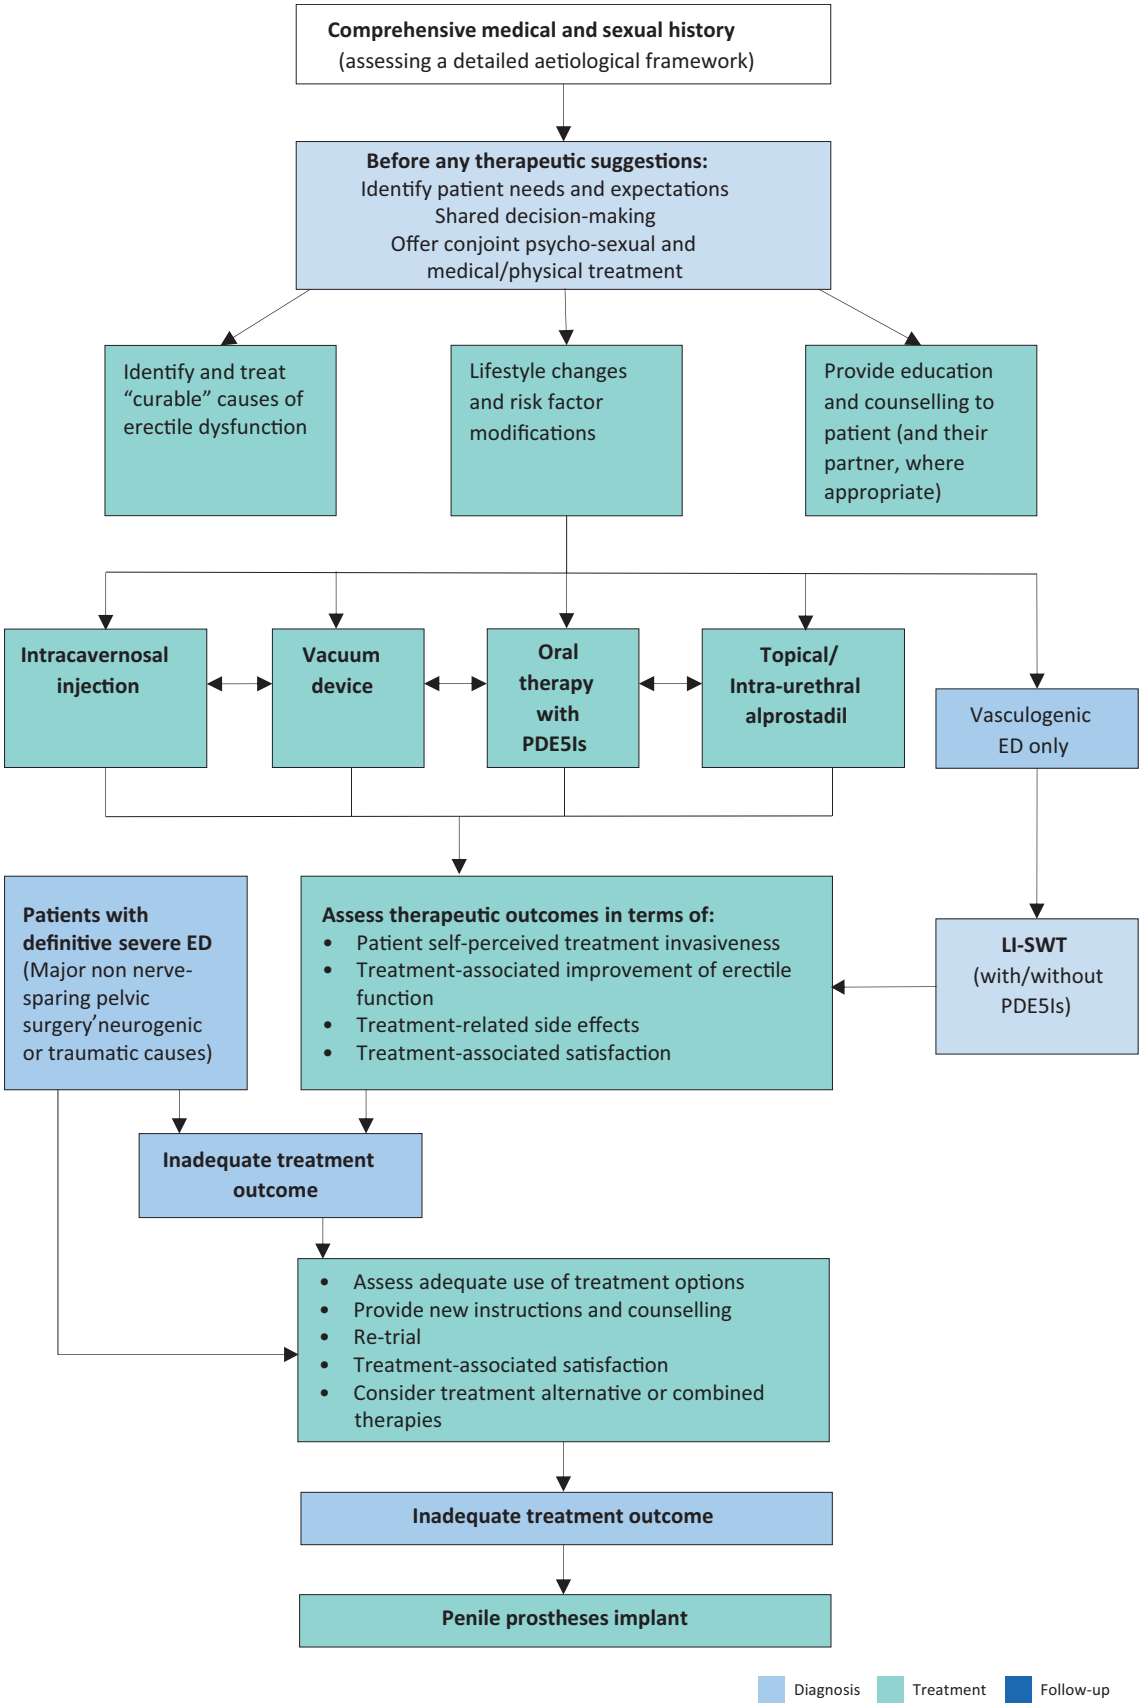
Recommendations	Strength rating
Take a comprehensive medical and sexual history in every patient presenting with erectile dysfunction (ED). Take a targeted psychosexual history, including life stressors, cultural aspects, and cognitive factors regarding patient sexual performance.	Strong
Use a validated questionnaire related to ED to assess all sexual function domains (e.g., International Index of Erectile Function) and the effect of a specific treatment modality.	Strong
Include a focused physical examination in the initial assessment of men with ED to identify underlying medical conditions and comorbid genital disorders that may be associated with ED.	Strong
Evaluate laboratory tests, including glucose and lipid profile and total testosterone, to identify and treat any reversible risk factors and lifestyle factors that can be modified.	Strong
Include specific diagnostic tests in the initial evaluation of ED in the presence of the conditions presented in Table 9.	Strong

5.6 Treatment of erectile dysfunction

The Guidelines Panel have developed a comprehensive therapeutic and decision-making algorithm (Figure 5) for treating ED. The treatment algorithm was developed as an alternative to the traditional three-tier concept, to support personalised treatment tailored to individual patients, according to the invasiveness, tolerability and effectiveness of the different therapeutic options and patients' expectations. In this context, patients should be fully counselled with respect to all available treatment modalities.

The majority of men with ED are not treated with cause-specific therapeutic options. This results in a tailored treatment strategy that depends on invasiveness, efficacy, safety and costs, as well as patient preference [339]; therefore, physician-patient dialogue is essential throughout the management of ED. A systematic review has shown a consistent discontinuation rate for all available ED treatment options. This highlights the importance of clinicians understanding patient's beliefs about ED treatment, therapeutic ineffectiveness, adverse effects, quality of intimate relationships and treatment costs all of which were shown to be the most prevalent barriers to treatment use [340].

Figure 5: Management algorithm for erectile dysfunction



ED = erectile dysfunction; PDE5Is = phosphodiesterase type 5 inhibitors; Li-SWT = low-intensity shockwave therapy.

*5.6.1 **Patient education***

Educational intervention is often the first approach to sexual complaints, and consists of informing patients about the psychological and physiological processes involved in the individual's sexual response, in ways the patient can understand. This baseline approach has been shown to favour sexual satisfaction in men with ED [341]. Accordingly, consultation with the patient should include a discussion of the expectations and needs of the patient's and his sexual partner. It should also review the patient's and partner's understanding of ED and the results of diagnostic tests, and provide a rationale for treatment selection [339].

*5.6.2 **Modifiable risk factors***

Erectile dysfunction may be associated with modifiable or reversible risk factors, including lifestyle or drug-related factors [342]. These factors may be modified either before, or at the same time as, specific therapies are used. Likewise, ED may be associated with concomitant and underlying conditions (e.g., endocrine disorders and metabolic disorders such as diabetes, and some cardiovascular problems such as hypertension) which should always be well-controlled as the first step of any ED treatment [343]. Overall, several studies have shown that lifestyle modifications including physical activity, weight loss and treatment for CVD risk factors and lipid-lowering therapy with statins may be of help in improving sexual function in men with ED [257, 342, 344-349].

*5.6.3 **Phosphodiesterase type 5 inhibitors***

Four potent selective PDE5Is have been approved by the EMA for the treatment of ED [350]. The efficacy of all four PD5EIs in almost every subgroup of patients with ED has been successfully established [350-353]. Efficacy is defined as an erection, with rigidity, sufficient for satisfactory intercourse [343]. In addition, adverse events for the four PDE5Is are generally mild and self-limiting [354-358]. The pharmacokinetic data for all four PDE5Is and their associated adverse events are presented in Tables 10 and 11, respectively. The choice of PDE5I depends on the frequency of intercourse and the patient's personal experience. Two meta-analyses demonstrated that ED patients who prioritise high efficacy should use sildenafil 50 mg whereas those who optimise tolerability should initially use tadalafil 10 mg [351, 359].

5.6.3.1 Sildenafil

Sildenafil is administered in doses of 25, 50 and 100 mg. The recommended starting dose is 50 mg and should be adapted according to the patient's response and adverse effects [360]. The window of effectiveness ranges from 30-60 minutes after administration [360] up to 12 hours [361]. In a 24-week dose-response study, improved erections were reported by 56%, 77% and 84% of general ED patients taking 25, 50 and 100 mg sildenafil, respectively, compared to 25% of men taking placebo [362]. Sildenafil also significantly improved patient scores for IIEF, sexual encounter profile question 2 (SEP2), SEP question 3 (SEP3), General Assessment Questionnaire (GAQ) and treatment satisfaction [362]. Furthermore, an orally disintegrating tablet (ODT) of sildenafil citrate at a dose of 50 mg has been developed, mainly for patients who have difficulty swallowing solid dosage forms.

5.6.3.2 Tadalafil

Tadalafil is administered in on-demand doses of 10 and 20 mg or a daily dose of 5 mg. The recommended on-demand starting dose is 10 mg and should be adapted according to the patient's response and adverse effects [363, 364]. The window of effectiveness ranges from 30 minutes after administration (peak efficacy after approximately 2 hours) up to 36 hours [363]. In a twelve-week dose-response study, improved erections were reported by 67% and 81% of men with ED taking 10 and 20 mg tadalafil, respectively, compared to 35% of men taking placebo [363]. Tadalafil has also been shown to have a net clinical benefit in the short-term on ejaculatory and orgasmic functions in ED patients [365].

Data have also shown that 40% of men aged > 45 years were combined responders for ED and LUTS/BPH when treated with tadalafil 5 mg once daily, with symptom improvement after twelve weeks [366]. Therefore, its use may be considered in both patients with ED only and in patients also complaining of concomitant LUTS, and wishing to benefit from a single therapy [367].

5.6.3.3 Vardenafil

Vardenafil is administered in on-demand doses of 5, 10 and 20 mg. The recommended starting dose is 10 mg and should be adapted according to the patient's response and adverse effects [356]. Vardenafil is effective from 30 minutes after administration [368], with one of three patients achieving satisfactory erections within 15 minutes of ingestion [369]. In a twelve-week dose-response study, improved erections were reported by 66%, 76% and 80% of men with ED taking 5, 10 and 20 mg vardenafil, respectively, compared with 30% of men taking placebo [356, 370]. Vardenafil significantly improved patient scores for IIEF, SEP2, SEP3, and GAQ and treatment satisfaction. An orodispersable tablet (ODT) formulation of vardenafil has also been released [370]. The efficacy of vardenafil ODT has been demonstrated in several RCTs and did not seem to differ from the regular formulation [371-373].

5.6.3.4 Avanafil

Avanafil is administered in on-demand doses of 50, 100 and 200 mg [357]. The recommended starting dose is 100 mg taken as needed 15-30 minutes before sexual activity and the dose may be adapted according to efficacy and tolerability [357, 358, 374]. In a general ED population the mean percentage of successful sexual attempts resulting in intercourse were 47%, 58% and 59% for the 50, 100 and 200 mg groups, respectively, as compared with 28% for the placebo group [357, 358]. A meta-analysis confirmed that avanafil had comparable efficacy with sildenafil, vardenafil and tadalafil [375].

5.6.3.5 Continuous use of PDE5Is

According to the EMA, a once-daily regimen with tadalafil 2.5 or 5 mg may be considered suitable, based on patients' choice and physicians' judgement. In these patients, the recommended dose is 5 mg, taken once daily at approximately the same time each day. Tadalafil, 5 mg once daily, provides an alternative to on-demand tadalafil for couples who prefer spontaneous rather than scheduled sexual activities or who anticipate frequent sexual activity, with the advantage that dosing and sexual activity no longer need to be linked. Regardless of the type of ED population, there is no clinically significant difference between a tadalafil treatment administered once daily vs. on-demand tadalafil [376]. Overall, treatment with tadalafil 5 mg once daily in men complaining of ED of various severities is well-tolerated and effective [377] and may improve EF among men who have a partial response to on-demand PDE5I therapy [378]. The appropriateness of the continuous use of a daily regimen should be re-assessed periodically [377, 379].

Table 10: Pharmacokinetics data for PDE5Is EMA approved for the treatment of ED*

Parameter	Sildenafil, 100 mg	Tadalafil, 20 mg	Vardenafil, 20 mg	Avanafil, 200mg
C_{max}	560 µg/L	378 µg/L	18.7 µg/L	5.2 µg/L
T_{max} (median)	0.8-1 hours	2 hours	0.9 hours	0.5-0.75 hours
T1/2	2.6-3.7 hours	17.5 hours	3.9 hours	6-17 hours
AUC	1,685 µg.h/L	8,066 µg.h/L	56.8 µg.h/L	11.6 µg.h/L
Protein binding	96%	94%	94%	99%
Bioavailability	41%	NA	15%	8-10%

** Fasted state, higher recommended dose. Data adapted from EMA statements on product characteristics.*
C_{max} = maximal concentration; T_{max} = time-to-maximum plasma concentration; T1/2 = plasma elimination halftime; AUC = area under curve or serum concentration-time curve.

Table 11: Common adverse events of the four PDE5Is currently EMA-approved to treat ED*

Adverse event	Sildenafil	Tadalafil	Vardenafil	Avanafil, 200mg
Headache	12.8%	14.5%	16%	9.3%
Flushing	10.4%	4.1%	12%	3.7%
Dyspepsia	4.6%	12.3%	4%	uncommon
Nasal congestion	1.1%	4.3%	10%	1.9%
Dizziness	1.2%	2.3%	2%	0.6%
Abnormal vision	1.9%		< 2%	None
Back pain		6.5%		< 2%
Myalgia		5.7%		< 2%

** Adapted from EMA statements on product characteristics.*

5.6.3.6 Safety concerns for PDE5Is

5.6.3.6.1 Cardiovascular safety

No RCTs or open-label studies have demonstrated an increase in myocardial infarction rates in patients receiving PDE5Is. None of the PDE5Is have an adverse effect on total exercise time or time-to-ischaemia during exercise testing in men with stable angina [350, 380]. This EAU Guidelines panel agrees to maintain the recommendations provided by the 3rd Princeton Consensus Panel in terms of the prescription of all PDE5Is in patients with CVD or in those with high CV risk [319, 321, 322].

5.6.3.6.2 Contraindications for the concomitant use of organic nitrates and nicorandil

An absolute contraindication to PDE5Is is the concomitant use of any form of organic nitrate or NO donors including recreational use of amyl nitrite or nitrate (poppers). Concomitant use results in cGMP accumulation unpredictable falls in blood pressure and symptoms of hypotension [381-384]. Concurrent use of nicorandil and PDE5Is is contraindicated due to the potential of the nitric oxide donating properties of nicorandil to increase cGMP levels [385].

5.6.3.6.3 Antihypertensive drugs

Co-administration of PDE5Is with antihypertensive agents may result in small additive decreases in blood pressure, which are usually minor [319]. In general, the adverse event profile of a PDE5I is not worsened by a background of antihypertensive medication, even when the patient is taking several antihypertensive agents [386].

5.6.3.6.4 Interactions with α-blockers

Tadalafil 5 mg is currently the only licensed drug for the treatment of both ED and LUTS demonstrating overall good efficacy in relieving urinary symptoms and improving EF [367]. Therefore, treatment with tadalafil 5 mg should be considered in patients suffering from mild to moderate LUTS associated with ED either alone or in combination with α-blockers. Conversely, as both drugs are vasodilators a certain degree of caution has been observed for combination therapy with PDE5Is and alpha-blockers due to the potential cumulative effects on blood pressure described in some studies [361, 369, 387]. However, a meta-analysis concluded that a concomitant treatment with α-blockers [both non-uroselective (e.g., terazosin and doxazosin) and uro-selective (e.g., alfuzosin, tamsulosin and silodosin] and PDE5Is may produce changes in haemodynamic parameters, but it does not increase the rate of adverse events due to hypotension [387]. Therefore, there is no current limitation in the simultaneous use of α-blockers and PDE5I.

5.6.3.7 Management of non- or poor-responders to PDE5Is

The management of non-responders depends upon identifying the underlying cause [388].

Clinicians should begin by ensuring that the medication has been properly prescribed, is being correctly used by the patient and that the patient has been using a licensed medication. Absorption of sildenafil, vardenafil and avanafil can be delayed by high-fat meals [389-391]. Timing is important and patients may be waiting either too short or too long after the medication before attempting sexual intercourse. Studies suggest that patient education can help salvage an apparent non-responder to a PDE5I [388, 392-395]. After emphasising the importance of dose, timing, and sexual stimulation to the patient, EF can be effectively restored following re-administration of the relevant PDE5I [388, 392, 393].

Studies have demonstrated that hypogonadal patients not responding to PDE5Is may improve their response to PDE5Is after initiating testosterone therapy [85, 343, 396]. Therefore, if diagnostic criteria suggestive of testosterone deficiency are present, testosterone therapy may be more appropriate even in ED patients [3, 85].

Limited data suggest that some patients might respond better to one PDE5I than to another [397], raising the possibility that, despite an identical mode of action, switching to a different PDE5I may be beneficial. However, no evidence for this has been reported in the available RCTs [398, 399].

In refractory, complex, or difficult-to-treat cases of ED combination therapy should be considered as a first-line approach. Although the available data are still limited, combining PDE5I with antioxidant agents, Li-SWT or a vacuum erection device (VED) improves efficacy outcomes, without any significant increase in adverse events [400]. Similarly, the association of daily tadalafil with a short-acting PDE5I (such as sildenafil) leads to improved outcomes, without any significant increase in adverse effects [401].

5.6.3.8 Topical/Intraurethral alprostadil

The vasoactive agent alprostadil can be administered inside the urethra in two different formulations. The first delivery method is topical, using a cream that includes a permeation enhancer to facilitate the absorption of alprostadil (200 and 300 µg) via the urethral meatus [402, 403]. Clinical data are still limited. Significant improvement compared to placebo was recorded for IIEF-EF domain score, SEP2 and SEP3 in a broad range of patients with mild-to-severe ED [404]. Adverse effects include penile erythema, penile burning, and pain that usually resolve within two hours of application. Topical alprostadil (VITAROSTM) at a dose of 300 µg is available in some European countries. Recently, a randomised cross-over clinical trial has shown that, compared to the standard administration route, direct delivery within the urethral meatus can increase efficacy and confidence among patients, without increasing adverse effects [405].

The second delivery method is by intra-urethral insertion of a specific formulation of alprostadil (125-1000 µg) in a medicated pellet (MUSE™) [229]. Erections sufficient for intercourse are achieved in 30-65.9% of patients. In clinical practice, it is recommended that intra-urethral alprostadil is initiated at a dose of 500 µg, as it has a higher efficacy than the 250 µg dose, with minimal differences with regards to adverse events. In case of unsatisfactory clinical response, the dose can be increased to 1000 µg [406-408]. Overall, the most common adverse events are local pain (29-41%) and dizziness with possible hypotension (1.9-14%). Penile fibrosis and priapism are rare (< 1%). Urethral bleeding (5%) and urinary tract infections (0.2%) are adverse events related to the mode of administration.

Efficacy rates are significantly lower than for intracavernous pharmacotherapy [409], with 30% adherence to long-term therapy. Intraurethral pharmacotherapy provides an alternative to intracavernous injections in patients who prefer a less-invasive, although less-efficacious treatment.

*5.6.4 **Psychosocial intervention and therapy***

Psychosocial interventions including different modalities (e.g., sexual skills training, marital therapy, psychosexual education) [341], and Cognitive and Behavioural Therapy (CBT - group or couple format), are recommended [336]. Cognitive and Behaviour Therapy is aimed at altering dysfunctional cognitive and behavioural patterns influencing ED, and increasing adjustment during the course of the disorder. The CBT approach combined with medical treatment for ED has received empirical support and is considered an optimal procedure [410].

*5.6.5 **Hormonal treatment***

When clinically indicated, testosterone therapy (intramuscular, transdermal, or oral) can be considered for men with low or low-normal testosterone levels and concomitant problems with their sexual desire, EF and dissatisfaction derived from intercourse and overall sex life (see Section 3.4 for a comprehensive discussion of testosterone therapy) [411].

*5.6.6 **Vacuum erection devices***

Published data report that efficacy, in terms of erections satisfactory for intercourse, is as high as 90%, regardless of the cause of ED and satisfaction rates range between 27% and 94% [412, 413]. Long-term use of VEDs decreases to 50-64% after two years [414]. The most common adverse events include pain, inability to ejaculate, petechiae, bruising, and numbness [413]. Serious adverse events (skin necrosis) can be avoided if patients remove the constriction ring within 30 minutes. Vacuum erection devices are contraindicated in patients with bleeding disorders or on anticoagulant therapy [415, 416]. Vacuum erection devices may be the treatment of choice in well-informed older patients with infrequent sexual intercourse and comorbidity requiring non-invasive, drug-free management of ED [412, 413, 417].

*5.6.7 **Intracavernous injections therapy***

Intracavernous administration of vasoactive drugs was the first medical treatment introduced for ED [395, 418]. Patients may be offered intracavernous injections at every stage of a tailored treatment work-up.

5.6.7.1 Alprostadil

Alprostadil (Caverject™, Edex/Viridal™) was the first and only drug approved for intracavernous treatment of ED [395, 419]. Intracavernous alprostadil is most efficacious as a monotherapy at a dose of 5-40 µg (40 µg may be offered off-label in some European countries). The erection appears after 5-15 minutes and lasts according to the dose injected, but with significant heterogeneity among patients. An office-training programme is required for patients to learn the injection technique. Efficacy rates for intracavernous alprostadil of > 70% have been found in the general ED population, as well as in patient subgroups (e.g., men with diabetes or CVD), with reported satisfaction rates of 87-93.5% in patients and 86-90.3% in partners after the injections [395, 418]. Complications of intracavernous alprostadil include penile pain (50% of patients reported pain only after 11% of total injections), excessively prolonged and undesired erections (5%), priapism (1%), and fibrosis (2%) [395, 418, 420]. Pain is usually self-limited after prolonged use and it can be alleviated with the addition of sodium bicarbonate or local anaesthesia [395, 418, 421]. Cavernosal fibrosis usually clears within a few months after temporary discontinuation of the injection programme. However, tunical fibrosis suggests early onset of Peyronie's disease and may indicate the need to discontinue intracavernous injections indefinitely. Systemic adverse effects are uncommon. The most common is mild hypotension, especially when using higher doses. Contraindications include men with a history of hypersensitivity to alprostadil, men at risk of priapism, and men with bleeding disorders. Despite these favourable data, drop-out rates of 41-68% have been reported for intracavernous pharmacotherapy [395, 418, 422, 423], with most discontinuations occurring within the first two to three months. Careful counselling of patients during the office-training phase as well as close follow-up are important in addressing patient withdrawal from an intracavernous injection programme [424-426].

5.6.7.2 Other vasoactive intracavernous treatments

Table 12 details the available intracavernous injection therapies (compounds and characteristics). Combination therapy enables a patient to take advantage of the different modes of action of the drugs being used, as well as alleviating adverse effects by using lower doses of each drug.

- Papaverine (20-80 mg) was the first oral drug used for intracavernous injections. It is most commonly used in combination therapy because of its high incidence of adverse effects as monotherapy. Papaverine is currently not licensed for the treatment of ED.
- Phentolamine has been used in combination therapy to increase efficacy. As monotherapy, it produces a poor erectile response. Phentolamine is currently not licensed for the treatment of ED.
- Limited data support the use of other drugs, such as vasoactive intestinal peptide (VIP), NO donors (linsidomine), forskolin, potassium channel openers, moxisylyte or calcitonin gene-related peptide, usually combined with the main drugs [427, 428]. Most combinations are not standardised and some drugs have limited availability worldwide.
- Bimix, (papaverine 7.5-45 mg plus phentolamine 0.25-1.5 mg) and Trimix (papaverine 8-16 mg plus phentolamine 0.2-0.4 mg plus alprostadil 10-20 µg), have been widely used with improved efficacy rates, although they have never been licensed for ED [429, 430]. Trimix has the highest efficacy rates, reaching 92%; this combination has similar adverse effects as alprostadil monotherapy, but a lower incidence of penile pain due to lower doses of alprostadil. However, fibrosis is more common (5-10%) when papaverine is used (depending on the total dose).
- Invicorp™: Vasoactive intestinal peptide (25 µg) plus phentolamine mesylate (1-2 mg Invicorp), is a combination of two active components with complementary modes of action. Clinical studies have shown that the combination is effective for intracavernous injections in > 80% of men with ED, including those who have failed to respond to other therapies and, unlike existing intracavernous therapies, is associated with a low incidence of penile pain and a virtually negligible risk of priapism [431].

Overall, despite high efficacy rates, 5-10% of patients do not respond to combination therapy with intracavernous injections.

Table 12: Intracavernous injection therapy - compounds and characteristics

Name	Substance	Dosage	Efficacy	Adverse Events	Comment
Caverject™ or Edex/Viridal™	Alprostadil	5-40 µg/mL	~ 70%	Penile pain, priapism, fibrosis	Easily available
Papaverine	Papaverine	20 - 80 mg	< 55%	Elevation of liver enzymes, priapism, fibrosis	Abandoned as monotherapy
Phentolamine	Phentolamine	0.5 mg/mL	Poor efficacy as monotherapy	Systemic hypotension, reflex tachycardia, nasal congestion, and gastrointestinal upset	Abandoned as monotherapy
Bimix	Papaverine + Phentolamine	30 mg/mL + 0.5 mg/mL	~ 90%	Similar to Alprostadil (less pain)	Not licensed for the treatment of ED
Trimix	Papaverine + Phentolamine + Alprostadil	30 mg/mL + 1 mg/mL + 10 µg/mL	~ 92%	Similar as Alprostadil (less pain)	Not licensed for the treatment of ED
Invicorp™	Vasoactive intestinal peptide (VIP) + Phentolamine	25 µg + 1-2 mg	~ 80%	Similar to Alprostadil without pain	Easily available

5.6.8 ***Innovative treatment modalities***

There are currently several potential novel treatment modalities for ED. Most of these therapeutic approaches require further investigation in large-scale, blinded, placebo-controlled randomised studies to achieve adequate evidence-based and clinically-reliable recommendation grades [432-437].

5.6.8.1 Regenerative medicine therapies

5.6.8.1.1 Shockwave therapy

The use of low-intensity extracorporeal shock wave therapy (Li-SWT) has been increasingly proposed as a treatment for vasculogenic ED over the last decade, and it's the only currently marketed treatment that might offer a cure, which is the most desired outcome for most men suffering from ED [328, 438-445].

Overall, several single-arm trials have shown a beneficial effect of Li-SWT on patient-reported EF, but data from prospective randomised trials are conflicting, and many questions remain to be answered due to the heterogeneity among shockwave generators, type of shockwaves delivered, set-up parameters and treatment protocols [446, 447]. In a trial trying to assess the best treatment parameters, no significant differences were observed between various energy flux density levels; although, a 0.10 mJ/mm^2 seems to perform slightly better than lower energies [448]. Most of the studies have suggested that Li-SWT can significantly increase IIEF and EHS scores in patients with mild vasculogenic ED, although this improvement appears modest and the rates of patients reporting a satisfactory improvement range between 40-80% [328, 446]. Few studies have shown an improvement in penile haemodynamic parameters after Li-SWT, but the clinical meaning of this improvement remains unclear [446, 449]. Likewise, data suggest that Li-SWT could ameliorate erection quality even in patients with severe ED who are either PDE5Is non-responders [443, 450, 451] or inadequate responders [452], thus reducing the immediate need for more invasive treatments. Treatment effect appears to be clinically evident starting from one to three months after treatment completion, with a subsequent progressive decrease of the achieved benefit in terms of EF over time, although some effects could be still detected up to five years after treatment [446, 448, 453]. Data from RCTs suggests that even better results could be achieved by combining Li-SWT with other treatments such as a VED in men with T2DM [454] or daily tadalafil [455, 456].

Findings from a recent meta-analysis showed that LI-ESWT has a positive effect on early recovery of EF in the context of penile rehabilitation of ED after RP. However, the authors clearly outlined that the level of evidence was low; therefore, careful interpretation of the results is required [457-459].

5.6.8.1.2 Platelet-Rich Plasma

Intracavernous injection of platelet-rich plasma (PRP) has been investigated in several prospective and retrospective trials [460-466]. The regenerative effect of PRP is deemed to be exerted through the high concentrations of platelets containing several growth factors including VEGF, EGF, IGF-1, PDGF and FGF [467]. These factors may be responsible for angiogenesis stimulation and stem cell recruitment [467].

In the first RCT investigated the effect of intracavernous injection of PRP for ED, 60 patients with mild to moderate vasculogenic ED were randomised to receive two injections of 10 mL PRP (n=30) or placebo (n=30) [466]. At one, three and six-month follow-up, the rate of patients reporting minimal clinically important difference (MCID) in the IIEF-EF score was significantly higher in the treatment group, with 69% achieving MCID six months after PRP vs. 27% in the placebo group ($p < 0.001$). IIEF-EF scores improved by a mean of 2.7 points at one-month and 3.9 points at six-month assessment after treatment. Regarding safety, no haemorrhagic events or other side effects were reported [466].

A prospective randomized, double-blind, placebo-controlled study was carried out on 109 patients, aged 45-65 years, with mild to moderate ED, following cessation of any ED treatment [468]. At one, three and six months after PRP injections, patients in the PRP group had a significant improvement compared to placebo in terms of IIEF-EF, SEP2 and SEP3. Moreover, at six months post-treatment follow-up, 70% of patients achieved an MCID in the PRP group compared to 16% in the placebo group [468]. Even more recently, a further prospective, randomized, double-blind, placebo-control study on a relatively small cohort of mild to moderate ED patients who have been treated with two PRP injections separated by one month showed that the treatment is safe, but the authors did not find any difference in efficacy between PRP and placebo [469]. Of clinical relevance, patients were allowed to keep PDE5is during the study [469].

As a whole, despite a number of promising results that have been obtained for the treatment of primary organic ED in terms of both efficacy and safety of PRP, the available evidence is still insufficient to provide a recommendation regarding the use of PRP for ED treatment in clinical practice [470]. In this context, an important heterogeneity among studies still exists in terms of timing and dosing regimens, with no consensus regarding the optimal activation method and platelet concentration for each PRP injection, and the need to measure qualitative and quantitative composition of growth factors and cytokines [470, 471]. Therefore, intracavernous injection of PRP should be used only in a clinical trial setting, as larger trials are needed to confirm original findings and define the efficacy and safety of PRP for ED.

5.6.8.1.3 Stem-cells

The use of stem cells as a regenerative treatment for ED is currently under investigation. A systematic review has concluded that five completed human clinical trials have shown promise for stem cell therapy as a restorative treatment for ED [472]. However, data are still insufficient for providing a clinical recommendation.

5.6.8.2 Botulinum Neurotoxin

Botulinum Neurotoxin A (BoNT-A) has been investigated as a possible ED treatment [473]. Two RCTs have investigated the effect of BoNT-A for the treatment of patients with ED who were non-responders to PDE5Is or ICI pro-erectile drugs [474, 475]. One trial randomised 70 patients with ED refractory to PDE5Is to receive a single ICI of 100 UI of BoNT-A or saline [474]. Patients in both groups were instructed to keep using on-demand high-dose PDE5Is. The RCT showed an improvement in EHS and PSV at two weeks post-treatment. At six weeks the treatment group showed a 5 points improvement in the SHIM score vs. no improvement in the placebo group, with 53% of patients reporting an erection hard enough for vaginal penetration [474]. The second trial randomised 176 patients, all non-responders to PDE5Is or ICI trimix, to three treatment groups: BoNT-A 100 UI; BoNT-A 50 UI; or placebo [475]. A significant improvement in SHIM, EHS and SEP scores was reported in both treatment groups with a maximum response rate being reacted three months after treatment. Overall, the RCT showed that up to 40% of patients were able to resume satisfactory sexual activity after treatment [475]. Both trials reported only mild local side-effects with no systemic complications.

Other single-arm, non-controlled studies have confirmed these findings [476, 477]; therefore, showing a promising role for BoNT-A in the treatment of patients who are non-responders to well-established ED therapies. However, at present no recommendation for its use in clinical practice can be provided as larger trials are needed to confirm original findings and define the efficacy and safety of BoNT-A for ED.

5.6.9 ***Herbal medicine and natural supplements***

In recent years there has been an exponential growth in the market of medicinal herbs and natural supplements for the treatment of ED, but with very little available evidence of robust scientific data to support their efficacy and safety. A Cochrane review showed that ginseng may only have trivial effects on erectile function or satisfaction with intercourse compared to placebo when assessed using validated tools [478]. Moreover, data suggested that daily administration of oral L-arginine, only when in combination with PDE5I use, improves sexual function [479].

5.6.10 ***Erectile dysfunction after radical prostatectomy***

The use of pro-erectile drugs following RP is important in achieving post-operative EF and allowing patients to resume sexual activity. Several trials have shown improvements in EF after RP in patients receiving drugs (any therapeutic or prophylactic) for ED. Early compared with delayed EF treatment affects the natural recovery time for EF [480], although there is limited data to support any specific regimen, which is either optimal for penile rehabilitation or may result in the achievement of spontaneous, non-pharmacologically assisted erections [289, 481, 482]. In prospective studies, there is no evidence that penile rehabilitation itself increases the chances of spontaneous recovery of EF in men following nerve-sparing RP (NSRP) [482]. The currently available therapeutic armamentarium follows the treatment algorithm for ED, which is shown in Figure 3.

In this context, PDE5Is have been considered as the first-line therapy in patients who have undergone NS surgery, regardless of the surgical technique used [289, 293]. Several clinical parameters have been identified as potential predictors of PDE5Is outcomes in men undergoing RP, i.e., patient age, baseline EF, and quality of NS technique are key factors in preserving post-RP EF [293, 296, 483].

A Cochrane review analysing data from eight RCTs showed that scheduled PDE5Is may have little or no effect on short-term (up to twelve months) self-reported potency when compared to placebo or no treatment [484]. In this study, a daily PDE5I made little to no difference in short- and long-term EF. The authors conclude that penile rehabilitation strategies using PDE5I following RP do not increase self-reported EF compared to on-demand use.

Intracavernous injections and penile implants have been traditionally suggested as second- and third-line treatments, respectively, when oral PDE5Is are not adequately effective or not suitable for post-operative patients [289, 485]. A meta-analysis showed that the early use of VED has an excellent therapeutic effect on post-RP patients and no serious adverse effects, therefore it should be considered as a therapeutic alternative [486]. Findings from two network meta-analyses showed that combination therapy with VED and PDE5is offers clear advantages over monotherapy, even in post-RP patients; therefore, this combined approach should be considered in the clinical management of ED after RP [487].

Findings from a systematic review suggested that pelvic floor muscle training (PFMT) combined with bio-feedback is a promising alternative to pharmacological treatments, although there is a need for future well-powered, rigorously designed RCTs to draw strong conclusions [488].

5.6.11 Surgical management

5.6.11.1 Surgery for post-traumatic arteriogenic ED

In young patients with pelvic or perineal trauma, surgical penile revascularisation has a 60-70% long-term success rate [416, 489]. The stenosis must be confirmed by penile pharmaco-arteriography. Corporeal veno-occlusive dysfunction is a contraindication to revascularisation.

5.6.11.2 Venous ligation surgery

Venous ligation surgery for veno-occlusive dysfunction is no longer recommended because of poor long-term results [489].

5.6.11.2.1 Penile prostheses

The surgical implantation of a penile prosthesis may be considered in patients who i) are not suitable for different pharmacotherapies or prefer a definitive therapy; and, ii) do not respond to other treatment modalities (Figure 5) [490].

The two currently available classes of penile implants include inflatable (two- and three-piece) and semi-rigid devices (malleable, mechanical and soft flexible) [293, 491-494]. There are currently no head to head studies comparing the different manufacturers' implants, demonstrating superiority of one implant type over another [495]. Patients may prefer the three-piece inflatable devices due to the more "natural" erections obtained, although no prospective RCTs have compared satisfaction rates with both types of implants. The two-piece inflatable prosthesis can be a viable option among patients who are deemed at high-risk of complications with reservoir placements (e.g., previous abdominal surgery). Semi-rigid prostheses result in a firm penis, which may be manually placed in an erect or flaccid state and offer the advantage of a simple implant technique, as well as easy use for the patient [293, 491-493]. Conversely, they can have the disadvantage of unnatural persistent erection and reduced concealability [493, 496]. They may also be an option in men with limited manual dexterity.

There are two main surgical approaches for penile prosthesis implantation: peno-scrotal and infrapubic [492, 493, 496, 497]. A systematic review comparing the satisfaction and complication rates of the different surgical approaches has shown that there is no specific advantage between the two, but rather it is recommended that surgeons have knowledge of both techniques and are capable of tailoring the incision strategy for complex cases [498]. Regardless of the indication, prosthesis implantation has one of the highest satisfaction rates (92-100% in patients and 91-95% in partners) among the treatment options for ED with appropriate counselling [293, 491, 492, 499-507]. Focused psychosexual counselling may improve sexuality and sexual well-being in both patients and their partners after penile implant surgery [508]. There is sufficient evidence to recommend this approach in patients who do not respond to less-invasive treatments due to its high efficacy, safety and satisfaction rate [509].

The two main complications of penile prosthesis implantation are mechanical failure and infection. Several technical modifications of the most commonly used three-piece prostheses (e.g., AMS 700CX/CXR™ and Titan Zero degree™) resulted in mechanical failure rates of < 5% after five years of follow-up [491, 510, 511]. Careful surgical techniques with appropriate antibiotic prophylaxis against Gram-positive and negative bacteria reduced infection rates to 2-3% with primary implantation in low-risk patients and high-volume centres [512-515]. The infection rate may be further reduced to 1-2% by implanting an antibiotic-impregnated prosthesis (AMS Inhibizone™) or hydrophilic-coated prosthesis (Coloplast Titan™) [491, 512, 516-519]. Methods that appear to decrease infection rates include using coated prosthesis and strictly adhering to surgical techniques and protocols that avoid prolonged wound exposure and minimise skin contact (i.e., no-touch technique).
Techniques that might prevent penile prostheses infection but lack definitive evidence include the use of prolonged post-operative antibiotics (> 24 hours), shaving with clippers, and preparation with chlorhexidine-alcohol [520, 521]. Identification and pre-treatment of patients who are colonised with nasal *Staphylococcus aureus* with mupirocin and chlorhexidine before surgery has been shown to reduce the incidence of post-operative surgical site infection from 4.4% to 0.9% RCT [522].

A large database-study has shown that diabetes mellitus is a risk factor for penile prostheses infection, highlighting the need for optimal patient selection [667]. Unfortunately, there are no RCTs determining the ideal and/or correct threshold of glycated haemoglobin that is acceptable prior to implant surgery in diabetic patients [523]. Also, there are no RCTs establishing the optimal or appropriate threshold of glycated haemoglobin deemed acceptable before implant surgery in diabetic patients [524]. A large-cohort, multicentre, retrospective analysis in men with diabetes who received a Coloplast Titan™ implant demonstrated that vancomycin plus gentamicin was the most efficacious combination of antibiotics used for implants dipping in terms of preventing postoperative infection and subsequent explantation and revision [525].

Prosthetic infection requires removal of the prosthesis and antibiotic administration. Alternatively, removal of the infected device with immediate salvage and replacement with a new prosthesis has been described using a wash-out protocol with successful salvages achieved in > 80% of cases [513, 526-528]. An absolute recommendation on how to proceed after explantation in this setting cannot be given and must be focused on the pros and cons of salvage therapy after full consultation with the patient.

Besides infection and mechanical failure, impending implant erosion involving the distal corpora, urethra, or glans can occur in 1-6% of cases after surgery [529]. Similarly, glans ischaemia and necrosis have been reported in about 1.5% of patients [529, 530]. Risk factors for these serious complications are higher in those patients with significant vascular impairment, such as patients with diabetes, or who have undergone concomitant lengthening procedures.

5.6.12 Summary of evidence and recommendations for treatment of ED

Summary of evidence
Lifestyle changes can lead to ED improvement in specific populations.
PDE5Is are associated with significant improvement of erectile function (EF) with a good overall safety profile.
There are no demonstrated differences among different PDE5Is in terms of treatment efficacy.
Topical/intraurethral alprostadil is effective in improving EF but data are still limited.
Vacuum therapy can improve EF with a wide range of treatment satisfaction rate.
Intracavernous injection with alprostadil is an effective treatment for ED; however, it has relatively high treatment drop-out rates.
Low-intensity shockwave therapy can a mild improvement in EF among patients with vasculogenic ED.
Intracavernous injections of PRP have led to a mild improvement of EF among patients with organic ED, but the available evidence is still insufficient to provide a recommendation regarding its use.
BoNT-A has been shown to improve response rate to medical treatment for ED in patients who were non-responsive to oral or injective therapies, but data are still limited.
Penile rehabilitation with PDE5Is after RP does not increase the chance of spontaneous EF recovery.
Penile prosthesis implantation is associated with high satisfaction rate among patients with ED.
There is no difference in terms of efficacy and safety among different penile implants available or surgical approaches used.

Recommendations	**Strength rating**
Fully inform patients of the mechanism of action and how phosphodiesterase type 5 inhibitors (PDE5Is) should be taken, as incorrect use/inadequate information is the main causes of a lack of response to PDE5Is.	Strong
Direct the patient to Cognitive Behaviour Therapy as a psychological approach (include the partner), when indicated, combined with medical treatment to maximise treatment outcomes.	Strong
Discuss with patients undergoing active treatment for prostate cancer (PCa) about the risk of sexual changes other than erectile dysfunction (ED), including sexual desire reduction, changes in orgasm, anejaculation, Peyronie like disease and penile size changes.	Strong
Initiate lifestyle changes and risk factor modification prior to, or at the same time as, initiating ED treatments.	Strong
Use PDE5Is as first-line therapy for the treatment of ED.	Strong

Use intracavernous injections as an alternative first-line therapy in well-informed patients or as second-line therapy.	Strong
Use topical/intra-urethral alprostadil as an alternative first-line therapy in well-informed patients who: • do not wish to have or are not suitable for oral vasoactive therapy; • do not wish to have intracavernous injections; • in patients who prefer a less-invasive therapy.	Weak
Use low-intensity shockwave treatment (Li-SWT) with/without PDE5Is in patients • with mild vasculogenic ED; • as an alternative therapy in well-informed patients who do not wish to have or are not suitable for oral vasoactive therapy; • who are vasculogenic ED patients who are poor responders to PDE5Is	Weak
Use vacuum erection devices in well-informed patients requesting non-invasive, drug-free management of ED.	Weak
Implant a penile prosthesis if other treatments fail or depending upon patient preference. Patients should be fully informed of the benefits and harms associated with the procedure.	Strong
Start pro-erectile treatments at the earliest opportunity after radical prostatectomy/pelvic surgery and other curative treatments for PCa.	Weak

5.7 *Follow-up*

Follow-up is important in order to assess the efficacy and safety of the treatment provided. It is also essential to assess patient satisfaction since successful treatment for ED goes beyond efficacy and safety. Physicians must be aware that there is no single treatment that fits all patients or all situations as described in detail in the previous section.

6. DISORDERS OF EJACULATION

6.1 Introduction

Ejaculation is a complex physiological process that comprises emission and expulsion processes and is mediated by interwoven neurological and hormonal pathways [531]. Any interference with those pathways may cause a wide range of ejaculatory disorders. The spectrum of ejaculation disorders includes premature ejaculation (PE), retarded or delayed ejaculation, anejaculation, painful ejaculation, retrograde ejaculation, anorgasmia and haemospermia.

6.2 Premature ejaculation

6.2.1 Epidemiology

Historically, the main problem in assessing the prevalence of PE has been the lack of a universally recognised definition at the time that surveys were conducted [532]. See Section 4.2 for a comprehensive discussion of the epidemiology of PE.

6.2.2 Pathophysiology and risk factors

The aetiology of PE is relatively unknown, with limited data to support suggested biological and psychological hypotheses, including anxiety [533-536], penile hypersensitivity [537-544] and 5-hydroxytryptamine (HT) receptor dysfunction [545-550]. The classification of PE into four subtypes [201] has contributed to a better delineation of lifelong, acquired, variable and subjective PE [551-553]. It has been hypothesised that the pathophysiology of lifelong PE is mediated by a complex interplay of central and peripheral serotonergic, dopaminergic, oxytocinergic, endocrinological, genetic and epigenetic factors [554]. Acquired PE may occur due to psychological problems - such as sexual performance anxiety, and psychological or relationship problems and/or co-morbidity, including ED, prostatitis, hyperthyroidism and poor sleep quality [555-558]. Variable PE is considered to be a normal variation of sexual function whereas subjective PE can stem from cultural or abnormal psychological constructs [201].

A significant proportion of men with ED also experience PE [205, 559]. High levels of performance anxiety related to ED may worsen PE, with a risk of misdiagnosing PE instead of the underlying ED. According to the National Health and Social Life Survey (NHSLS), the prevalence of PE is not affected by age [197], unlike ED, which increases with age. Premature ejaculation is not affected by marital or income status [197, 560].

However, PE is more common in Black men, Hispanic men, and men from regions where an Islamic background is common [197, 561, 562] and the prevalence may be higher in men with a lower educational level [197, 205]. Other reported risk factors for PE include genetic predisposition [550, 563-566], poor overall health status and obesity [197], prostate inflammation [567-571], hyperthyroidism [555], low prolactin levels [572], high testosterone levels [573], vitamin D and B12 deficiency [574, 575], diabetes [576, 577], MetS [578, 579], lack of physical activity [580], emotional problems and stress [197, 581, 582], depressive symptoms [582], and traumatic sexual experiences [197, 205].

*6.2.3 **Impact of PE on quality of life***

Men with PE are more likely to report low satisfaction with their sexual relationship, low satisfaction with sexual intercourse, difficulty relaxing during intercourse, and less-frequent intercourse [583-585]. Premature ejaculation can have a detrimental effect on self-confidence and the relationship with the partner, and may sometimes cause mental distress, anxiety, embarrassment and depression [583, 586, 587]. Moreover, PE may also affect the partner's sexual functioning and their satisfaction with the sexual relationship decreases with increasing severity of the patient's condition [588-590]. Despite the possible serious psychological and QoL consequences of PE, few men seek treatment [198, 205, 591-594].

*6.2.4 **Classification***

There is still little consensus about the definition and classification of PE [595]. It is now universally accepted that "premature ejaculation" is a broad term that includes several concepts belonging to the common category of PE. The most recent definition comes from the International Classification of Diseases 11th Revision, where PE was renamed as Early Ejaculation [596]: *"Male early ejaculation is characterized by ejaculation that occurs prior to or within a very short duration of the initiation of vaginal penetration or other relevant sexual stimulation, with no or little perceived control over ejaculation. The pattern of early ejaculation has occurred episodically or persistently over a period of at least several months and is associated with clinically significant distress."*

This definition includes four categories: male early ejaculation, lifelong generalised and situational, acquired generalised and situational, and unspecified.

> The Diagnostic and Statistical Manual of Mental Disorders V (DSM-V) [207] and the International Society for Sexual Medicine (ISSM) [597] published definitions for lifelong and acquired PE. These definitions are overlapping, with 3 shared factors (1. Time to ejaculation assessed by IELT; 2. Perceived control; and, 3. Distress, bother, frustration, interpersonal difficulty related to the ejaculatory dysfunction), resulting in a multi-dimensional diagnosis [597].

Two more PE syndromes have been proposed [552]:

- 'Variable PE' is characterised by inconsistent and irregular early ejaculations, representing a normal variation in sexual performance.
- 'Subjective PE' is characterised by subjective perception of consistent or inconsistent rapid ejaculation during intercourse, while ejaculation latency time is in the normal range or can even last longer. It should not be regarded as a symptom or manifestation of true medical pathology [598].

*6.2.5 **Diagnostic evaluation***

Diagnosis of PE is based on the patient's medical and sexual history [599-602]. History should classify PE as lifelong or acquired and determine whether PE is situational (under specific circumstances or with a specific partner) or consistent. Special attention should be given to the duration time of ejaculation, degree of sexual stimulus, impact on sexual activity and QoL, and drug use or abuse. It is also important to distinguish PE from ED. Many patients with ED develop secondary PE caused by the anxiety associated with difficulty in attaining and maintaining an erection [559, 603]. Furthermore, some patients are unaware that loss of erection after ejaculation is normal and may erroneously complain of ED, while the actual problem is PE [594].

6.2.5.1 Intravaginal ejaculatory latency time (IELT)

Although it has been suggested as an objective diagnostic criterion and treatment outcome measure [604, 605], the use of IELT alone is not sufficient to define PE, as there is significant overlap between men with and without PE [606, 607]. Moreover, some men may experience PE in their non-coital sexual activities (e.g., during masturbation, oral sex or anal intercourse); thus, measuring IELT will not be suitable for their assessment. Although PE is apparently less prevalent and less bothersome among men who have sex with men (MSM) [608], many of them may also suffer from PE and IELT cannot be applied to them [609, 610]. Although some studies demonstrated that MSM report longer ejaculation latency time compared to straight men [608], some others failed to demonstrate such a difference [611].

In everyday clinical practice, self-estimated IELT is sufficient [612]. Self-estimated and stopwatch-measured IELT are interchangeable and correctly assign PE status with 80% sensitivity and 80% specificity [613].

Measurement of IELT with a calibrated stopwatch is mandatory in clinical trials. For any drug treatment study of PE, Waldinger *et al.,* suggested using geometric mean instead of arithmetic mean IELT because the distributed IELT data are skewed. Otherwise, any treatment-related ejaculation delay may be overestimated if the arithmetic mean IELT is used instead of the geometric mean IELT [614].

6.2.5.2 Premature ejaculation assessment questionnaires

The need to objectively assess PE has led to the development of several questionnaires based on using PROMs. Only two questionnaires can discriminate between patients who have PE and those who do not:

- Premature Ejaculation Diagnostic Tool (PEDT): A five-item questionnaire based on focus groups and interviews from the USA, Germany, and Spain assesses control, frequency, minimal stimulation, distress and interpersonal difficulty [615]. A total score of > 11 suggests a diagnosis of PE, 9 or 10 suggests a probable diagnosis, and < 8 indicates a low likelihood of PE.

- Arabic Index of Premature Ejaculation (AIPE): A seven-item questionnaire developed in Saudi Arabia assesses sexual desire, hard erections for sufficient intercourse, time to ejaculation, control, satisfaction of the patient and partner, and anxiety or depression [616]. A cut-off score of 30 (range 7-35) discriminates PE diagnosis best. The severity of PE is classified as severe (score: 7-13), moderate (score: 14-19), mild-to-moderate (score: 20-25) and mild (score: 26-30).

Other questionnaires used to characterise PE and determine treatment effects include the Premature Ejaculation Profile (PEP) [607], Index of Premature Ejaculation (IPE) [617] and Male Sexual Health Questionnaire Ejaculatory Dysfunction (MSHQ-EjD) [618]. Currently, their role is optional in everyday clinical practice. The Masturbatory Premature Ejaculation Diagnostic Tool (MPEDT) has also been recently proposed [619], due to fact since PE patients report longer IELTs and lesser bother/distress during masturbation than partnered sex [620]; however, further validation studies are required before the routine use of this questionnaire in this population.

6.2.5.3 Physical examination and investigations

Physical examination may be part of the initial assessment of men with PE. It may include a focused examination of the urological, endocrine and neurological systems to identify underlying medical conditions associated with PE or other sexual dysfunctions, such as endocrinopathy, Peyronie's disease, urethritis or prostatitis. Laboratory or physiological testing should be directed by specific findings from history or physical examination and is not routinely recommended [601].

6.2.5.4 Recommendations for the diagnostic evaluation of PE

Summary of evidence	**LE**
A comprehensive medical history and a thorough physical examination can serve as valuable tools for clinicians in identifying the underlying medical factors contributing to PE.	3
PE can negatively impact self-confidence, strain partner relationships, and potentially lead to emotional distress, anxiety, shame, and depression.	2a
Several questionnaires can be used for the diagnosis of PE (PEDT, AIPE) and for assessing the therapeutic outcomes of PE interventions (PEP).	2b
Although relying on IELT is inadequate for characterizing PE, self-reported IELT proves satisfactory in routine clinical contexts.	3

Recommendations	**Strength rating**
Perform the diagnosis and classification of premature ejaculation (PE) based on medical and sexual history, which should include assessment of intravaginal ejaculatory latency time (IELT) (self-estimated), perceived control, distress and interpersonal difficulty due to the ejaculatory dysfunction.	Strong
Use patient-reported outcomes in daily clinical practice.	Weak

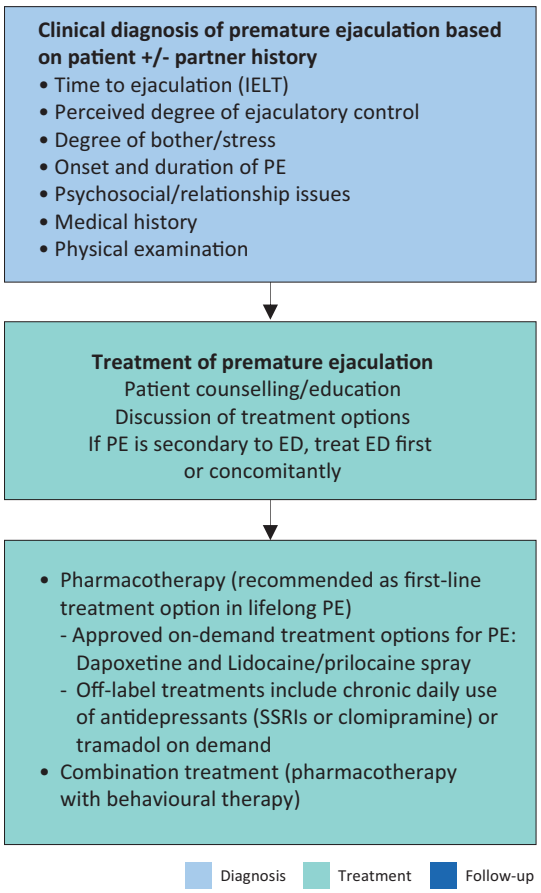
Include physical examination in the initial assessment of PE to identify anatomical abnormalities that may be associated with PE or other sexual dysfunctions, particularly erectile dysfunction.	Strong
Do not perform routine laboratory or physiological tests. They should only be directed by specific findings from history or physical examination.	Strong

6.2.6 Disease management

Before commencing any treatment, it is essential to define the subtype of PE and discuss patient's expectations thoroughly. Pharmacotherapy must be considered the first-line treatment for patients with lifelong PE, whereas treating the underlying cause (e.g., ED, prostatitis, LUTS, anxiety and hyperthyroidism) must be the initial goal for patients with acquired PE [601]. Various behavioural techniques may be beneficial in treating variable and subjective PE [621]. Psychotherapy can also be considered for PE patients who are uncomfortable with pharmacological therapy or in combination with pharmacological therapy [622, 623]. However, there is weak and inconsistent evidence regarding the effectiveness of these psychosexual interventions and their long-term outcomes in PE are unknown [624].

Dapoxetine (30 and 60 mg) is the first on-demand oral pharmacological agent approved for lifelong and acquired PE in many countries, except for the USA [625]. The metered-dose aerosol spray of lidocaine (150 mg/mL) and prilocaine (50 mg/mL) combination is the first topical formulation to be officially approved for on-demand treatment of lifelong PE by the EMA in the European Union [626]. All other medications used in PE are off-label indications [627]. In this context, daily or on-demand use of selective serotonin re-uptake inhibitors (SSRIs) and clomipramine and on-demand topical anaesthetic agents have consistently shown efficacy in PE [628-631]. The long-term outcomes of pharmacological treatments are unknown. An evidence-based analysis of all current treatment modalities was performed. Levels of evidence and grades of recommendation are provided, and a treatment algorithm is presented (Figure 6).

Figure 6: Management of premature ejaculation*

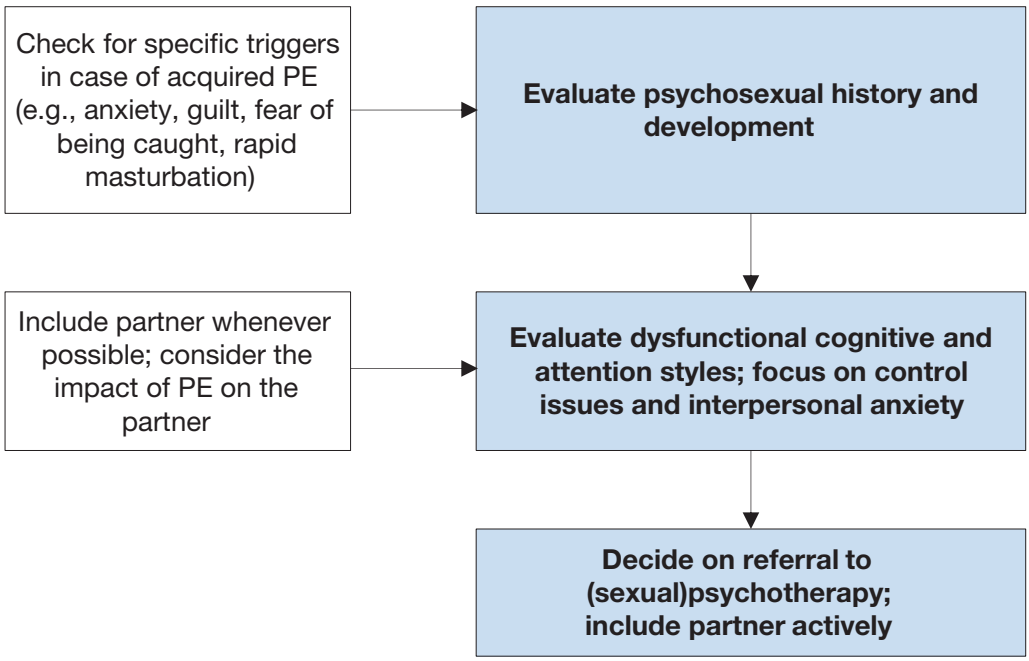


ED = erectile dysfunction; PE = premature ejaculation; IELT = intravaginal ejaculatory latency time; SSRI = selective serotonin receptor inhibitor.

6.2.6.1 Psychological aspects and intervention

Psychosexual interventions, whether behavioural, cognitive, or focused on the couple, are aimed at teaching techniques to control/delay ejaculation, gaining confidence in sexual performance, reducing anxiety, and promoting communication and problem-solving within the couple [621]. Interventions with a focus on sexual education or acceptance may be positive as well [632]. However, psychosexual interventions alone regarding PE lack empirical support. Recent evidence suggests that start-stop exercises, combined with psycho-education and mindfulness techniques improve PE symptoms, as well as PE-associated distress, anxiety and depression [633]. The potential benefits of mindfulness have been reported [634]. Behavioural therapy may be most effective when used to 'add value' to medical interventions. Smartphone-delivered psychological intervention, aimed at improving behavioural skills for ejaculatory delay and sexual self-confidence, has positive effects, supporting E-health in the context of PE [635].

Figure 7: Key aspects of psychosexual evaluation



6.2.6.1.1 Summary of evidence and recommendations for the assessment and treatment (psychosexual approach) of PE

Summary of evidence	**LE**
The incorporation of a psychosexual approach, alongside psycho-educational guidance and mindfulness techniques, ameliorates symptoms of PE and alleviate the associated distress, anxiety, and depression.	2b
The combination of psychosexual approaches and pharmacological treatments yields superior outcomes compared to pharmacological interventions alone.	3

Recommendations for assessment	**Strength rating**
Assess sexual history and psychosexual development.	Strong
Assess anxiety, and interpersonal anxiety; focus on control issues.	Strong
Include the partner if available; check for the impact of PE on the partner.	Strong
Recommendations for treatment (psychosexual approach)	
Use behavioural, cognitive and/or couple therapy approaches in combination with pharmacotherapy. Discuss the use of mindfulness exercises.	Weak

6.2.6.2 Pharmacotherapy

6.2.6.2.1 Dapoxetine

Dapoxetine hydrochloride is a short-acting SSRI with a pharmacokinetic profile suitable for on-demand treatment for PE [636]. It has a rapid T_{max} (1.3 hours) and a short half-life (95% clearance rate after 24 hours) [637, 638]. It is approved for on-demand treatment of PE in European countries and elsewhere, but not in the USA. Both available doses of dapoxetine (30 mg and 60 mg) have shown 2.5- and 3.0-fold increases, respectively, in IELT overall, rising to 3.4- and 4.3-fold in patients with a baseline average IELT < 30 seconds [639].

In RCTs, dapoxetine, 30 mg or 60 mg 1-2 hours before intercourse, was effective at improving IELT and increasing ejaculatory control, decreasing distress, and increasing satisfaction [639]. Dapoxetine has shown a similar efficacy profile in men with lifelong and acquired PE [639, 640]. Treatment-related adverse effects were dose-dependent and included nausea, diarrhoea, thirst, headache and dizziness [640]. Treatment-emergent adverse events (TEAEs) were responsible for study discontinuation in 4% (30 mg) and 10% (60 mg) of subjects [612]. There was no indication of an increased risk of suicidal ideation or suicide attempts and little indication of withdrawal symptoms with abrupt dapoxetine cessation [639, 640]. Dapoxetine is safer than formal anti-depressant compounds used for treatment of PE [641].

A low rate (0.1%) of vasovagal syncope was reported in phase 3 studies [642]. According to the summary of product characteristics, vital orthostatic signs (blood pressure and heart rate) must be measured prior to starting dapoxetine, and dose titration must be considered [643]. The EMA assessment report for dapoxetine concluded that the potentially increased risk for syncope had been proven manageable with adequate risk minimisation measures [644]. No cases of syncope were observed in a post-marketing observational study, which identified patients at risk for the orthostatic reaction using the patient's medical history and orthostatic testing [645].

Many patients and physicians may prefer using dapoxetine in combination with a PDE5I to extend the time until ejaculation and minimise the risk of ED due to dapoxetine treatment. Phase 1 studies of dapoxetine have confirmed that it has no pharmacokinetic interactions with PDE5Is (i.e., tadalafil 20 mg and sildenafil 100 mg) [646]. When dapoxetine is co-administered with PDE5Is, it is well tolerated, with a safety profile consistent with previous phase 3 studies of dapoxetine alone [647]. An RCT, including PE patients without ED, demonstrated that a combination of dapoxetine with sildenafil could significantly improve IELT values and PROs compared with dapoxetine alone or sildenafil alone, with tolerable adverse events [648]. The efficacy and safety of dapoxetine/sildenafil combination tablets for the treatment of PE have also been reported [649].

The discontinuation rates of dapoxetine seem moderate to high [650]. The cumulative discontinuation rates increase over time, reaching 90% at two years after initiation of therapy. The reasons for the high discontinuation rate are cost (29.9%), disappointment that PE was not curable and the on-demand nature of the drug (25%), adverse effects (11.6%), perceived poor efficacy (9.8%), a search for other treatment options (5.5%), and unknown (18.3%) [651]. Similarly, it was confirmed that many patients on dapoxetine treatment spontaneously discontinued treatment, while this rate was reported at 50% for other SSRIs and 28.8% for paroxetine, respectively [652]. In a Chinese cohort study, 13.6% of the patients discontinued dapoxetine due to lack of efficacy (62%), adverse effects (24%), and low frequency of sexual intercourse (14%) [653].

6.2.6.2.2 Off-label use of antidepressants

Selective serotonin re-uptake inhibitors are used to treat mood disorders but can delay ejaculation and therefore have been widely used 'off-label' for PE since the 1990s [654-656]. Commonly used SSRIs include continuous intake of citalopram, fluoxetine, fluvoxamine, paroxetine and sertraline, all of which have similar efficacy, whereas paroxetine exerts the most substantial ejaculation delay [604, 657, 658]. A novel 5-HT1A receptor antagonist, GSK958108, significantly delayed ejaculation in a double-blind, placebo-controlled trial [659].

Clomipramine, the most serotoninergic tricyclic antidepressant, was first reported in 1977 as an effective PE treatment [660, 661]. In an RCT, on-demand use of clomipramine 15 mg, two to six hours before sexual intercourse was found to be associated with IELT fold change and significant improvements in PRO measures in the treatment group as compared with the placebo group (4.66 ± 5.64 vs. 2.80 ± 2.19, $P < 0.05$) [662, 663]. The most commonly reported TEAEs were nausea in 15.7% and dizziness in 4.9% of men, respectively [662, 663].

Several meta-analyses suggest SSRIs may increase the geometric mean IELT by 2.6-13.2-fold [664]. Paroxetine is superior to fluoxetine, clomipramine and sertraline [665, 666]. Sertraline is superior to fluoxetine, whereas the efficacy of clomipramine is not significantly different from that of fluoxetine and sertraline. Paroxetine was evaluated in doses of 20-40 mg, sertraline 25-200 mg, fluoxetine 10-60 mg and clomipramine 25-50 mg [664-666].

Ejaculation delay may start a few days after drug intake, but it is more evident after one to two weeks as receptor desensitisation requires time to occur. Although efficacy may be maintained for several years, tachyphylaxis (decreasing response to a drug following chronic administration) may occur after six to twelve months [660]. Common TEAEs of SSRIs include fatigue, drowsiness, yawning, nausea, vomiting, dry mouth, diarrhoea and perspiration; TEAEs are usually mild and gradually improve after two to three weeks of treatment [660, 667]. Decreased libido, anorgasmia, anejaculation and ED have also been reported.

Because of the risk of suicidal ideation or suicide attempts, caution is suggested in prescribing SSRIs to young adolescents aged ≤ 18 years with PE, and to men with PE and a comorbid depressive disorder, particularly when associated with suicidal ideation. Patients should be advised to avoid sudden cessation or rapid dose reduction of daily-dosed SSRIs, which may be related to SSRI withdrawal syndrome [612]. Moreover, PE patients trying to conceive should avoid using these medications because of their detrimental effects on sperm cells [668-672].

6.2.6.2.3 Topical anaesthetic agents

The use of local anaesthetics to delay ejaculation is the oldest form of pharmacological therapy for PE [673]. Several trials [540, 675] support the hypothesis that topical desensitising agents reduce the sensitivity of the glans penis thereby delaying ejaculatory latency, but without adversely affecting the sensation of ejaculation. Meta-analyses have confirmed the efficacy and safety of these agents for the treatment of PE [676]. In a meta-analysis, the efficacy of local anaesthetics was best among the other treatment options including SSRIs, dapoxetine 30 and 60 mg, PDE5Is and tramadol for < 8 weeks of therapy [676].

6.2.6.2.3.1 Lidocaine/prilocaine cream

Lidocaine/prilocaine creams can significantly increase the stopwatch-measured IELT from 1-2 minutes to 6-9 minutes [677, 678]. Although no significant TEAEs have been reported, topical anaesthetics are contraindicated in patients or partners with an allergy to any ingredient in the product. These anaesthetic creams/gels may be transferred to the partner, resulting in vaginal numbness. Therefore, patients are advised to use a condom after applying the cream to their penis. Alternatively, the penis can be washed to clean off any residual active compound prior to sexual intercourse. Since these chemicals may be associated with cytotoxic effects on fresh human sperm cells, couples seeking parenthood should not use topical lidocaine/prilocaine-containing substances [679].

6.2.6.2.3.2 Lidocaine/prilocaine spray

The eutectic lidocaine/prilocaine spray is a metered-dose aerosol spray containing purely base forms of lidocaine (150 mg/mL) and prilocaine (50 mg/mL), which has been officially approved by the EMA for the treatment of lifelong PE [680]. Compared to topical creams, the metered-dose spray delivery system has been proved to deposit the drug in a dose-controlled, concentrated film covering the glans penis, maximising neural blockage and minimising the onset of numbness [681], without absorption through the penile shaft skin [682].

Several studies have demonstrated the efficacy of lidocaine/prilocaine spray in improving both IELT and PROs three sprays administered 5 minutes before sexual intercourse [683, 684]. Published data showed that lidocaine/prilocaine spray increases IELT over time up to 6.3-fold over three months, with a month-by-month improvement through the course of the treatment in long-term studies [685]. A low incidence of local TEAEs in both patients and partners has been reported, including genital hypoaesthesia (4.5% and 1.0% in men and female partners, respectively) and ED (4.4%), and vulvovaginal burning sensation (3.9%), but is unlikely to be associated with systemic TEAEs [686, 687].
Lidocaine-only sprays are also available and found to be effective in the treatment of PE [688, 689].

6.2.6.2.4 Tramadol

Tramadol is a centrally-acting analgesic agent that combines opioid receptor activation and serotonin and noradrenaline re-uptake inhibition. Tramadol is a mild-opioid receptor agonist, but it also displays antagonistic properties on transporters of noradrenaline and 5-HT [690]. This mechanism of action distinguishes tramadol from other opioids, including morphine. Tramadol is readily absorbed after oral administration and has an elimination half-life of 5-7 hours.

Several clinical trials evaluated the efficacy and safety of tramadol ODT (62 and 89 mg) and tramadol HCl in the treatment of PE [691]. Up to 2.5-fold increases in the median IELT have been reported among patients who received on-demand tramadol treatment [692, 693].

Adverse effects were reported at doses used for analgesic purposes (≤ 400 mg daily) and included constipation, sedation and dry mouth. In May 2009, the US FDA released a warning letter about tramadol's potential to cause addiction and difficulty in breathing [694]. The tolerability during the twelve-week study period in men with PE was acceptable [695]. Several other studies have also reported that tramadol exhibits a significant dose-related efficacy along with potential adverse effects during the treatment of PE [692, 693]. The Guidelines Panel considers tramadol as a potential alternative treatment to established first-line therapeutic options in men with PE; however, it should be clearly outlined that the use of tramadol has to be considered with caution since there is a lack of data on the long-term safety of the compound in this setting.

6.2.6.2.5 Phosphodiesterase type 5 inhibitors

Although IELT was not significantly improved, sildenafil increased confidence, the perception of ejaculatory control and overall sexual satisfaction, reduced anxiety and the refractory time to achieve a second erection after ejaculation [696, 697]. Several open-label studies have shown that a combination of PDE5Is and SSRIs is superior to SSRI monotherapy, which has also been recently confirmed by a Bayesian network meta-analysis [676, 698].

6.2.6.2.6 Other drugs

In addition to the aforementioned drugs, there is continuous research into other treatment options. Considering the abundant α1a-adrenergic receptors in seminal vesicles and the prostate and the role of the sympathetic system in ejaculation physiology, the efficacy of selective α-blockers in the treatment of PE has been assessed [699-701]. A study demonstrated that the wake-promoting agent modafinil may be effective in delaying ejaculation and improving PROMs [702]. Decreasing penile sensitivity with glans penis augmentation using hyaluronic acid for the treatment of PE was initially proposed by Korean researchers in 2004 [703]. Since then, it has gained popularity mainly in Asian countries [704, 705]. Randomised controlled studies demonstrated that hyaluronic acid glans injections were safe, with a modest but significant increase in IELT along with improvements in PRO measures [704, 705]. No serious TEAEs were reported related to glans penis injections with hyaluronic acid. However, this procedure may result in serious complications, and more safety studies must be conducted before recommending this treatment to PE patients [706]. Selective dorsal neurectomy has also been suggested for the treatment of PE, mainly by Asian researchers [707-713]. However, considering the irreversible nature of these procedures, more safety data are warranted.

Considering the importance of central oxytocin receptors in the ejaculation reflex, several researchers have assessed the efficacy and safety of oxytocin receptor antagonists in the treatment of PE [714]. Epelsiban [715] and cligosiban [716-719] have been found to be safe and mildly effective in delaying ejaculation, but further controlled trials are needed [718, 719]. Delayed ejaculation was associated with the use of pregabalin, a new generation of gabapentinoids, as a side-effect. On-demand oral pregabalin 150 mg was found to increase the IELTs of patients 2.45 ± 1.43-fold. Treatment-emergent side effects (blurred vision, dizziness, vomiting) were minimal and did not lead to drug discontinuation [720].

The role of other proposed treatment modalities for the treatment of PE, such as penis-root masturbation [721], vibrator-assisted start-stop exercises [633], transcutaneous functional electric stimulation [722, 723], transcutaneous posterior tibial nerve stimulation [724], acupuncture [725-727] and practising yoga [728] need more evidence to be considered in the clinical setting.

*6.2.7 **Summary of evidence and recommendations for the treatment of PE***

Summary of evidence	**LE**
Pharmacotherapy includes either dapoxetine on-demand (an oral short-acting SSRI) and eutectic lidocaine/prilocaine spray (a topical desensitising agent), which are the only approved treatments for PE, or other off-label antidepressants (daily/on-demand SSRIs and clomipramine).	1a
Both on-demand dapoxetine treatment and daily SSRI treatment improve IELT values significantly.	1a
Both on-demand dapoxetine treatment and daily SSRI treatment have generally tolerable side effects when used for the treatment of PE.	1a
Daily/on-demand clomipramine treatments improve IELT values significantly and have generally tolerable side effects when used for the treatment of PE.	1a
Cream and spray forms of lidocaine/prilocaine improve IELT values significantly and have safe a profile.	1b
Tramadol is effective in the treatment of PE but the evidence is still inadequate for its long-term safety profile including addiction potential.	1a

Combination of PDE5Is and SSRIs overtakes SSRI monotherapy in effectiveness.	1a
Hyaluronic acid injections are effective in decreasing penile sensitivity.	2b

Recommendations for assessment	Strength rating
Treat erectile dysfunction (ED), other sexual dysfunction or genitourinary infection (e.g., prostatitis) first.	Strong
Use either dapoxetine or the lidocaine/prilocaine spray as first-line treatments for lifelong premature ejaculation (PE).	Strong
Use off-label oral treatment with daily selective serotonin re-uptake inhibitor (SSRIs) or daily/on-demand clomipramine as a viable alternative for second-line treatments.	Strong
Use off-label tramadol with caution as a viable on-demand third-line treatment alternative to on-demand/daily antidepressants (SSRIs or clomipramine).	Strong
Use PDE5Is alone or in combination with other therapies in patients with PE (without ED).	Strong
Use psychological/behavioural therapies in combination with pharmacological treatment in the management of acquired PE.	Weak
Use hyaluronic acid injection with caution as a treatment option for PE compared to other more established treatment modalities.	Weak
Do not perform dorsal neurectomy because more safety data are warranted.	Weak

6.3 Delayed Ejaculation (DE)

6.3.1 ***Definition and classification***

The American Psychiatric Association defines DE as requiring one of two symptoms; marked delay, infrequency or absence of ejaculation on 75-100% of occasions that persists for at least 6 months and causes personal distress [207]. However, in a recent study, while ejaculatory latency and control were significant criteria to differentiate men with DE from those without ejaculatory disorders, bother/distress did not emerge as a significant factor [729]. Similar to PE, there are distinctions among lifelong, acquired and situational DE [207]. A study demonstrated that men with lifelong DE are younger, report greater DE symptomatology, are less likely to have a medical issue or medication that can cause DE and are more likely to masturbate for anxiety/distress reduction than for pleasure as compared with men with acquired delayed ejaculation [730]. Although the evidence is limited, the prevalence of lifelong and acquired DE is estimated at around 1% and 4%, respectively [208].

6.3.2 ***Pathophysiology and risk factors***

The aetiology of DE can be psychological, organic (e.g., incomplete spinal cord lesion or iatrogenic penile nerve damage), or pharmacological (e.g., SSRIs, antihypertensive drugs, or antipsychotics) [731, 732] (Table 18). Other factors that may play a role in the aetiology of DE include tactile sensitivity and tissue atrophy [632]. Although low testosterone level has been considered a risk factor in the past [573, 733], more contemporary studies have not confirmed any association between ejaculation times and serum testosterone levels [734, 735]. Idiosyncratic masturbation and lack of desire for stimuli are also proposed risk factors for DE [736-738].

Table 13: Aetiological causes of delayed ejaculation and anejaculation [739-742]

Ageing Men	Degeneration of penile afferent nerves inhibited ejaculation
Congenital	Mullerian duct cyst Wolfian duct abnormalities Prune Belly Syndrome Imperforate Anus Genetic abnormalities
Anatomic causes	Transurethral resection of prostate Bladder neck incision Circumcision Ejaculatory duct obstruction (can be congenital or acquired)

Neurogenic causes	Diabetic autonomic neuropathy Multiple sclerosis Spinal cord injury Radical prostatectomy Proctocolectomy Bilateral sympathectomy Abdominal aortic aneurysmectomy Para-aortic lymphadenectomy
Infective/Inflammation	Urethritis Genitourinary tuberculosis Schistosomiasis Prostatitis Orchitis
Endocrine	Hypogonadism Hypothyroidism Prolactin disorders Disorders of lipid metabolism
Medication	Antihypertensives; thiazide diuretics Alpha-adrenergic blockers Antipsychotics and antidepressants Alcohol Antiandrogens Ganglion blockers
Psychological	Anxiety Psychoses Acute psychological distress Relationship distress Psychosexual skill deficit Disconnect between arousal and sexual situations Masturbation style

*6.3.3 **Investigation and treatment***

Patients should have a full medical and sexual history performed along with a detailed physical examination when evaluating for DE. Understanding the details of the ejaculatory response, sensation, frequency, and sexual activity/techniques; cultural context and history of the disorder; quality of the sexual response cycle (desire, arousal, ejaculation, orgasm, and refractory period); partner's assessment of the disorder and if the partner suffers from any sexual dysfunction her/himself; and the overall satisfaction of the sexual relationship are all important to garner during history-taking [602]. It is incumbent on the clinician to diagnose medical pathologies that cause or contribute to DE, such as assessing the hormonal milieu, anatomy, and overall medical condition.

6.3.3.1 Psychological aspects and intervention

There is scarce literature on the psychological aspects relating to DE, as well as on empirical evidence regarding psychological treatment efficacy. Studies on psychological aspects have revealed that men with DE show a strong need to control their sexual experiences. Delayed ejaculation is associated with difficulties surrendering to sexual pleasure during sex - i.e., the sense of *letting go* [743] - which denotes a underlying psychological mechanism influencing the reaching of orgasm [744]. As for psychological treatments, these may include, but are not limited to: increased genital-specific stimulation; sexual education; role-playing on his own and in front of his partner; retraining masturbatory practices; anxiety reduction on ejaculation and performance; and, re-calibrating the mismatch of sexual fantasies with arousal (such as with pornography use and fantasy stimulation compared to reality). Masturbation techniques that are either solo or partnered can be considered practice for the "real performance", which can eventually result in greater psychosexual arousal and orgasm for both parties [738]. Although masturbation with fantasy can be harmful when not associated with appropriate sexual arousal and context, fantasy can be supportive if it allows blockage of critical thoughts that may prevent orgasm and ejaculation. Techniques geared towards reducing anxiety are important skills that can help overcome performance anxiety, as this can often interrupt the natural erectile function through orgasmic progression. Referral to a sexual therapist, psychologist or psychiatrist is appropriate and often warranted.

6.3.3.2 *Pharmacotherapy*

Several pharmacological agents, including cabergoline, bupropion, alpha-1-adrenergic agonists (pseudoephedrine, midodrine, imipramine and ephedrine), buspirone, oxytocin, testosterone, bethanechol, yohimbine, amantadine, cyproheptadine and apomorphine have been used to treat DE with varied success [632]. Unfortunately, there is no FDA or EMA-approved medications to treat DE, as most of the cited research is based on case-cohort studies that were not randomised, blinded, or placebo-controlled. Many drugs have been used as primary treatments and/or antidotes to other medications that can cause DE. A survey of sexual health providers demonstrated an overall treatment success of 40% with most providers commonly using cabergoline, bupropion or oxytocin [745]. However, this survey measured the anecdotal results of practitioners. There was no proven efficacy or superiority of any drug due to a lack of placebo-controlled, randomised, blinded, comparative trials [739]. In addition to pharmacotherapy, penile vibratory stimulation (PVS) is also used as an adjunct therapy for DE [746]. Another study that used combined therapy of midodrine and PVS to increase autonomic stimulation in 158 men with spinal cord injury led to ejaculation in almost 65% of the patients [747].

Summary of evidence	**LE**
Delayed ejaculation can be caused by several aetiologies including congenital, anatomic, neurogenic, infective, hormonal, drug-related and psychological.	3
There is not enough evidence to support a definitive treatment for DE.	3

6.4 Anejaculation

6.4.1 ***Definition and classification***

Anejaculation involves the complete absence of antegrade or retrograde ejaculation. It is caused by the failure of semen emission from the seminal vesicles, prostate, and ejaculatory ducts into the urethra [748]. True anejaculation is usually associated with a normal orgasmic sensation and is always associated with central or peripheral nervous system dysfunction or with drugs [749].

6.4.2 ***Pathophysiology and risk factors***

Generally, anejaculation shares similar aetiological factors with DE and retrograde ejaculation (Table 13).

6.4.3 ***Investigation and treatment***

Drug treatment for anejaculation caused by lymphadenectomy and neuropathy, or psychosexual therapy for anorgasmia, is not effective. In all these cases, and in men who have a spinal cord injury, PVS (i.e., application of a vibrator to the penis) is the first-line therapy. In anejaculation, PVS evokes the ejaculation reflex [750], which requires an intact lumbosacral spinal cord segment. If the quality of semen is poor or ejaculation is retrograde, the couple may enter an *in vitro* fertilisation program whenever fathering is desired. If PVS has failed, electro-ejaculation can be the therapy of choice [751]. Other sperm-retrieval techniques may be used when electro-ejaculation fails or cannot be carried out [752]. Anejaculation following either retroperitoneal surgery for testicular cancer or total mesorectal excision can be prevented using unilateral lymphadenectomy or autonomic nerve preservation [753], respectively.

6.5 Painful Ejaculation

6.5.1 ***Definition and classification***

Painful ejaculation is a condition in which a patient feels mild discomfort to severe pain during or after ejaculation. The pain can involve the penis, scrotum, and perineum [754].

6.5.2 ***Pathophysiology and risk factors***

Many medical conditions can result in painful ejaculation, but it can also be an idiopathic problem. Initial reports demonstrated possible associations of painful ejaculation with calculi in the seminal vesicles [755], sexual neurasthenia [756], sexually transmitted diseases (STIs) [754, 757], inflammation of the prostate [228, 758], PCa [759, 760], BPH [226], prostate surgery [761, 762], pelvic radiation [763], herniorrhaphy [764] and antidepressants [765-767]. Further case reports have suggested that mercury toxicity or Ciguatera toxin fish poisoning may also result in painful ejaculation [768, 769]. Psychological issues may also be the cause of painful ejaculation, especially if the patient does not experience this problem during masturbation [770].

6.5.3 ***Investigation and treatment***

Treating painful ejaculation must be tailored to the underlying cause if detected. Psychotherapy or relationship counselling, withdrawal of suspected agents (drugs, toxins, or radiation) [765, 766, 771] or the prescription of appropriate medical treatment (antibiotics, α-blockers or anti-inflammatory agents) may ameliorate painful ejaculation. Behavioural therapy, muscle relaxants, antidepressant treatment, anticonvulsant drugs and/or opioids, and pelvic floor exercises, may be implemented if no underlying cause can be identified [772, 773].

6.5.3.1 Surgical intervention

If medical treatments fail, surgical operations such as TURP, transurethral resection of the ejaculatory duct (TURED) and neurolysis of the pudendal nerve have been suggested [774, 775]. However, there is no strong supporting evidence that surgical therapy improves painful ejaculation: therefore, it must be used with caution.

6.6 Retrograde ejaculation

*6.6.1 **Definition and classification***

Retrograde ejaculation is the total, or sometimes partial, absence of antegrade ejaculation, due to semen passing backwards through the bladder neck into the bladder. Patients may experience a normal or decreased orgasmic sensation. The causes of retrograde ejaculation can be divided into neurogenic, pharmacological, urethral, or bladder neck incompetence [754].

*6.6.2 **Pathophysiology and risk factors***

The process of ejaculation requires complex co-ordination and interplay between the epididymis, vas deferens, prostate, seminal vesicles, bladder neck and bulbourethral glands [776]. Upon ejaculation, sperm are rapidly conveyed along the vas deferens and into the urethra via the ejaculatory ducts. From there, the semen progresses in an antegrade fashion, partly maintained by coaptation of the bladder neck and rhythmic contractions of the periurethral muscles, co-ordinated by a centrally mediated reflex [776]. Closure of the bladder neck and seminal emission is initiated via the sympathetic nervous system from the lumbar sympathetic ganglia and subsequently hypogastric nerve. Prostatic and seminal vesicle secretion, as well as contraction of the bulbo-cavernosal, ischio-cavernosal and pelvic floor muscles are initiated by the S 2-4 parasympathetic nervous system via the pelvic nerve [776].

Any factor that disrupts this reflex and inhibits contraction of the bladder neck (internal vesical sphincter) may lead to retrograde passage of semen into the bladder. These can be broadly categorised as pharmacological, neurogenic, anatomic and endocrinal causes of retrograde ejaculation (Table 14).

Table 14: Aetiology of retrograde ejaculation [754]

Neurogenic	Spinal cord injury Cauda equina lesions Multiple sclerosis Autonomic neuropathy Retroperitoneal lymphadenectomy Sympathectomy or aortoiliac surgery Prostate, colorectal and anal surgery Parkinson´s disease Diabetes mellitus Psychological/behavioural
Urethral	Ectopic ureterocele Urethral stricture Urethral valves or verumontaneum hyperplasia Congenital dopamine β-hydroxylase deficiency
Pharmacological	Antihypertensives, thiazide diuretics α-1-Adrenoceptor antagonists Antipsychotics and antidepressants
Endocrine	Hypothyroidism Hypogonadism Hyperprolactinaemia
Bladder neck incompetence	Congenital defects/dysfunction of hemitrigone Bladder neck resection (transurethral resection of the prostate) Prostatectomy

6.6.3 ***Disease management***

6.6.3.1 Pharmacological

Sympathomimetics stimulate the release of noradrenaline and activate α- and β-adrenergic receptors, resulting in the closure of the internal urethral sphincter, restoring the antegrade flow of semen. The most common sympathomimetics are synephrine, pseudoephedrine hydrochloride, ephedrine, phenylpropanolamine and midodrine [777]. Unfortunately, as time progresses, their effect diminishes [778]. Many studies published about the efficacy of sympathomimetics in the treatment of retrograde ejaculation suffer from small sample size, with some represented by case reports.

An RCT randomised patients to receive one of four α-adrenergic agents (dextroamphetamine, ephedrine, phenylpropanolamine and pseudoephedrine) with or without histamine. The patients suffered from failure of ejaculation following retroperitoneal lymphadenectomy. They found that four days of treatment prior to ejaculation was the most effective and that all the adrenergic agonists restored antegrade ejaculation [777]. In a systematic review, the efficacy of this group of medications was found to be 28% [211]. The adverse effects of sympathomimetics include dryness of mucous membranes and hypertension.

The use of antimuscarinics has been described, including brompheniramine maleate and imipramine, as well as in combination with sympathomimetics. The calculated efficacy of antimuscarinics alone or in combination with sympathomimetics is 22% and 39%, respectively [211]. Combination therapy appears to be more effective, although statistical analysis is not yet possible due to the small sample sizes.

6.6.3.2 Management of infertility

Infertility has been the major concern of patients with retrograde ejaculation. Beyond standard sperm-retrieval techniques, such as testicular sperm aspiration/extraction (TESA/TESE), three different methods of sperm acquisition have been identified for managing infertility in patients with retrograde ejaculation. These include: i) centrifugation and resuspension of post-ejaculatory urine specimens; ii) the Hotchkiss (or modified Hotchkiss) technique; and, iii) ejaculation on a full bladder.

1. *Centrifugation and resuspension.* In order to improve the ambient conditions for the sperm, the patient is asked to increase their fluid intake or take sodium bicarbonate to dilute or alkalise the urine, respectively. Afterwards, a post-orgasmic urine sample is collected by introducing a catheter or spontaneous voiding. This sample is then centrifuged and suspended in a medium. The types of suspension fluids are heterogeneous and can include bovine serum albumin, human serum albumin, Earle's/Hank's balanced salt solution and the patient's urine. The resultant modified sperm mixture can then be used in assisted reproductive techniques. A systematic review of studies in couples in which the male partner had retrograde ejaculation found a 15% pregnancy rate per cycle (0-100%) [211].
2. *Hotchkiss method.* The Hotchkiss method involves emptying the bladder prior to ejaculation, using a catheter, and then washing out and instilling a small quantity of Lactated Ringers to improve the ambient condition of the bladder. The patient then ejaculates, and semen is retrieved by catheterisation or voiding [779]. Modified Hotchkiss methods involve variance in the instillation medium. Pregnancy rates were 24% per cycle (0-100%) [211].
3. *Ejaculation on a full bladder.* The patient is encouraged to ejaculate on a full bladder and semen is suspended in Baker's Buffer. The pregnancy rate in the two studies, which included only five patients, have described results using this technique [780, 781].

6.7 Anorgasmia

6.7.1 ***Definition and classification***

Anorgasmia is the perceived absence of orgasm and can give rise to anejaculation. Regardless of the presence of ejaculation, anorgasmia can be a lifelong (primary) or acquired (secondary) disorder [208].

6.7.2 ***Pathophysiology and risk factors***

Primary anorgasmia starts from a man's first sexual intercourse and lasts throughout his life, while secondary anorgasmia patients should have a normal period before the problem starts [782]. Substance abuse, obesity and some non-specific psychological aspects, such as anxiety and fear, are considered risk factors for anorgasmia. Only a few studies have described anorgasmia alone and generally, it has been considered a symptom linked to ejaculatory disorders, especially with DE, and therefore, they are believed to share the same risk factors. However, psychological factors are for 90% of anorgasmia problems [783]. The causes of delayed orgasm and anorgasmia are shown in Table 15 [782].

Table 15: Causes of delayed orgasm and anorgasmia [782]

Endocrine	Testosterone deficiency Hypothyroidism
Medications	Antidepressants Antipsychotics Opioids
Psychosexual causes	
Hyperstimulation	
Penile sensation loss	

6.7.3 ***Disease management***

The psychological/behavioural strategies for anorgasmia are similar to those for DE. The patient and his partner should be examined physically and psychosexually in detail, including determining the onset of anorgasmia, medication and disease history, penile sensitivity and psychological issues. Adjunctive laboratory tests can also be used to rule out organic causes, such as testosterone, prolactin and TSH levels. Patients who have loss of penile sensitivity require further investigations [782].

6.7.3.1 Psychological/behavioural strategies

Lifestyle changes can be recommended to affected individuals, including changing masturbation style, taking steps to improve intimacy, and decreasing alcohol consumption. Several psychotherapy techniques or their combinations have been offered, including alterations in arousal methods, reduction of sexual anxiety, role-playing an exaggerated orgasm and increased genital stimulation [744, 784]. However, it is difficult to determine the success rates from the literature.

6.7.3.2 Pharmacotherapy

Several drugs have been reported to reverse anorgasmia, including cyproheptadine, yohimbine, buspirone, amantadine and oxytocin [785-790]. However, these reports are generally from case-cohort studies and drugs have limited efficacy and significant adverse effect profiles. Therefore, current evidence is not strong enough to recommend drugs to treat anorgasmia.

6.7.3.3 Management of infertility

If patients fail the treatment methods mentioned above, penile vibratory stimulation, electro-ejaculation or TESE are options for sperm retrieval in anorgasmia cases [782].

6.8 Haemospermia

6.8.1 ***Definition and classification***

Haemospermia is defined as the appearance of blood in the ejaculate. Although it is often regarded as a symptom of minor significance, blood in the ejaculate causes anxiety in many men and may indicate underlying pathology [231].

6.8.2 ***Pathophysiology and risk factors***

Several causes of haemospermia have been acknowledged and can be classified into the following sub-categories; idiopathic, congenital malformations, inflammatory conditions, obstruction, malignancies, vascular abnormalities, iatrogenic/trauma and systemic causes (Table 16) [791].

Table 16: Pathology associated with haemospermia [791-794]

Category	Causes
Congenital	Seminal vesicle (SV) or ejaculatory duct cysts
Inflammatory	Urethritis, prostatitis, epididymitis, tuberculosis, CMV, HIV, Schistosomiasis, hydatid, condyloma of urethra and meatus, urinary tract infections
Obstruction	Prostatic, SV and ejaculatory duct calculi, post-inflammatory, seminal vesicle diverticula/cyst, urethral stricture, utricle cyst, BPH
Tumours	Prostate, bladder, SV, urethra, testis, epididymis, melanoma

Vascular	Prostatic varices, prostatic telangiectasia, haemangioma, posterior urethral veins, excessive sex or masturbation
Trauma/iatrogenic	Perineum, testis, instrumentation, post-haemorrhoid injection, prostate biopsy, vaso-venous fistula
Systemic	Hypertension, haemophilia, purpura, scurvy, bleeding disorders, chronic liver disease, renovascular disease, leukaemia, lymphoma, cirrhosis, amyloidosis
Idiopathic	-

The risk of any malignancy in patients presenting with haemospermia is approximately 3.5% (0-13.1%) [793, 795]. In a study in which 342 patients with haemospermia were included, the most relevant aetiology for haemospermia was inflammation/infection (49.4%) while genitourinary cancers (i.e., prostate and testis) only accounted for 3.2% of the cases [796].

*6.8.3 **Investigations***

As with other clinical conditions, a systematic clinical history and assessment is undertaken to help identify the cause of haemospermia. Although the differential diagnosis is extensive, most cases are caused by infections or other inflammatory processes [231].

The basic examination of haemospermia should start with a thorough symptom-specific and systemic clinical history. The first step is to understand if the patient has true haemospermia. Pseudo-haemospermia may occur as a consequence of haematuria or even suction of a partner's blood into the urethra during copulation [754, 797, 798]. A sexual history should be taken to identify those whose haemospermia may be a consequence of a STI. Recent foreign travel to areas affected by schistosomiasis or tuberculosis should also be considered. The possibility of co-existing systemic diseases such as hypertension, liver disease and coagulopathy should be investigated along with systemic features of malignancy such as weight loss, loss of appetite or bone pain. Examination of the patient should also include measurement of blood pressure, as there have been several case reports suggesting an association between uncontrolled hypertension and haemospermia [799, 800].

Most authors who propose an investigative baseline agree on the initial diagnostic tests, but there is no consensus in this regard [791, 792, 795, 797]. Urinalysis should be performed along with sending the urine for culture and sensitivity testing, as well as microscopy. If tuberculosis or schistosomiasis is the suspected cause, the semen or prostatic secretions should be sent for analysis. A full sexually-transmitted disease screen, including first-void urine as well as serum and genitourinary samples, should be tested for *Chlamydia, Ureaplasma* and Herpes Simplex virus. Using this strategy, it may be possible to find an infectious agent among cases that would have been labelled as idiopathic haemospermia [801].

Serum PSA should be taken in men aged > 40 years who have been appropriately counselled [232]. Blood work, including a full blood count, liver function tests, and a clotting screen should be taken to identify systemic diseases. The question of whether further investigation is warranted depends on clinician judgment, patient age and an assessment of risk factors [791]. Digital rectal examination should also be performed, and the meatus re-examined after DRE for bloody discharge [802]. Detection of a palpable nodule in the prostate is important because an association between haemospermia and PCa has been postulated, although not completely proven.

Magnetic resonance imaging (MRI) is being increasingly used as a definitive means to investigate haemospermia. The multiplanar ability of MRI to accurately represent structural changes in the prostate, seminal vesicles, ampulla of vas deferens, and ejaculatory ducts has enabled the technique to be particularly useful in determining the origin of midline or paramedian prostatic cysts and in determining optimal surgical management [803]. The addition of an endorectal coil can improve diagnostic accuracy for identifying the site and possible causes of haemorrhage [804].

Cystoscopy has been included in most suggested investigative protocols in patients with high-risk features (patients who are refractory to conservative treatment and who have persistent haemospermia). It can provide valuable information as it allows direct visualisation of the main structures in the urinary tract that can be attributed to causes of haemospermia, such as polyps, urethritis, prostatic cysts, foreign bodies, calcifications and vascular abnormalities [805, 806].

With the advancement of optics, the ability to create ureteroscopes of diameters small enough to allow insertion into the ejaculatory duct and seminal vesicles has been made possible [806, 807]. In a prospective study, 106 patients with prolonged haemospermia underwent transrectal US and seminal vesiculoscopy. With both methods combined, the diagnosis was made in 87.7% of patients. When compared head-to-head, the diagnostic yield for TRUS vs. seminal vesiculoscopy was 45.3% and 74.5%, respectively ($P < 0.001$) [808].

Melanospermia is a consequence of malignant melanoma involving the genitourinary tract and is a rare condition that has been described in two case reports [809, 810]. Chromatography of the semen sample can be used to distinguish the two by identifying the presence of melanin if needed.

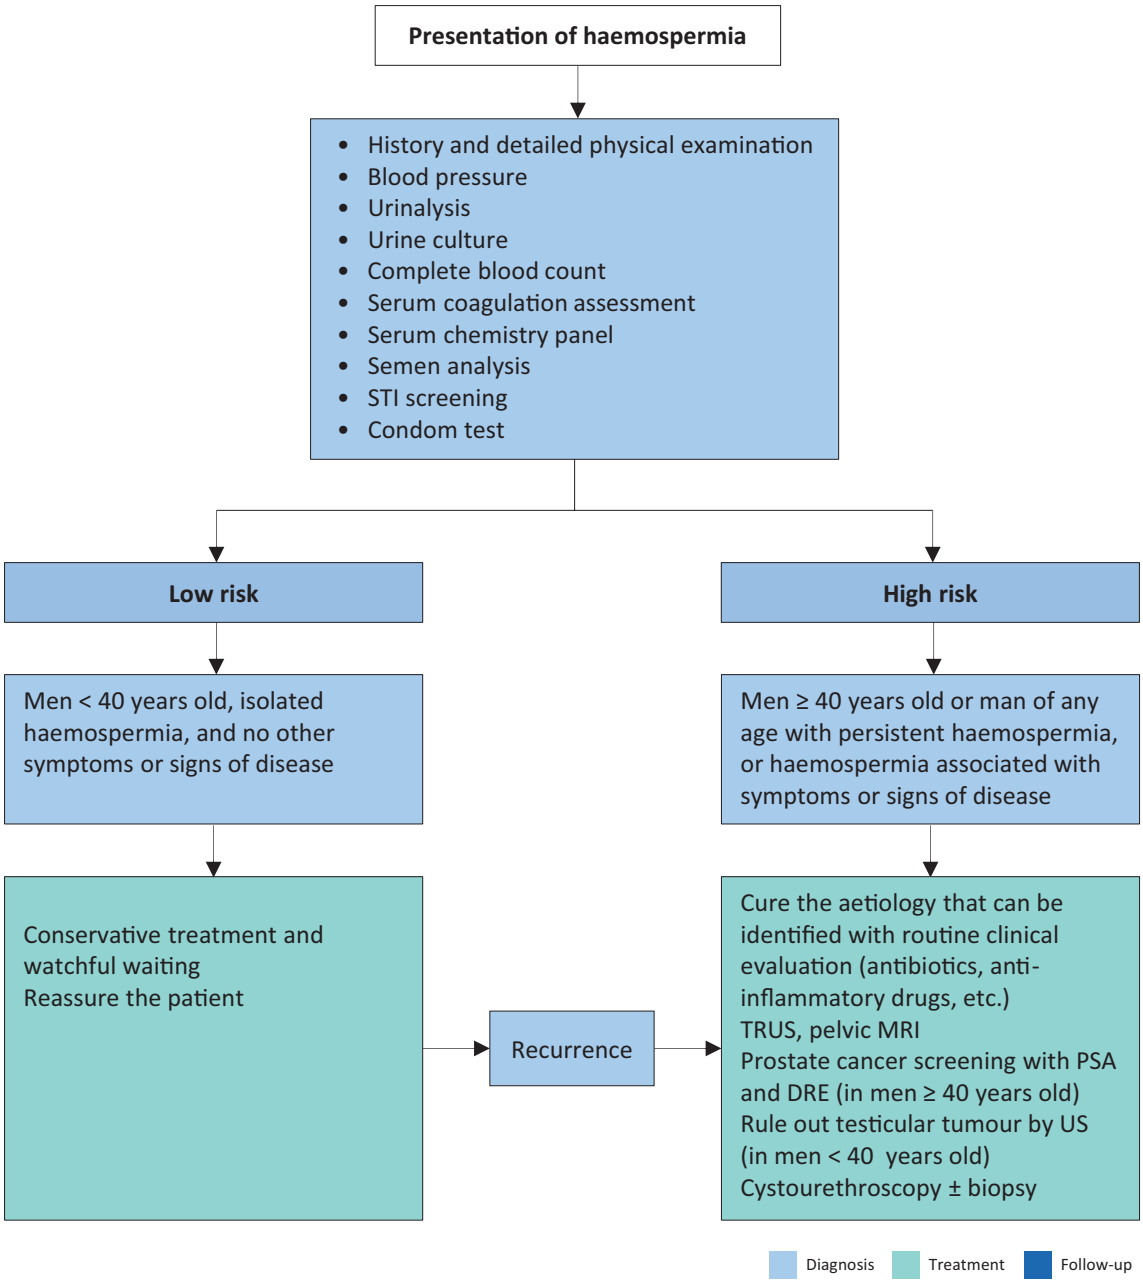
*6.8.4 **Disease management***

Conservative management is generally the primary treatment option when the patients are aged < 40 years and have a single episode of haemospermia. The primary goal of treatment is to exclude malignant conditions like prostate and bladder cancer and treat any other underlying cause. If no pathology is found, then the patient can be reassured [231, 791].

Middle-aged patients with recurrent haemospermia warrant more aggressive intervention. Appropriate antibiotic therapy should be given to patients who have urogenital infections or STIs. Urethral or prostate varices or angiodyplastic vessels can be fulgurated, whereas cysts, either of the seminal vesicles or prostatic urethra, can be aspirated transrectally [231]. Ejaculatory duct obstruction is managed by transurethral incision at the duct opening [811, 812]. Systemic conditions should be treated appropriately [795, 798, 813, 814].

Defining a management algorithm for haemospermia is based on the patient's age and degree of haemospermia. Patients often find blood in the ejaculate alarming, and investigations should be aimed at excluding a serious, despite infrequent, underlying cause (e.g., cancer), while at the same time preventing over-investigation and alleviating patient anxiety. The literature describes a multitude of causes for haemospermia, although many of these are not commonly found after investigation. However, men may be stratified into higher-risk groups according to several factors including: age > 40 years, recurrent or persistent haemospermia, the actual risk for PCa (e.g., positive family history), and concurrent haematuria. Based on the literature, a management algorithm is proposed (Figure 8) [795, 798, 813, 814].

Figure 8: Management algorithm for haemospermia [795, 798, 813, 814]



STI = Sexually transmitted infections; PSA = Prostate specific antigen; DRE = Digital rectal examination; US = Ultrasonography; TRUS = Transrectal ultrasonography; MRI = Magnetic resonance imaging.

6.8.5 *Summary of evidence and recommendations for the investigation and management of haemospermia*

Summary of evidence	LE
While haemospermia has traditionally been attributed to benign causes, it is a potential indicator warranting thorough diagnostic evaluation and, if necessary, targeted treatment.	3
The principal objective of treatment is to rule out malignancies, while addressing any other underlying causes as well.	3

Recommendations	Strength rating
Perform a full medical and sexual history with detailed physical examination.	Strong
Use a risk-stratification system to manage the disease systematically.	Weak

7. LOW SEXUAL DESIRE AND MALE HYPOACTIVE SEXUAL DESIRE DISORDER

7.1 Definition, classification and epidemiology

It has always been a challenge to define sexual desire properly because it has a complicated nature and it can be conceptualised in many different ways. According to the International Classification of Diseases 10th edition (ICD-10), lack or loss of sexual desire should be the principal problem and not other sexual problems accompanying it such as ED [815]. In the DSM-V, male hypoactive sexual desire disorder (HSDD) is defined as "the persistent or recurrent deficiency (or absence) of sexual or erotic thoughts or fantasies and desire for sexual activity". The clinician makes the judgment of deficiency, taking into account factors that affect sexual functioning, such as age and general and socio-cultural contexts of the individual's life [207]. According to the fourth International Consultation on Sexual Medicine (ICSM), the definition of male HSDD was proposed as a "persistent or recurrent deficiency or absence of sexual or erotic thoughts or fantasies and desire for sexual activity (clinical principle)" [816]. Although the exact prevalence of low sexual desire (LSD) is unknown, a prevalence of 4.7% was reported in a survey of a population-based sample of middle-aged German men (n = 12,646) [817].

7.2 Pathophysiology and risk factors

Several aetiological factors are considered to contribute to the pathophysiology of LSD. Levine proposed three components of sexual desire drive (biological), motivation (psychological) and wish (cultural) [818]. However, it is believed that both in the surveys and clinical practice those three components are usually found interwoven [819].

*7.2.1 **Psychological aspects***

The endorsement of negative thoughts during sexual intercourse (i.e., concerns about erection, lack of erotic thoughts, and restrictive attitudes toward sexuality) predicts LSD in men [820, 821]. Furthermore, feeling shame during sexual intercourse, because of negative sexual thoughts (e.g., concern about achieving an erection), characterises men with LSD as opposed to women with the same condition [822]. Psychopathological symptoms stemming from a crisis context negatively impacted male sexual desire [332], as well. In addition, dyadic male sexual desire was best accounted for by sexual satisfaction [823]. It is worth noting that, despite LSD being less common in men than in women [816], it is the most frequent complaint in couples' therapy [824]. Therefore, the role of relationship factors must be addressed. In addition, anxiety proneness has been associated with LSD in men and is expected to shift men's attention from erotic cues to worrying thoughts, thereby decreasing sexual desire [825]. Finally, it is worth noting that current approaches focus on sexual desire discrepancies between partners; the focus on discrepancies rather than on the partner who presents low desire not only reduces stigma, but also provides new opportunities for managing desire in the relationship context [826].

*7.2.2 **Biological aspects***

Testosterone seems to be essential for a man's sexual desire; however, sexual desire does not directly relate to the circulating level of testosterone, especially in older men [827]. The biological and psychological components that take place in the pathophysiology of LSD are shown in Table 22 [819, 828]. In addition to these factors, there is some speculation about the role of the thyroid and oxytocin hormones [555, 829].

Table 22: Common causes of low sexual desire in men [819, 828]

Androgen deficiency
Hyperprolactinaemia
Anger and anxiety
Depression
Relationship conflict
Stroke
Antidepressant therapy
Epilepsy
Post-traumatic stress syndrome

Renal failure
Coronary disease and heart failure
Ageing
HIV infection
Body-building and eating disorders
Erectile dysfunction
Prostatitis/chronic pelvic pain syndrome

*7.2.3 **Risk factors***

In an international survey aimed at estimating the prevalence and correlates of sexual problems in 13,882 women and 13,618 men from 29 countries (Global Study of Sexual Attitudes and Behaviours), risk factors for male LSD were age 60-69 and 70-80 years, poor overall health, vascular diseases, being a current smoker, belief that ageing reduces sex, divorce in the past 3 years, financial problems in the last 3 years, major depression, being worried about the future of a relationship and less than one sexual relation in a week [205]. In a recent study that determined the factors associated with LSD in a large sample of middle-aged German men, PE, ED, and lower urinary tract symptoms were associated with LSD [817]. In contrast, men having more than two children, higher frequency of solo masturbation, perceived importance of sexuality, and higher sexual self-esteem were less likely to have LSD [817].

7.3 Diagnostic work-up

*7.3.1 **Assessment questionnaires***

Sexual Desire Inventory (SDI) evaluates different components influencing the development and expression of sexual desire [830]. This self-administered questionnaire consists of 14 questions that weigh the strength, frequency, and significance of an individual's desire for sexual activity with others and by themselves. The SDI suggests that desire can be split into two categories: dyadic and solitary desire. While dyadic desire refers to "interest in or a wish to engage in sexual activity with another person and desire for sharing and intimacy with another", solitary desire refers to "an interest in engaging in sexual behaviour by oneself and may involve a wish to refrain from intimacy and sharing with others" [830].

*7.3.2 **Physical examination and investigations***

Similar to other forms of sexual dysfunctions, a thorough medical and sexual history must be obtained from men who complain of LSD. The depressive symptoms of the patients must be assessed [831] and relationship problems (e.g., conflict with the sexual partner) must be questioned. In the presence of accompanying symptoms suggestive of endocrinological problems, circulating total testosterone [832], prolactin [833] and thyroid hormones [555] levels can be evaluated.

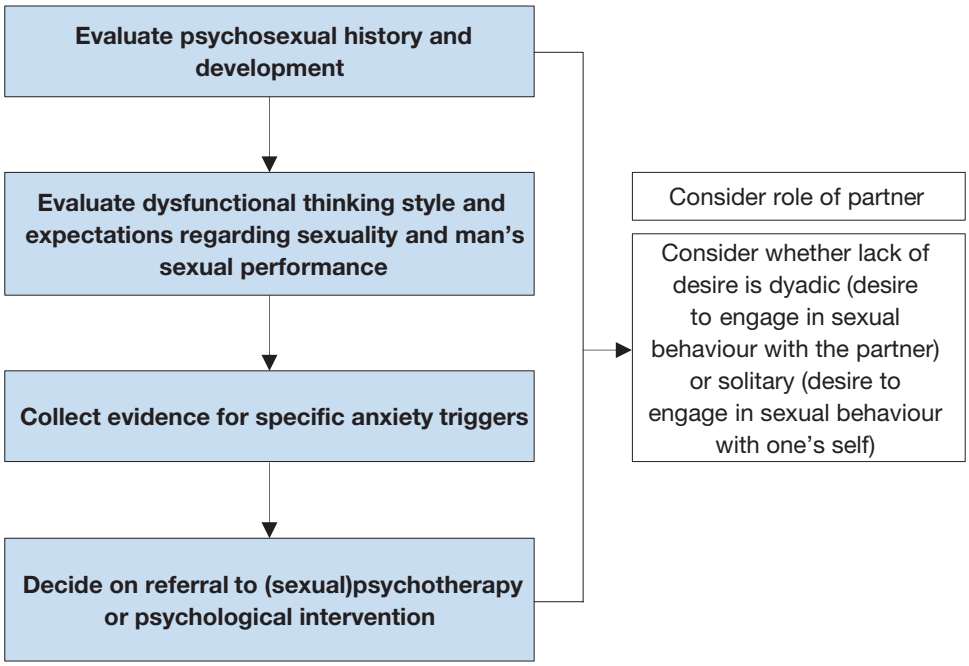
7.4 Disease management

Treatment of LSD should be tailored according to the underlying aetiology.

*7.4.1 **Psychological intervention***

Data on the efficacy of psychological interventions for LSD are scarce. Accordingly, recommendations must be interpreted with caution. Psychological interventions with a focus on cognitive and behavioural strategies may be beneficial for LSD in men [336, 834] (Figure 9). Mindfulness treatments may be a strong candidate, as well [834]. Since both members of a couple may experience age-related changes concurrently and interdependently, it could be helpful to address the sexual health needs of the ageing couple (including LSD) as a whole rather than treating the individual patient [835]. Indeed, psychologists are putting more emphasis on the concept of sexual desire discrepancy. Sexual desire discrepancy is often found in couples or partners, and mirror a natural part of life and partners' dynamics. Clinical approaches based on this lens are less stigmatising as they consider the normal variations in sexual desire that occur throughout the lifespan. This intervention option targets couples distressed by sexual desire discrepancies rather than a single individual targeted as the one presenting low sexual desire [826].

Figure 9: Flow-diagram of psychological evaluation of patients with low sexual desire



7.4.2 ***Pharmacotherapy***

Low sexual desire secondary to low testosterone levels can be treated with different formulations of testosterone. The favourable effect of testosterone therapy on sexual motivation and the presence of sexual thoughts was shown in a meta-analysis [832]. The aim of treatment should be to reach the physiological range of testosterone (see Section 3.3).

Hyperprolactinaemia can also cause LSD and one of the most relevant aetiological factors is prolactin-secreting pituitary adenomas. These adenomas can be easily diagnosed with an MRI of the pituitary gland and can be treated with dopamine agonist agents [836]. The other accompanying endocrine disorders, such as hypothyroidism, hyperthyroidism and diabetes, should be treated accordingly.

Pharmacotherapy can also be used to treat major depression; however, it should be remembered that antidepressants may negatively affect sexual functioning; therefore, antidepressant compounds with less effect on sexual function should be chosen. Psychotherapy can increase the efficacy of pharmacotherapy, especially for patients whose LSD is due to depression [837].

7.5 Recommendations for the treatment of low sexual desire

Recommendations	Strength rating
Perform the diagnosis and classification of low sexual desire (LSD) based on medical and sexual history, which could include validated questionnaires.	Weak
Include physical examination in the initial assessment of LSD to identify anatomical abnormalities that may be associated with LSD or other sexual dysfunctions, particularly erectile dysfunction.	Weak
Perform laboratory tests to rule out endocrine disorders.	Strong
Modulate chronic therapies which can negatively impact toward sexual desire.	Weak
Provide testosterone therapy if LSD is associated with signs and symptoms of testosterone deficiency.	Strong

8. PENILE CURVATURE

8.1 Congenital penile curvature

8.1.1 Epidemiology/aetiology/pathophysiology

Congenital penile curvature (CPC) is a rare condition, with a reported incidence of < 1% [838], although some studies have reported higher prevalence rates of 4-10%, in the absence of hypospadias [839]. Congenital penile curvature results from disproportionate development of the tunica albuginea of the corporal bodies and is not associated with urethral malformation. In most cases, the curvature is ventral, but it can also be lateral or, more rarely, dorsal [840].

8.1.2 Diagnostic evaluation

Taking a medical and sexual history is usually sufficient to establish a diagnosis of CPC. Patients usually present after reaching puberty as the curvature becomes more apparent with erections and sexual activity. The more severe curvatures can make intercourse difficult or impossible. Physical examination and photographic documentation during erection (preferably after intracavernous injection [ICI] of vasoactive drugs) are both mandatory to document the curvature and exclude other pathologies [840].

8.1.3 Disease management

Surgery is the definitive treatment for this disorder and can be deferred until after puberty. However, a survey has suggested that men with untreated ventral penile curvature report more dissatisfaction with penile appearance, increased difficulty with intercourse, and psychological problems; supporting surgical correction of CPC in childhood, although this should be discouraged as penile growth will not have maximised [841]. Surgical treatments for CPC generally share the same principles as in PD. Plication techniques (Nesbit, 16-dot, Yachia, Essed-Schröeder, and others) with or without neurovascular bundle elevation (medial/lateral) and complete penile degloving, have been described [842-851]. Other approaches are based on corporal body de-rotation with different technical refinements that enable correction of a ventral curvature, with reported minimal narrowing and shortening [852-855]. There are no direct comparative studies; therefore, no single technique can be recommended for surgical correction.

8.1.4 Summary of evidence and recommendation for diagnosis and treatment of congenital penile curvature

Summary of evidence	LE
Medical and sexual history are usually sufficient to establish a diagnosis of CPC. Physical examination and photographic documentation during erection (preferably after ICI of vasoactive drugs) are mandatory to document the curvature.	3
Surgery is the only treatment option for CPC, which should be deferred until after puberty and performed at any time in adult life in individuals with significant functional impairment during intercourse.	3

8.1.5 Recommendation for the treatment of congenital penile curvature

Recommendation	Strength rating
Use the Nesbit procedure or plication techniques with or without neurovascular bundle dissection (medial/lateral) for satisfactory curvature correction.	Strong

8.2 Peyronie's Disease

(A discussion on the Aetiology, Risk factors and Pathophysiology of PD can be found in Appendix 4, online supplementary evidence.)

8.2.1 Epidemiology

Epidemiological data on PD are limited. Prevalence rates of 0.4-20.3% have been reported, with a higher prevalence in patients with ED and diabetes [856-864]. A recent survey has indicated that the prevalence of definitive and probable cases of PD in the USA is 0.7% and 11%, respectively, suggesting that PD is an under-diagnosed condition [865]. Peyronie's disease often occurs in older men with a typical age of onset of 50-60 years. However, PD also occurs in younger men (< 40 years), with a reported prevalence of 1.5-16.9% [860, 866, 867].

*8.2.2 **Diagnostic evaluation***

The initial evaluation aims to obtain information on the presenting symptoms and their duration (e.g., pain on erection, palpable nodules, deformity, length and girth and erectile function). It is important to obtain information on the distress caused by the symptoms and the potential risk factors for ED and PD. A disease-specific questionnaire (Peyronie's disease questionnaire [PDQ]) has been developed for use in clinical practice and trials. The Peyronie's disease questionnaire measures three domains, including psychological and physical symptoms, penile pain and symptom bother [868].

Clinicians should take a focused history to distinguish between active and stable disease, as this will influence medical treatment and the timing of surgery. Patients who are still likely to have active disease are those with a shorter symptom duration, pain on erection, or a recent change in penile deformity. Resolution of pain and stability of the curvature for at least three months are accepted criteria of disease stabilisation as well as patients' referral for specific medical therapy [869, 870] or surgical intervention, if indicated [871].

The examination should start with a focused genital assessment that is extended to the hands and feet for detecting possible Dupuytren's contracture or Ledderhose scarring of the plantar fascia [872]. A penile examination is performed to assess the presence of a palpable nodule or plaque. There is no correlation between plaque size and degree of curvature [873]. Measurement of the stretched or erect penile length is important because it may have an impact on the subsequent treatment decisions and potential medico-legal implications [874-876].

An objective assessment of penile curvature with an erection is mandatory. This can be obtained by several approaches, including home (self) photography of a natural erection (preferably), using a vacuum-assisted erection test or an ICI using vasoactive agents. However, it has been suggested that the ICI method is superior, as it can induce an erection similar to or better than that which the patient would experience when sexually aroused [877-879]. Computed tomography and MRI have a limited role in the diagnosis of the curvature and are not recommended on a routine basis. Erectile function can be assessed using validated instruments such as the IIEF although this has not been validated in PD patients [880]. Erectile dysfunction is common in patients with PD (30-70.6%) [881, 882]. The presence of ED and psychological factors may also have a profound impact on the chosen treatment strategy [883]. Ultrasound measurement of plaque size is not accurate but may be helpful to assess the presence of the plaque and its calcification and location [884, 885]. Doppler US may be used for the assessment of penile haemodynamics and ED aetiology [882]. In particular to assess penile arterial inflow in the context of the interventional modality to be undertaken (eg plaque incision and grafting) to exclude arteriogenic ED.

8.2.2.1 Summary of evidence and recommendations for diagnosis of Peyronie's disease

Summary of evidence	**LE**
Ultrasound measurement of plaque size is inaccurate and operator-dependent.	3
Doppler US may be used to assess penile haemodynamic and vascular anatomy.	2a
Intracavernous injection method is superior to other methods in providing an objective assessment of penile curvature with an erection.	4

Recommendations	**Strength rating**
Take a medical and sexual history of patients with Peyronie's disease (PD), including duration of the disease, pain on erection, penile deformity, difficulty in vaginal/anal intromission due to the deformity and erectile dysfunction (ED).	Strong
Perform a physical examination, including assessment of palpable plaques, stretched or erect penile length, degree of curvature (self-photography, vacuum-assisted erection test or pharmacological-induced erection) and any other related diseases (e.g., Dupuytren's contracture, Ledderhose disease) in patients with PD.	Strong
Use the intracavernous injection (IC) method in the diagnostic work-up of PD to provide an objective assessment of penile curvature with an erection.	Weak
Use the PD specific questionnaire especially in clinical trials, but routine use in daily clinical practice is not mandatory.	Weak

Do not use ultrasound (US), computed tomography or magnetic resonance imaging to assess plaque size and deformity in routine clinical practice.	Weak
Use penile Doppler US in the case of diagnostic evaluation of ED, to evaluate penile haemodynamic and vascular anatomy, and to assess location and calcification of plaques, especially prior to surgery.	Weak

*8.2.3 **Disease management***

8.2.3.1 Conservative treatment

Conservative treatment of PD is primarily focused on patients in the early stage of the disease as an adjunct treatment to relieve pain and prevent disease progression or if the patient declines other treatment options during the active phase [871, 872]. Several options have been suggested, including oral pharmacotherapy, intralesional injection therapy, shockwave therapy (SWT) and other topical treatments (Table 16).

The results of the studies on conservative treatment for PD are often contradictory, making it difficult to provide recommendations in everyday, real-life settings [886]. The Guidelines do not recommend the use of oral treatments for PD including pentoxifylline, vitamin E, tamoxifen, procarbazine, potassium para-aminobenzoate (potaba), omega-3 fatty acids or a combination of vitamin E and L-carnitine because of their lack of proven efficacy [871, 887-889]. Studies of these treatments have numerous methodological problems including their uncontrolled nature, the limited number of patients treated, the short-term follow-up and the different outcome measures used [890, 891]. Even in the absence of adverse events, treatment with these agents may delay the use of other more efficacious treatments.

Table 16: Conservative treatments for PD

Oral treatments
Nonsteroidal anti-inflammatory drugs (NSAIDs)
Phosphodiesterase type 5 inhibitors (PDE5Is)
Intralesional treatments

Clostridium collagenase
Interferon α2B
Hyaluronic acid
Botulinum toxin
Topical treatments
H-100 gel
Other
Traction devices
Multimodal treatment
Extracorporeal shockwave treatment
Vacuum Erection Device

8.2.3.1.1 Oral treatment

Phosphodiesterase type 5 inhibitors

Phosphodiesterase type 5 inhibitors were first suggested as a treatment for PD in 2003 to reduce collagen deposition and increase apoptosis through the inhibition of transforming growth factor (TGF)-b1 [892-894]. The results of a retrospective study of 65 men indicated that treatment with tadalafil was helpful in decreasing helped decrease curvature and remodel septal scars when compared to controls [895]. Another study concluded that sildenafil was able to improve erectile function and pain in PD patients. Thirty-nine patients with PD were divided into two groups receiving vitamin E (400 IU) or sildenafil 50 mg for twelve weeks with significantly better outcomes in pain and mean IIEF scores were seen in the sildenafil group [896]. Findings from a observational retrospective study including patients in the acute phase of PD and ED who had been treated with Tadalafil 5 mg once daily compared to patients with comparable baseline parameters who decided not to take the daily compound (i.e., 108 intervention vs. 83 controls) showed that treated men had lower curvature progression rates at 12 weeks (25.9% vs. 39.7%, p = 0.042) [897]. Similarly, mean SHIM score and PDQ-Overall and PDQ-Penile Pain scores significantly improved in the intervention group ($p < 0.001$).

Nonsteroidal anti-inflammatory drugs
Nonsteroidal anti-inflammatory drugs (NSAIDs) may be offered to patients in active-phase PD to ameliorate penile pain. Pain levels should be periodically reassessed whilst monitoring treatment efficacy.

8.2.3.1.2 Intralesional treatment
Injection of pharmacologically active agents directly into penile plaques represents another treatment option. It allows a localised delivery of a pharmacological agent that provides higher concentrations of the drug inside the plaque. However, delivery of the compound to the target area is difficult to ensure, particularly when a dense or calcified plaque is present.

Calcium channel antagonists: verapamil and nicardipine
The rationale for intralesional use of channel antagonists in patients with PD is based on *in vitro* research [898, 899]. Due to the use of different dosing schedules and the contradictory results obtained in published studies, the evidence is not strong enough to support the clinical use of injected channel blockers verapamil and nicardipine and the results do not demonstrate a meaningful improvement in penile curvature compared to placebo [900-905]. In fact, most of the studies did not perform direct statistical comparisons between these groups.

Collagenase of Clostridium histolyticum
Collagenase of *Clostridium histolyticum* (CCH) is a chromatographically purified bacterial enzyme that selectively targets collagen, the primary component of the PD plaque [906-909]. Intralesional injection of CCH has been used in the treatment of PD since 1985. In 2014 the EMA approved CCH for the non-surgical treatment of the stable phase of PD in men with palpable dorsal plaques in whom abnormal curvature of 30-90o and non-ventrally located plaques are present. It should be administered by a healthcare professional who is experienced and properly trained in the administration of CCH treatment for PD [910, 911]. However, CCH has been officially withdrawn from the European market by its manufacturer. Despite this the evidence and recommendations for CCH have been maintained by the Guidelines for completeness.

The original treatment protocol in all studies consists of two injections of 0.58 mg of CCH 24-72 hours apart every six weeks for up to four cycles. Data from IMPRESS (Investigation for Maximal Peyronie´s Reduction Efficacy and Safety Studies) II and II studies [976], as well as post-approval trials [912], which demonstrated the efficacy and safety of this treatment, are summarised in Table 8.2 online Appendix 5.

The average improvement in curvature was 34% compared to 18.2% in the placebo group. Three adverse events of corporeal rupture were surgically repaired. The greatest chance of curvature improvement was for curvatures between 30° and 60°, longer duration of disease, IIEF > 17, and no calcification [870]. An 18.2% improvement from baseline in the placebo arm was also observed. These findings raise questions regarding the proposed role of plaque injection and penile modelling, regardless of the medication, in improving outcomes in men with PD as the placebo or modelling arm resulted in relatively high curvature reduction compared to the treatment arm.

The conclusion of the IMPRESS I and II studies is that CCH improves PD both physically and psychologically [913]. A *post hoc* meta-analysis of the IMPRESS studies demonstrated better results in patients with curvatures < 60º, > 2 years of onset, no calcification in the plaque and good erectile function [912].

Thereafter, a modified short protocol consisting of administration of a single (0.9 mg, one vial) injection per cycle distributed along three lines around the point of maximum curvature up to three cycles, separated by 4-weekly intervals, has been proposed and rapidly popularised replacing physician modelling with a multi-modal approach through penile stretching, modelling and VED at home [914]. The results from this modified protocol were comparable to the results of the IMPRESS trials and appeared to decrease the cost and duration of treatment, although these studies were non-randomised. However, these results were further explored in a prospective non-randomised multi-centre study [982]. In another large single-arm multi-centre clinical study using the shortened protocol, longer PD duration, greater baseline PC and basal and dorsal plaque location were identified as clinically significant predictors of treatment success [915]. Accordingly, a nomogram developed to predict treatment success after CCH for PD showed that patients with longer PD duration, greater baseline penile curvature and basal plaque location had a greater chance of treatment success [915]; however, these findings need to be externally validated.

Regarding safety concerns, most PD patients treated with CCH experienced at least one mild or moderate adverse event localised to the penis (penile haematoma (50.2%), penile pain (33.5%), penile swelling (28.9%) and injection site pain (24.1%), which resolved spontaneously within 14 days of injection [916]. The adverse reaction

profile was similar after each injection, regardless of the number of injections administered. Serious treatment-emergent adverse events (TEAEs) (0.9%) included penile haematoma and corporeal rupture that require surgical treatment. According to IMPRESS data and the shortened protocol, to prevent serious TEAEs men should be advised to avoid sexual intercourse in the four weeks following injection. Recent preliminary data suggest that treatment in the acute phase of the disease is effective and safe [880, 917-921].

In conclusion, CCH is a safe and established treatment for stable-phase disease wit more recent evidence suggesting that CCH also has a role in affecting the progression of active-phase disease. It should also be noted that there is a large effect of traction or modelling in controlled studies, whilst studies reporting on modified protocols have small numbers of patients and are largely uncontrolled. Therefore, patients should be counselled fully on the efficacy of collagenase and the high cost of treatment.

It has been suggested that those patients with severe curvature may also benefit from CCH injections because of a potential downgrading of the penile curvature: a decrease in curvature may allow for a penile plication procedure instead of a plaque incision and grafting procedure, therefore avoiding the more negative impact on erectile function from plaque incision and grafting. However, further studies are required to validate these initial findings [880, 921].

Interferon α-2b

Intralesional injections (5x10^6 units of IFN-α2b in 10 mL saline every 2 weeks over 12 weeks for a total of six injections) significantly improved penile curvature, plaque size and density, and pain compared to placebo. Additionally, penile blood flow parameters are benefited by IFN-α2b [911, 922, 923]. Regardless of plaque location, IFN-α2b is an effective treatment option. Treatment with IFN-α2b provides a > 20% reduction in curvature in most men with PD, independent of plaque location [924]. Given the mild adverse effects, which include sinusitis and flu-like symptoms, which can be effectively treated with NSAIDs before IFN-α2b injection, and the moderate strength of data available, IFN-α2b is currently recommended for treatment of stable-phase PD.

Steroids, hyaluronic acid and botulinum toxin (botox)

In the only single-blind, placebo-controlled study with intralesional administration of betamethasone, no statistically significant changes in penile deformity, penile plaque size, and penile pain during erection were reported [925]. Adverse effects include tissue atrophy, thinning of the skin and immunosuppression [926]. The effect of hyaluronic acid treatment in patients with PD was investigated in a non-randomised study; intralesional injection of hyaluronic acid was compared to intralesional verapamil in acute phase PD and significant improvement of pain, curvature and IIEF-15 were observed [927]. In an RCT, oral administration of hyaluronic acid combined with intralesional injection was found to be superior to intralesional injection only and an improvement of 7.8±3.9 degrees in curvature and reduction in plaque size of 3.0 mm was observed [928]. There is only a single study evaluating intralesional botox injections in men with PD; therefore, there is insufficient evidence to support this treatment in clinical practice [929].

Platelet Rich Plasma (PRP)

Few studies in humans have evaluated the effect of PRP on penile curvature, plaque size, PDQ and IIEF [930-935]. The effect of PRP in patients with PD remains to be proven and should be considered experimental. An ongoing phase 2b randomized placebo-controlled crossover trial has enrolled 25 patients with a planned target of 80 men with PD: first ongoing data on nine patients in the treatment group vs eight in the placebo group showed no difference in curvature at three months in comparison to baseline [936].

8.2.3.1.3 Topical treatments

Topical verapamil and H-100 Gel

There is insufficient evidence that topical treatments (verapamil and H-100 Gel) applied to the penile shaft, with or without the use of iontophoresis (now known as transdermal electromotive drug administration), result in adequate levels of the active compound within the tunica albuginea [937-940].

8.2.3.1.4 Other treatments

Extracorporeal shockwave treatment

The mechanism of action involved in ESWT for PD is still unclear.

Four RCTs and one meta-analysis [941-945] assessed the efficacy of ESWT for PD. Three were sham-controlled trials while one compared ESWT with the combination of ESWT and PDE5I (tadalafil) [946].

All trials showed positive findings in terms of pain relief, but no effect on penile curvature and plaque size. Inclusion criteria varied widely among studies and further investigation is needed. Therefore, ESWT should not be used as a primary treatment for penile curvature in men with PD. The results are summarised in Table 8.4 online Appendix 5.

Penile traction therapy

In men with PD, potential mechanisms for disease modification with penile traction therapy (PTT) have been proposed, including collagen remodelling via decreased myofibroblast activity and matrix metalloproteinase up-regulation [947, 948].

The stated clinical goals of PTT are to non-surgically reduce curvature, enhance girth, and recover lost length, which are attractive to patients with PD. However, clinical evidence is limited due to the small number of patients included (267 in total), the heterogeneity in the study designs, and the non-standardised inclusion and exclusion criteria which make it impossible to draw any definitive conclusions about this therapy [949-953].

Most of the included patients will need further treatment to ameliorate their curvature for satisfactory sexual intercourse. Moreover, the effect of PTT in patients with calcified plaques, hourglass or hinge deformities which are, theoretically, less likely to respond to PTT has not been systematically studied. In addition, the treatment can result in discomfort and be inconvenient as the device needs to be used for an extended period (2-8 hours daily), but has been shown to be tolerated by highly-motivated patients. There were no reported serious adverse effects, including skin changes, ulcerations, hypo-aesthesia or diminished rigidity [951, 954].
In conclusion, PTT seems to be effective and safe for patients with PD [955], but there is still lack of evidence to give any definitive recommendation in terms of its use as a monotherapy for PD.

Vacuum erection device

Vacuum erection device (VED) therapy results in dilation of cavernous sinuses, decreased retrograde venous blood flow and increased arterial inflow [956]. Intracorporeal molecular markers are affected by VED application, including decreases in hypoxia-inducible factor-1α, TGF-β1, collagenase, and apoptosis, and increases in endothelial nitric oxide synthase (eNOS) and α-smooth muscle actin, given their role in the pathogenesis of PD [957]. Only two retrospective studies assessed the efficacy of VED therapy in mechanically straightening the penile curvature of PD as monotherapy and further studies are needed [958, 959].

Multimodal treatment

There is some evidence suggesting that a combination of different oral agents can be used for the treatment of the acute phase of PD. However, there does not seem to be a consensus on which drugs to combine or the optimum drug dosage; nor has there been a comparison of different drug combinations.

A long-term study assessing the role of multimodal medical therapy (injectable verapamil associated with antioxidants and local diclofenac) demonstrated that treatment was efficacious to treat PD patients. It concluded that combination therapy reduced pain more effectively than verapamil alone, making this specific combination treatment more effective compared to monotherapy [957]. Furthermore, combination protocols including injectable therapies, such as CCH, have been studied in controlled trials. The addition of adjunctive PTT and VED has been described; however, limited data are available regarding their use [960].

Penile traction therapy has been evaluated as an adjunct therapy to intralesional injections with interferon, verapamil, or CCH [901, 961, 962]. These studies have failed to demonstrate significant improvements in penile length or curvature, except for one subset analysis identifying a 0.4 cm length increase among men using the devices for > 3 hours/day [962]. A meta-analysis demonstrated that men who used PTT as an adjunct to surgery or injection therapy for PD had, on average, an increase in stretched penile length (SPL) of 1 cm compared to men who did not use adjunctive PTT. There was no significant change in curvature between the two groups [963].

Data available on the combined treatment of CCH and the use of VED between injection intervals have shown significant mean improvements in curvature (-17º) and penile length (+0.4 cm) after treatment. However, it is not possible to determine the isolated effect of VED because of a lack of control groups [914, 963].

Also, a combination of PDE5I (sildenafil 25 mg twice daily) after CCH treatment (shortened protocol combined with VED) is superior to CCH alone for improving penile curvature and erectile function [964]. Further studies are necessary to externally validate those findings.

8.2.3.1.5 Summary of evidence and recommendations for conservative treatment of Peyronie's disease

Summary of evidence	LE
Conservative treatment for PD is primarily aimed at treating patients in the early stage of the disease in order to relieve symptoms and prevent progression.	3c
There is no convincing evidence supporting oral treatment with acetyl esters of carnitine, vitamin E, potassium para-aminobenzoate (potaba) and pentoxifylline.	3c
Due to adverse effects, treatment with oral tamoxifen is no longer recommended.	3c
Nonsteroidal anti-inflammatory drugs can be used to treat pain in the acute phase.	4
Contradictory evidence is available for intralesional treatment with calcium channel antagonists: verapamil and nicardipine.	4
Intralesional treatment with Collagenase clostridium histolyticum showed significant decreases in penile curvature, plaque diameter and plaque length in men with stable disease.	1b
Intralesional treatment with interferon may improve penile curvature, plaque size, density, and pain.	2b
Intralesional treatment with steroids hase been shown to have adverse effects, including tissue atrophy, thinning of the skin and immunosuppression.	3c
No high-level evidence is available to support treatment with intralesional hyaluronic acid or botulinum toxin.	3c
Intralesional hyaluronic acid may be used to improve pain, penile curvature and IIEF scores.	2b
A combination of oral and intralesional hyaluronic acid treatment improves penile curvature and plaque size.	1b
There is no evidence that topical treatments applied to the penile shaft result in adequate levels of the active compound within the tunica albuginea.	3c
There is no efficacy data for the use of iontophoresis.	3c
Extracorporeal shockwave treatment may be offered to treat penile pain, but it does not improve penile curvature and plaque size.	2b
Treatment with penile traction therapy alone or in combination with injectable therapy as part of a multimodal approach may reduce penile curvature and increase penile length, although the available studies have considerable limitations.	3c

Recommendation	Strength rating
Offer conservative treatment to patients not fit for surgery or when surgery is not acceptable to the patient.	Strong
Fully counsel patients regarding all available treatment options and outcomes before starting any treatment.	Strong
Do not offer oral treatment with vitamin E, potassium para-aminobenzoate (potaba), tamoxifen, pentoxifylline, colchicine and acetyl esters of carnitine to treat Peyronie's disease (PD).	Strong
Use nonsteroidal anti-inflammatory drugs to treat penile pain in the acute phase of PD.	Strong
Use extracorporeal shockwave treatment (ESWT) to treat penile pain in the acute phase of PD.	Weak
Use phosphodiesterase type 5 inhibitors to treat concomitant erectile dysfunction or if the deformity results in difficulty in penetrative intercourse in order to optimise penetration.	Weak
Offer intralesional therapy with interferon alpha-2b to patients with stable curvature dorsal or lateral > 30^{o} seeking a minimal invasive procedure.	Weak
Offer intralesional therapy with Collagenase *Clostridium Histolyticum* to patients with stable PD and dorsal or lateral curvature > 30^{0}, who request non-surgical treatment, although the placebo effects are high.	Strong
Do not offer intralesional treatment with steroids to reduce penile curvature, plaque size or pain.	Strong

Do not use intralesional platelet-rich plasma or hyaluronic acid, either alone or in combination with oral treatment, to reduce penile curvature, plaque size or pain outside the confines of a clinical trial.	Strong
Do not offer ESWT to improve penile curvature and reduce plaque size.	Strong
Offer penile traction devices and vacuum devices to reduce penile deformity or as part of a multimodal therapy approach, although outcome data is limited.	Weak

8.2.3.2 Surgical treatment

Although conservative treatment for PD may resolve painful erections in most men, only a small percentage experience significant straightening of the penis. The aim of surgery is to correct curvature and allow penetrative intercourse. Surgery is indicated in patients with significant penile deformity and difficulty with intercourse associated with sexual bother. Patients must have a stable disease for three to six months (or more than nine to twelve months after onset of PD) [871, 965, 966]. In addition to this requirement, other situations that may precipitate an indication for surgery, such as failed conservative or medical therapies, extensive penile plaques, or patient preference, when the disease is stable [967, 968].

Before considering reconstructive surgery, it is recommended to document the size and location of penile plaques, the degree of curvature, complex deformities (hinge or hourglass), the penile length and the presence or absence of ED. The potential aims and risks of surgery should be fully discussed with the patient so that he can make an informed decision [966]. Specific issues that should be mentioned during this discussion are: risk of penile shortening; ED, penile numbness; and delayed orgasm, the risk of recurrent curvature, potential for palpation of knots and stitches underneath the skin, potential need for circumcision at the time of surgery, residual curvature and the risk of further penile wasting with shortening procedures [871, 969]. Selection of the most appropriate surgical intervention is based on penile length assessment, curvature severity and erectile function status, including response to pharmacotherapy in cases of ED [871]. Patient expectations from surgery must also be included in the pre-operative assessment. The main objective of surgery is to achieve a “functionally straight” penis, and this must be fully understood by the patient to achieve the best possible satisfaction outcomes after surgery [966, 970].

Three major types of reconstruction may be considered for PD: (i) tunical shortening procedures; (ii) tunical lengthening procedures; and, (iii) penile prosthesis implantation, with or without straightening techniques in the presence of concomitant ED and residual curvature [971, 972].

Penile degloving with associated circumcision (as a means of preventing post-operative phimosis) should be considered the standard approach for all types of procedures, although modifications have been described. Only one study has suggested that circumcision is not always necessary (e.g., in cases where the foreskin is normal pre-operatively) [973]. Non-degloving techniques have been described that have been shown to prevent ischaemia and lymphatic complications after subcoronal circumcision [974, 975].

There are no standardised questionnaires for the evaluation of surgical outcomes. Data from well-designed prospective studies are scarce, with low levels of evidence. Data are mainly based on retrospective single-centre studies, typically non-comparative and non-randomised, or expert opinion [871]. Therefore, surgical outcomes must be treated with caution.

8.2.3.2.1 Tunical shortening procedures

Tunical shortening procedures achieve straightening of the penis by shortening the longer, convex side of the penis. For men with good erectile function, adequate penile length, without complex deformities, such as an hourglass or hinge type narrowing abnormalities, and non-severe curvature, a tunical shortening procedure can be considered an appropriate surgical approach. Numerous different techniques have been described, although they can be classified as excisional, incisional and plication techniques. The Nesbit procedure operation is based on an elliptical excision of tunica albuginea opposite to the point of maximum curvature [977, 978].

The Yachia technique is based on a completely different concept, as it utilises the Heinke-Mikowitz principle for which a longitudinal tunical incision is closed transversely to shorten the convex side of the penis. This technique, initially described by Lemberger in 1984, was popularised by Yachia in 1990, when he reported a series of 10 cases [979-984].

Pure plication techniques are simpler to perform. They are based on single or multiple plications performed without making excisions or incisions on the tunical albuginea, to limit the potential damage to the veno-

occlusive mechanism [874, 985-1001]. Another modification described the '16-dot' technique that consists of the application of two pairs of parallel Essed-Schroeder plications tensioned more or less depending on the degree of curvature [1002-1005]. Results and satisfaction rates are similar to both incision/excision techniques.

In general, using these tunical shortening techniques, complete penile straightening is achieved in > 85% of patients. Recurrence of the curvature and penile hypo-aesthesia is uncommon (~10%) and the risk of post-operative ED is low. Penile shortening is the most commonly reported adverse outcome of these procedures. Shortening of 1-1.5 cm has been reported for 22-69% of patients, which is rarely the cause of post-operative sexual dysfunction and patients may perceive the loss of length as greater than it actually is. It is therefore strongly advisable to measure and document the penile length peri-operatively, both before and after the straightening procedure, whichever technique is used (Table 17).

As mentioned above, there are multiple techniques with small modifications and all of them have been reported in retrospective studies, most of them without appropriate comparison between techniques and therefore the level of evidence is not sufficient to recommend one particular method over another.

Table 17: Results of tunical shortening procedures for PD (data from different, non-comparable studies) [874, 979-1002, 1006-1009]

	Tunical shortening procedures				
	Nesbit	**Modified Nesbit**	**Yachia**	**16-dot / mod16-dot**	**Simple plication**

**Data are expressed as weighted average. † Defined as > 30 degrees of curvature. Ranges are in parentheses. ED = Erectile dysfunction.*

8.2.3.2.2 Tunical lengthening procedures

Tunical lengthening procedures are performed on the concave side of the penis after making an incision or partial excision of the plaque, with coverage of the defect with a graft. Although tunical lengthening procedures rarely lead to long-term penile length gain, they aim to minimise penile shortening caused by plication of the tunica albuginea, and correct complex deformities. In practice, tunical lengthening procedures are often combined with penile plication or shortening procedures to correct residual curvature and therefore may also result in penile shortening [1010]. Tunical lengthening surgery is preferable in patients with significant penile shortening, severe curvature and/or complex deformities (hourglass or hinge) but without underlying ED. The definition of severe curvature has been proposed to be > 60°, although no studies have validated this threshold. On the concave side of the penis, at the point of maximum curvature, which usually coincides with the location of the plaque, an incision is made, creating a defect in the albuginea that is covered with a graft. Complete plaque removal or plaque excision may be associated with higher rates of post-operative ED due to venous leak, but partial excision in cases of florid calcification may be permissible [1011, 1012]. Patients who do not have pre-operative ED should be informed of the significant risk of post-operative ED of up to 50% [969].

A large number of different grafts have been used. The ideal graft should be resistant to traction, easy to suture and manipulate, flexible (although not too much, to avoid aneurysmal dilations), readily available, cost-effective, and morbidity should be minimal, especially when using autografts. No graft material meets all of these requirements. Moreover, the studies performed did not compare different types of grafts and biomaterials and were often single-centre retrospective studies so there is not a single graft that can be recommended for

surgeons [1013]. The use of geometric principles introduced by Egydio may help to determine the exact site of the incision, and the shape and size of the defect to be grafted [1014].

Grafts for PD surgery can be classified into four types (Table 18) [1015]:

- Autografts: taken from the individual himself, they include the dermis, vein, temporalis fascia, fascia lata, tunica vaginalis, tunica albuginea and buccal mucosa.
- Allografts: also of human origin but from a deceased donor, including the pericardium, fascia lata and dura mater.
- Xenografts: extracted from different animal species and tissues, including bovine pericardium, porcine small intestinal submucosa, bovine and porcine dermis, and TachoSil® (matrix of equine collagen).
- Synthetic grafts: these include Dacron® and Gore-Tex®.

All the autologous grafts have the inconvenience of possible graft harvesting complications. Dermal grafts are commonly associated with veno-occlusive ED (20%) due to lack of adaptability, so they have not been used in contemporary series [1013, 1016-1027]. Vein grafts have the theoretical advantage of endothelial-to-endothelial contact when grafted to underlying cavernosal tissue. The saphenous vein has been the most commonly used vein graft [1028-1043]. For some extensive albuginea defects, more than one incision may be needed. Tunica albuginea grafts have perfect histological properties but have some limitations: the size that can be harvested, the risk of weakening penile support and making future procedures (penile prosthesis implantation) more complicated [1044-1046]. Tunica vaginalis is easy to harvest and has little tendency to contract due to its low metabolic requirements, although better results can be obtained if a vascular flap is used [1047-1051]. Under the pretext that by placing the submucosal layer on the corpus cavernosum the graft feeds on it and adheres more quickly, the buccal mucosal graft has recently been used with good short-term results [1052-1058].

Cadaveric dura mater is no longer used due to concerns about the possibility of infection [1059, 1060]. Cadaveric pericardium (Tutoplast©) offers good results by coupling excellent tensile strength and multidirectional elasticity/expansion by 30% [950, 1012, 1023, 1061, 1062]. Cadaveric or autologous fascia lata or temporalis fascia offers biological stability and mechanical resistance [1063-1065].

Xenografts have become more popular in recent years. Small intestinal submucosa (SIS), a type I collagen-based xenogenic graft derived from the submucosal layer of the porcine small intestine, has been shown to promote tissue-specific regeneration and angiogenesis, and supports host cell migration, differentiation and growth of endothelial cells, resulting in tissue structurally and functionally similar to the original [1066-1075]. As mentioned above, pericardium (bovine, in this case) has good traction resistance and adaptability, and good host tolerance [1043, 1076-1079]. Grafting by collagen fleece (TachoSil©) in PD has some major advantages such as decreased operating times, easy application and an additional haemostatic effect [1080-1085].

It is generally recommended that synthetic grafts, including polyester (Dacron®) and polytetrafluoroethylene (Gore-Tex®) are avoided, due to increased risks of infection, secondary graft inflammation causing tissue fibrosis, graft contractures, and possibility of allergic reactions [982, 1086-1089].

Post-operative penile rehabilitation to improve surgical outcomes has been suggested with a number of studies describing the use of VED and PTT to prevent penile length loss of up to 1.5 cm [1090]. Daily nocturnal administration of PDE5I enhances nocturnal erections, encourages perfusion of the graft, and may minimise post-operative ED rates [1091]. Massages and stretching of the penis have also been recommended once wound healing is complete.

Table 18: Results of tunical lengthening procedures for PD (data from different, non-comparable studies) [950, 982, 1012, 1016-1085, 1092, 1093]

	Year of publication	No. of patients / studies	Success (%)*	Penile shortening (%)*	*De novo* ED (%)*	Follow-up (mo)*
Autologous grafts						
Dermis	1974-2019	718 / 12	81.2% (60-100)	59.9% (40-75)	20.5% (7-67)	(6-180)
Vein grafts	1995-2019	690 / 17	85.6% (67-100)	32.7% (0-100)	14.8% (0-37)	(12-120)
Tunica albuginea	2000-2012	56 / 3	85.2% (75-90)	16.3% (13-18)	17.8% (0-24)	(6-41)
Tunica vaginalis	1980-2016	76 / 5	86.2% (66-100)	32.2% (0-83)	9.6% (0-41)	(12-60)
Temporalis fascia / Fascia lata	1991-2004	24 / 2	100%	0%	0%	(3-10)
Buccal mucosa	2005-2016	137 / 7	94.1% (88-100)	15.2% (0-80)	5.3% (0-10)	(12-45)
Allografts (cadaveric)						
Pericardium	2001-2011	190 / 5	93.1% (56-100)	23.1% (0-33)	37.8% (30-63)	(6-58)
Fascia lata	2006	14 / 1	78.6%	28.6%	7.1%	31
Dura matter	1988-2002	57 / 2	87.5%	30%	17.4% (15-23)	(42-66)
Xenografts						
Porcine SIS	2007-2018	429 / 10	83.9% (54-91)	19.6% (0-66)	21.9% (7-54)	(9-75)
Bovine pericardium	2002-2020	318 / 6	87.4% (76.5-100)	20.1% (0-79.4)	26.5% (0-50)	(14-67)
Bovine dermis	2016	28 / 1	93%	0%	25%	32
Porcine dermis	2020	19 / 1	73.7%	78.9%	63%	85
TachoSil®	2002-2020	529 / 7	92.6% (83.3-97.5)	13.4% (0-93)	13% (0-21)	(0-63)

**Data are expressed as weighted average. Ranges are in parentheses.*
ED = Erectile dysfunction; SIS = Small intestinal submucosa.

It must be emphasised that there have been no RCTs comparing surgical outcomes in PD. The risk of ED seems to be greater for penile lengthening procedures [871]. Recurrent curvature is likely to be the result of failure to wait until the disease has stabilised before surgery is undertaken, re-activation of the condition following the development of stable disease, or the use of early re-absorbable sutures (e.g., Vicryl) that lose their tensile strength before ensuing fibrosis has resulted in acceptable strength of the repair. Accordingly, it is recommended that only non-absorbable sutures or slowly re-absorbed absorbable sutures (e.g., polydioxanone) should be used. With non-absorbable sutures, the knot should be buried to avoid troublesome irritation of the penile skin, but this issue may be alleviated by the use of slowly re-absorbable sutures (e.g., polydioxanone) [1094]. Penile numbness is a potential risk of any surgical procedure, involving mobilisation of the dorsal neurovascular bundle. This is usually a temporary neuropraxia, due to bruising of the dorsal sensory nerves. Given that the usual deformity is dorsal, the procedure most likely to induce this complication is a lengthening (grafting) procedure, or the association with (albeit rare) ventral curvature [971].

8.2.3.2.3 Penile prosthesis

Penile prosthesis (PP) implantation is typically reserved for the treatment of PD in patients with concomitant ED not responding to conventional medical therapy (PDE5I or intracavernous injections of vasoactive agents) [871]. Although inflatable prostheses (IPPs) have been considered more effective in the general population with ED, some studies support the use of malleable prostheses in these patients with similar satisfaction rates [871, 1095, 1096]. The evidence suggests that there is no real difference between the available IPPs [1097]. Surgeons can and should advise on which type of prosthesis best suits their patients but it is the patient who should ultimately choose the prosthesis to be implanted [1098].

Most patients with mild-to-moderate curvature can expect an excellent outcome simply by cylinder insertion [1041, 1099]. If the intra-operative curvature after placement of the prosthesis is < 30° no further action is indicated, since the prosthesis itself will act as an internal tissue expander to correct the curvature during the subsequent six to nine months. If, the curvature is > 30°, the first-line treatment should be modelling with the prosthesis maximally inflated (manually bent on the opposite side of the curvature for 90 seconds, often accompanied by an audible crack) [1100, 1101]. If, after performing this manoeuvre, a deviation > 30° persists,

subsequent steps to be considered include incision with or without collagen fleece coverage (if the defect is small, it can be left uncovered) or plaque incision and grafting are performed [1102-1107]. However, the defect may be covered if it is larger, and this can be accomplished using grafts commonly used in grafting surgery (described above) which prevent herniation and recurrent deformity and buckling due to the scarring of the defect [1108, 1109]. The risk of complications (infection, malformation, etc.) is not increased compared to that in the general population. However, a small risk of urethral perforation (3%) has been reported in patients with 'modelling' over the inflated prosthesis [1100].

In selected cases of end-stage PD with ED and significant penile shortening, a lengthening procedure, which involves simultaneous PP implantation and penile length restoration, such as the "sliding" technique has been proposed [1110]. However, the "sliding" technique is not recommended due to reported cases of glans necrosis because of the concomitant release of the neurovascular bundle and urethra, new approaches for these patients have been recently described, such as the MoST (Modified Sliding Technique), MUST (Multiple-Slit Technique) or MIT (Multiple-Incision Technique) techniques, but these should only be used by experienced high-volume surgeons and after full patient counselling [1111-1114].

While patient satisfaction after IPP placement in the general population is high, satisfaction rates have been found to be significantly lower in those with PD. Despite this, depression rates decreased after surgery in PD patients (from 19.3%-10.9%) [1115]. The main cause of dissatisfaction after PPI in the general population is shortening; therefore, patients with PD undergoing PP surgery must be counselled that the prostheses are not designed to restore the previous penile length [1115, 1116].

8.2.3.2.4 Summary of evidence and recommendations for surgical treatment of Peyronie's disease

Summary of evidence	**LE**
Surgery for PD should only be offered in patients with stable disease and with functional impairment.	2b
In patients with concomitant PD and ED without response to medical treatment, penile prosthesis implantation with or without additional straightening manoeuvres is the technique of choice.	2a
In other cases, factors such as penile length, rigidity of erection, degree of curvature, presence of complex deformities and patient choice must be taken into account when deciding whether to undertake tunical shortening or lengthening procedures.	3

Recommendation	**Strength rating**
Perform surgery only when Peyronie's disease (PD) has been stable for at least three months (without pain or deformity deterioration), which is usually the case after twelve months from the onset of symptoms, and intercourse is compromised due to the deformity.	Strong
Assess penile length, curvature severity, erectile function (including response to pharmacotherapy in case of erectile dysfunction [ED]) and patient expectations prior to surgery.	Strong
Use tunical shortening procedures as the first treatment option for congenital penile curvature and for PD with adequate penile length and rigidity, less severe curvatures and absence of complex deformities (hourglass or hinge). The type of procedure used is dependent on surgeon and patient preference, as no procedure has proven superior to its counterparts.	Weak
Use tunical lengthening procedures for patients with PD and normal erectile function, without adequate penile length, severe curvature or presence of complex deformities (hourglass or hinge). The type of graft used is dependent on the surgeon and patient preference, as no graft has proven superior to its counterparts.	Weak
Do not use the sliding technique as there is a significant risk of life changing complications (e.g., glans necrosis).	Strong
Do not use synthetic grafts in PD reconstructive surgery.	Strong
Use penile prosthesis implantation, with or without any additional straightening procedures (modelling, plication, incision or excision with or without grafting), in PD patients with ED not responding to pharmacotherapy.	Strong

9. PENILE SIZE ABNORMALITIES AND DYSMORPHOPHOBIA

9.1 Definition, epidemiology and classification

9.1.1 ***History***

Throughout history, the size of the penis has symbolised a marker of masculinity [1117] and has created intense debate in societies with different social and cultural implications [1118]. Indeed, along with the capacity for vaginal penetration, the penis is linked to an ancestral sense of men's fertility and sexual performance, making the size of the penis a source of distinguishing male identity [1119, 1120]. Evidence of male supremacy and dominance as represented by phallometric designs can be found across cultures and history and is still currently supported by contemporary media, including the pornographic industry [1121, 1122].

Overall, cosmetic surgery has the potential to restore self-esteem, reduce anxiety, social phobia and depressive mood states regarding body concerns, increasing individuals' well-being and quality of life (QoL) [1123, 1124]. Yet, some candidates for cosmetic surgery may have psychopathological conditions and surgery may result in negative outcomes [1124, 1125].

In the real-life setting, it is interesting to note that 84% of women report being satisfied with their male partners' penile size whereas 55% of the male partners were satisfied with their penile size and 45% of them report that they would like to have a larger penis [1126]. In this context, men with a high level of social-desirability were more likely than others to self-report having a larger penis [1127]. A recent study also demonstrated that reducing the depth of penetration led to a statistically significant 18% reduction of overall sexual pleasure with an average 15% reduction in the length of the penis [1128].

Additionally, the subjective impression of penile size may have a negative effect on sexual functioning and QoL, impacting sexual life in about 10% of men [1129-1131]. This prevalence sharply rises in patients seeking penile augmentation procedures [1132, 1133].

Furthermore, the fact that a subgroup of men does not achieve reasonable levels of satisfaction and emotional adjustment after penile augmentation procedures, underlines that with certain psychopathological conditions men will not benefit from such invasive procedures [1134]. These men may represent a psychologically vulnerable group of individuals in whom penile augmentation procedures will have negative effects and, as such, require clinical and psychological support. Clinicians should possess the skills to anticipate and address such vulnerability through a personalized psychological assessment. Additionally, they should take into account cultural norms to facilitate an understanding of patient expectations [1135].

With the increased use of penile augmentation procedures worldwide, either medical or surgical, it becomes crucial to create evidence-based recommendations to guide clinicians in this challenging and controversial area.

9.1.2 ***Definition***

To date short penis condition represents both a diagnostic and treatment challenge [1136, 1137]. An accurate measurement of the penile shaft is a mandatory step in the assessment of patients complaining of a short penis and defining the norm [1138]. Indeed, a standard tool to address penile measurements and to counsel patients seeking penile augmentation procedures is needed. To date, the standard penile size has yet to be clearly defined. Even though several investigators have attempted to provide objective measurements to define a normal penile size, there is still no consensus on this (Table 19).

Table 19: Summary of papers reporting objective penile measurements

Authors	Year	Patients, n	Age, years	Flaccid length, cm	Stretched length, cm	Erect length, cm	Flaccid circum-ference, cm	Erect circum-ference, cm

Measurements are expressed as median/mean, (IQR)/±SD

The other factor that strongly affects penile measurements is the interobserver variability and the underestimation of the stretched penile length (SPL) when compared to the erect state [1163].

Despite the aforementioned limitations, SPL, defined as the distance between the pubic symphysis and the apex of the glans, represents the most overlapping measurement of the erect penis. Accordingly, a SPL of less than 2.5 standard deviations (SD) below the mean for the male's age and race is considered as micropenis [1164, 1165].

Summary of evidence	**LE**
There is a difference between true micropenis (anatomical-endocrinological)/short penis (complaint)/ buried penis (complaint short penis + obesity) (panel consensus). Small penis anxiety/syndrome refers to a man's excessive anxiety regarding his normal-sized penis.	4
A true micropenis is a congenital condition where the stretched penile length is 2.5 SD cm less than the average length in the population group and is the result of an underlying genetic or endocrine condition.	3
A buried penis is a normal-sized penis where there is a functional and visible loss of penile length due to an underlying pathological condition such as obesity or traumatic loss of length. The penis is covered by prepubic, scrotal or penile subcutaneous tissue or skin.	3
Penile Dysmorphic Disorder is a shorthand concept applied to Body Dysmorphic Disorder cases characterised by a strong focus on a perceived deficiency or flaw in a normal size or shape penis, resulting in mental health impairment and significant damage in important areas of the individual's life.	3

9.1.3 Epidemiology and Classification

The overall incidence of micropenis in the male population is not clearly documented. Epidemiological studies demonstrate that between 0.015% - 0.66% of male newborns have a micropenis [1166, 1167]. There are concerns that the prevalence of this congenital abnormality is increasing due to *in-utero* exposure to endocrine-disrupting chemicals before and during pregnancy [1167]. Despite the limited prevalence of micropenis, there is a major demand for penile augmentation procedures worldwide. This phenomenon can be partially explained by the increased interest in pornography in recent years and the altered perception of a normal penile size [1118, 1168, 1169].

Due to the heterogeneity of clinical situations related to short penis conditions, a classification based on the underlying aetiology is provided below (Table 20).

Table 20: Classification of the clinical conditions underlying a short penis condition or dysmorphophobia in the adult

Group name	**Aetiology**	**Definition**	**Pathogenesis**	**Prevalence, %**
False penile shortness	Acquired	Reduced exposure of the penile shaft in the presence of normal penile size	Adult acquired buried penis	NA
Intrinsic penile shortness	Congenital	Small penis due to an incomplete genital development secondary to a congenital condition	• Hypogonadotropic hypogonadism • Genetic syndromes • Bladder exstrophy–epispadias complex	0.9 - 2.1

Intrinsic penile shortness	Acquired	Shortening/shrinking of the corpora cavernosa due to an acquired pathological process	• Peyronie's Disease • Radical prostatectomy • Radical cystectomy • Radiation therapy • Low flow priapism • Multiple penile operations (e.g., urethral surgery or PP infection) • Penile traumatic event (traumatic or surgical amputation for penile cancer)	NA
Body dysmorphic disorder	Acquired	Perceived defect or flaw in the individual's physical appearance followed by significant distress or impairment in important areas of the individual's life	• Penile Dysmorphic Disorder	1.8 – 9.5

9.1.3.1 False penile shortness - congenital or acquired

Among causes underlying a false penile shortness, the buried penis is the only well-known condition. Historically, a buried penis has been considered a congenital disease affecting children: the so-called "concealed penis" or "webbed penis" [1170, 1171]. Indeed, an abnormal development of the dartos fascia may lead to the entrapment of the penile shaft to the peri-genital tissue leading to this clinical manifestation. On the other hand, a buried penis in the adult is widely recognised as an acquired condition, termed the adult acquired buried penis (AABP) [1172].

The aetiology underlying the development of AABP is deemed to be related to a chronic inflammatory state of the penile dartos which leads to a progressive retraction and scarring of the peri-genital teguments [1173, 1174]. The progressive entrapment of the phallus causes a moist environment which facilitates bacterial and fungal growth causing chronic inflammation [1175]. The ensuing fibrosis results in further entrapment of the penile shaft in the peri-genital tissue [1174, 1175].

Although the exact prevalence of AABP is unknown, its incidence seems to be increasing along with the growing prevalence of obesity, which represents the main risk factor [1176]. Other factors contributing to AABP include aggressive circumcision, following surgical treatment in the obese or penile cancer (PC), or chronic dermatological conditions such as lichen sclerosis (LS) [1177-1179].

The AABP is commonly associated with erectile and voiding dysfunctions, difficulties in maintaining adequate genital hygiene and a poor QoL [1177-1179]. A summary of risk factors for AABP and underlying issues requiring surgery is detailed in Table 21.

Table 21: Summary of studies reporting clinical characteristics of patients with AABP

Study	Year	n	Age, yr	BMI	DM (%)	HT (%)	Smoking habits (%)	History of penile cancer (%)	History of LS (%)	Underlying issues requiring surgery (%)

Measurements are expressed as median/mean, (IQR)/±SD
BMI = body mass index; DM = diabetes mellitus; HT = hypertension; LS = lichen sclerosis.

The aim of AABP treatment is to restore the functional genital anatomy and to improve QoL [1177, 1178]. So far, different authors have proposed a number of classifications for AABP based upon both clinical presentation and the surgical procedure required [1172, 1191].

9.1.3.2 Intrinsic penile shortness – congenital

This category encompasses the so-called "true micropenis" [1199-1201]. Despite male genital malformations being recognised as the most common birth defects, they represent a rare clinical entity with a prevalence between 0.9% and 2.1% [1202, 1203]. Normal genital development is under the influence of hormonal stimulation during the fetal and pubertal periods [1204]. Several genetic syndromes may cause disturbance of the physiological hormonal axis needed for a normal genital development [1199, 1205]. Micropenis may also exist as an isolated finding without a definitive etiological cause in up to 25% of the cases. The classification of the clinical conditions associated with intrinsic penile shortness in the adult is presented in Table 22.

Table 22: Classification of the clinical conditions underlying intrinsic penile shortness in the adult

Aetiology	Disturbs
Hypogonadotropic hypogonadism	• Genetic diseases • Iatrogenic or traumatic injury to pituitary gland or hypothalamus
Hypergonadotropic Hypogonadism	• Chromosomal alterations (e.g., Klinefelter Syndrome) • Androgen Synthesis Defects • Dysgenetic gonads
Syndromic or Multiple Congenital Anomalies	• Bladder exstrophy–epispadias complex • Hypospadias
Unknown	-

Amongst the pre-existing clinical entities associated with micropenis, the bladder exstrophy–epispadias complex (BEEC) is the most studied [1177, 1178, 1201]. It represents a spectrum of genitourinary malformations ranging in severity from epispadias to bladder exstrophy or exstrophy of the cloaca. It is considered as a rare disease, with a prevalence at birth of 1/10,000 [1199, 1201, 1203, 1206]. Even though surgical reconstruction aims to improve body image, this clinical entity is frequently burdened by psychosocial and psychosexual dysfunctions in the long term [1207-1213]. Additionally, male infertility is frequently associated due to poor sperm quantity or quality and hormonal impairment [1214].

9.1.3.3 Intrinsic penile shortness – acquired

This category includes a series of pathological entities that lead to the shortening of the corpora cavernosa. The mechanism underlying intrinsic penile shortening can be acute, as in the case of penile trauma or surgical amputation due to penile cancer or chronic due to a progressive fibrotic process involving the corpora cavernosa [1215-1217].

Traumatic genital injuries may commonly result from traffic accidents and gunshot wounds [1217]. Rarely, a penile amputation can be the result of circumcision and genital surgical procedures such as hypospadias repair, penile prosthesis implantation or urethroplasty, and may result in a decrease in penile length [1218-1222].

Among chronic causes of penile shortening, Peyronie's disease (PD), treatments for prostate cancer, particularly radical prostatectomy (RP) and radical cystectomy represent the most common [1132, 1215, 1216, 1223-1231].

9.1.3.4 Body dysmorphic disorder

Body dysmorphic disorder (BDD) is a clinical diagnosis defined by the American Psychiatric Association (APA; DSM-5) as the strong distress generated by perceived defect(s) or flaw(s) in the individual's physical appearance. This flaw is not observable to others, or, in case it exists, it appears only slightly [1232]. This condition is followed by significant impairment in important areas of the individual's social or occupational life. Body dysmorphic disorder has been allocated to the Obsessive Compulsive and Related Disorders section [1232]. Muscle dysmorphia is a typology within BDD characterising individuals – usually men – with a strong pre-occupation with their perceived small muscles and body shape. Sometimes, men with BDD/muscle dysmorphia also present with an exaggerated focus on the size or shape of their penis. In those cases, Penile Dysmorphic Disorder (PDD) can be used as a shorthand concept – not listed in APA's DSM-5 coding system. Both BDD and PDD are conceptually different from small penis anxiety (SPA) or small penis syndrome, which refers to a man's excessive anxiety regarding his normal-sized penis. Small penis anxiety is not included under APA's nomenclature but men with SPA may be at risk for BDD [1233]. All these definitions exclude men with true micropenis [1232, 1234, 1235]. Prevalence data shows that 2.2% of men in the USA and 1.8% in Germany suffer from BDD [1232]. Between 3%-16% of patients undergoing cosmetic surgery are expected to present BDD, a higher rate in men (15.3%) than in women (10.9%) [1236].

These psychopathological entities must be differentiated from Gender Dysphoria, i.e., the clinical distress associated with the incongruence between gender identity and the gender assigned at birth; and from Koro, i.e., sudden anxiety about the penis falling back into the abdomen [1232].

*9.1.4 **Summary of evidence and recommendations for classification***

Summary of evidence	**LE**
Male genital malformations represent a rare clinical entity with an overall prevalence between 0.9% and 2.1%.	3
Obesity, lichen sclerosis and penile cancer treatment are risk factors for AABP.	4
Adult acquired buried penis (AABP) is commonly associated with erectile and voiding dysfunctions, difficulties in maintaining adequate genital hygiene and a poor quality of life.	3
Adult acquired buried penis condition can be staged upon both clinical presentation and the surgical procedure required according to available classification systems	3
Bladder exstrophy–epispadias complex (BEEC) is a rare clinical condition frequently associated with male genital malformations, particularly micropenis.	2b
Penile trauma and surgical amputation due to penile cancer are the most common acute causes of intrinsic penile shortening.	3
The most frequent aetiologies leading to a chronic intrinsic penile shortening are PD, treatments for prostate cancer (RP, radiation therapy and androgen-deprivation therapy) and radical cystectomy.	2b

Body dysmorphic disorder (BDD) is a clinical entity associated with a significant distress or impairment in important areas of the individual's life.	2b
Penile Dysmorphic Disorder (PDD) can be used as a shorthand concept to describe BDD patients mainly focused on penile size/shape.	4
Body dysmorphic disorder /PDD can be revealed in patients requiring cosmetic surgery.	3

Recommendations	Strength rating
A detailed genital examination should be considered in all men and particularly in men with BMI > 30, lichen sclerosis or penile cancer history and complaints of urinary/sexual difficulties or poor cosmesis to exclude the presence of an adult acquired buried penis (AABP) condition.	Strong
Use classification systems to classify AABP clinical presentation and surgical management.	Weak
Inquire on the presence of body dysmorphic disorder/penile dysmorphic disorder in patients with normal-sized penis complaining of short penile size.	Strong

9.2 Diagnosis

*9.2.1 **Medical history, physical examination and psychological assessment***

9.2.1.1 Medical History

The first step in the evaluation of short penis is a detailed medical history [1237]. Common causes of penile shortness should be screened and observed (e.g., history of phimosis, priapism, hypospadias/epispadias, penile trauma, penile cancer, prostate cancer, penile pain with or without acquired penile curvature suggestive of PD). A past or present diagnosis of BDD should also be noted.

9.2.1.2 Sexual history

Besides a comprehensive clinical interview with open questions regarding sexual education, development, or previous sexual experiences and fantasies, psychometric tools can be used. These include measurements of sexual functioning (e.g., The International Index of Erectile Function [IIEF]), sexual distress (e.g., The Sexual Distress Scale for men), and sexual satisfaction (e.g., Global Measure of Sexual Satisfaction) [307, 1238, 1239]. The propensities for sexual excitation and sexual inhibition may be further considered, (e.g., Sexual Inhibition/ Sexual Excitation Scales), as well as measurements of relationship satisfaction (e.g., Global Measure of Relationship Satisfaction) [1239, 1240]. Special focus should be put on the assessment of sexual performance expectations (e.g., The Dysfunctional Sexual Beliefs Questionnaire) [1241]. As a complementary assessment, body image perception can be further considered (e.g., The Body-Image Questionnaire).

9.2.1.3 Physical examination and penile size measurements

An accurate physical examination focused on the genital area is essential to the patient's initial assessment. The assessment of penile size and shape is mandatory to plan any subsequent medical or surgical treatment but methods for penile measurements seem to vary amongst surgeons [1138, 1242]. The EAU Guidelines Panel on Sexual and Reproductive Health considers a stretch penile length measurement as the bare minimum. If possible, the Panel also advocates additional measurements in both flaccid and erect state after intracavernosal injection of erectogenic agents, compulsory before any surgical indication. Stretched penile length (SPL) can be measured both dorsally and/or ventrally from the penopubic skin junction-to-glans tip (STT) or dorsally from the pubic bone-to-glans tip (BTT) using either a measuring tape or a Vernier calliper. Overall, the measurement of penile size has not been standardised and to date there is no consensus definition due to high heterogeneity in terms of data assessment and reporting methodologies amongst different studies [1242].

Moreover, penile girth should be noted in every patient. As for girth, both distal (coronal) and mid-shaft measurements should be recorded. Furthermore, both measures of circumference can be compared to the head-to-base ratio. The former can help classify penile shape which can be documented through photography [1243]. Although used as a surrogate, STT underestimates erect penile length by about 20% [876, 1244]. Nonetheless, it is important to note that BTT seems to have a better correlation with erect penile length, especially in overweight and obese men [876].

Table 23: Penile size measurement

Length
State Erect, stretched or flaccid ***Anatomic Landmarks*** Dorsally and/or ventrally from the penopubic skin junction-to-glans tip (STT) Dorsally from the pubic bone-to-glans tip (BTT)

State Erect or flaccid ***Anatomic Landmarks*** Proximal (penopubic skin junction) Middle shaft Distal (Coronal or subcoronal)
Shape
Head-to-base ratio Standardised photography

9.2.1.4 Psychological assessment

A sub-group of men requesting penile augmentation procedures, usually surgery, present with strong psychological vulnerability, including BDD [1233]. This subgroup of men may be at risk for increasing psychopathology and suicide attempts and will be unlikely to achieve their surgery expectations [1245]. Currently, there is a set of freely available self-reported tools that may be used to screen patients at risk for psychopathology or poor surgical outcomes, including the Body Dysmorphic Disorder Questionnaire and The Cosmetic Procedure Screening Scale for Penile Dysmorphic Disorder, screening for psychopathological cases regarding body and penile dysmorphic disorder [1233, 1246]. Likewise, The Male Genital Self-Image Scale, and the Index of Male Genital Image, measure men's perceptions and satisfaction regarding their genitals [1247, 1248]. In addition, the Beliefs About Penile Size Scale captures beliefs about the size of the penis as well as internal psychological processes [1249]. However, evidence on BDD/PDD, further psychopathological comorbidities, and the differential diagnosis regarding personality disorders, and disorders from the obsessive-compulsive, psychotic, or emotional spectrum, should be performed by an accredited mental health expert. In addition, the subjective penile size perception should be evaluated [1134].

9.2.1.5 Counselling and outcomes assessment - Validated questionnaires

The Augmentation Phalloplasty Patient Selection and Satisfaction Inventory (APPSSI) questionnaire is a 5-item questionnaire proposed for the assessment and counselling about penile augmentation surgical treatment [1250]. The Beliefs about Penis Size (BAPS) is a 10-item questionnaire created for audit and outcome research to assess men's beliefs about penile size [1249]. Both questionnaires have failed to correlate with penile size and lack of objective validation has restricted their use.

Other well-known self-reported psychosexual questionnaires may be considered: the IIEF-15 and the Male Sexual Health Questionnaire (MSHQ) should be administered to record baseline sexual function status and can also be used to assess its changes after treatment; the Erectile Dysfunction Inventory of Treatment Satisfaction (EDITS) can also be helpful to assess patient and partner's treatment satisfaction [307, 1251, 1252].

9.2.2 ***Imaging***

There is a lack of evidence regarding the use of imaging techniques in the assessment of patients complaining about penile shortness. Although a penile Doppler ultrasound or a penile magnetic resonance imaging may provide additional data regarding the penile anatomy and the extent of penile burying, there is no evidence that this additional information could contribute to the physical examination to justify its routine use in this clinical scenario [1138, 1253-1256].

Summary of evidence	LE
Medical/sexual history taking and physical examination are essential parts of the evaluation of men with a short penis complaint.	4
Among stretched penile measurements dorsal and/or ventrally from the penopubic skin junction-to-glans tip (STT) may underestimate erect penile length.	2b
Among stretched penile measurements dorsally from the pubic bone-to-glans tip (BTT) has a better correlation with erect penile length, especially in overweight and obese men.	2b
Flaccid and erect state measurements to assess penile length may add useful information on penile size.	4
Penile girth assessment may add useful information on penile size and shape.	4
The Body Dysmorphic Disorder Questionnaire, The Cosmetic Procedure Screening Scale for Penile Dysmorphic Disorder, The Male Genital Self-Image Scale and the Index of Male Genital Image are self-reported tools useful to screen patients at risk for psychopathology.	2b
Mental health counselling helps detect men requesting penile augmentation procedures present with strong psychological vulnerability, including BDD/PDD.	2b
Validated questionnaire (e.g., APPSSI, BAPS, IIEF-15, MSHQ, EDITS) help assess baseline sexual function and beliefs about penile size.	4

Recommendations	Strength rating
Take a comprehensive medical and sexual history from every patient presenting complaining of short penile size.	Strong
Use stretched penile measurements (skin junction-to-glans tip or dorsally from the pubic bone-to-glans tip) to define penile length.	Weak
Measure flaccid and erect measurements to assess penile length in detail.	Weak
Measure penile girth in every patient presenting complaining of a short penile size.	Weak
Use validated questionnaires to screen for body dysmorphic disorder (BDD) in cases of a normal-sized penis.	Weak
Use validated questionnaires (e.g., IIEF-15, BAPS) to assess baseline sexual function and beliefs concerning penile size.	Weak
Refer patients with suspected BDD for mental health counselling.	Strong

9.3 Management

*9.3.1 **Non-surgical Treatments***

9.3.1.1 Psychotherapy

Penile augmentation is often motivated by the desire to improve self-perception and self-esteem [1257]. Cosmetic treatments may help increase individuals' well-being and QoL, improving self-esteem and emotional states [1123, 1124, 1138]. Still, psychotherapy is recommended when psychopathological comorbidities are detected, or when aversive relationship dynamics may underly the request for penile augmentation. Addressing patients' and partners' motivations and expectations regarding penile augmentation seems to be a key psychotherapeutic target while no other empirical evidence is described. Similarly, men with BDD and SPA present a significant discrepancy between the perceived and ideal size of the penis, internalising the belief they should have a larger penis [1258]. Cognitive behaviour therapy for BDD could be applied to cases of anxiety regarding penis size, although no clinical trials have been reported [1259]. In all, it is worth noting that psychotherapy should normalise the great variability of genital shape and size [1133]. Managing patient expectations could be a means to improve results and well-being associated with the surgery process.

9.3.1.2 Penile traction therapy

Despite the various surgical techniques, there are also non-invasive methods that are used to enhance penile length, including penile traction therapy (PTT) [1260]. In a pilot phase-II prospective study that evaluated the efficacy and tolerability of a penile-extender device in the treatment of short penis, Gontero *et al.*, used the same traction device for at least 4 hours/day for 6 months and achieved a significant gain in length, of +2.3 and +1.7 cm for the flaccid and stretched penis, respectively (both $p < 0.001$) [1261]. However, the change in the penile girth was not significant. In a further prospective study, these results were confirmed by Nikoobakht *et al.*, who found a significant improvement in the mean length both for the flaccid (8.8 ± 1.2 cm to 10.5 ± 1.2 cm, $P < 0.05$) and the stretched state (11.5 ± 1.0 cm to 13.2 ± 1.4 cm, $p < 0.05$) following 3 months of use of a penile traction device [1262]. At six-month follow-up, compared to baseline, a mean gain of +1.7 ± 0.8, +1.3 ± 0.4, and +1.2 ± 0.4

cm was reported for the flaccid, stretched, and erect penile lengths, respectively ($p < 0.001$, for all). The broad spectrum of available PTT studies is summarised in Table 24.

Overall, PTT seems effective in lengthening the penis both in the flaccid and stretched state with minimal side effects. Yet it is not effective for penile girth enhancement. However, the quality of evidence is poor due to the lack of RCTs, and the availability of only heterogeneous and small PTT cohorts has also been proven effective in the restoration of length or correction of deformities due to several diseases, including PD, or post-RP conditions [955, 1263-1265].

Table 24: Penile traction therapy (PPT)

Author (year)	Year	n	Study design	Device	Treatment protocol	Mean age ± SD	Mean gain in penile dimensions cm (SD)
Nowroozi *et al.* [1266]	2015	54	Prospective	AndroPenis	4-6 hours per day for 6 months	30.1 ± 4.8	Flaccid length: 1.7 ± 0.8 Stretched length: 1.3 ± 0.4 Erected length: 1.2 ± 0.4
Nikoobakht *et al.* [1262]	2011	23	Prospective	Golden Erect	4–6 hours per day during the first 2 weeks and then 9 hours per day until the end of the third month	26.5 ± 8.1	Flaccid length: 1.7 Stretched length: 1.71 Circumference: -0.22 Glans penis circumference: -0.35
Gontero *et al.* [1261]	2008	21	Prospective	Golden Erect	at least 4 h/day for 6 months	45.7 ± 11.1	Flaccid length: 2.3 Stretched length: 1.7 Circumference: NR

NR = not reported.

9.3.1.3 Vacuum erection device

Vacuum erection devises (VED) are generally considered for patients who fail oral ED therapies [413, 1237]. In contrast, data regarding the use of VEDs on penile elongation is scarce. In a study with 27 men whose SPL was < 10 cm, the use of a VED three times a week for 20 minutes on each occasion, for six months, did not result in a significant increase in flaccid or SPL [1267]. On the other hand, the benefits of using a VED following PPI and RP have been demonstrated in the literature [1267-1272].

9.3.1.4 Endocrinological therapies

Testosterone administration has been used for a long time to increase the length of the penis in infant or pre-pubertal boys with micropenis. Topical administration of T or DHT has also been proposed by other authors with reported better outcomes with DHT, especially in poor responders to T or in those with type 2 alpha reductase deficiency [1273, 1274]. Finally, the possible use of the combination of hCG and FSH treatment has also been proposed with positive outcomes [1275, 1276]. Despite the treatment suggested it should be recognised that no face-to-face comparisons are available so far.

9.3.1.5 Summary of evidence and recommendations for the non-surgical management of short penile size

Summary of evidence	LE
Psychotherapy should not be undertaken in the realm of preventing individuals' legitimate choice to improve their lives. Conversely, psychotherapy is recommended when psychopathological comorbidities are detected, or when aversive relationship dynamics may underly the request for penile augmentation.	3
Cognitive behaviour therapy for BDD could be applied to cases of anxiety regarding penis size.	3
Penile traction therapy proved to be an effective treatment to achieve penile lengthening.	3
Vacuum erection devices proved to be an ineffective treatment in achieving penile lengthening.	3
Testosterone therapy, transdermal dihydrotestosterone and recombinant gonadotropins can restore penile size in boys with micropenis or disorders of sex development.	2b
Testosterone therapy does not increase penile size in adult men and in men with late-onset hypogonadism.	3

Recommendations	Strength rating
Consider psychotherapy when psychopathological comorbidities are detected, or when aversive relationship dynamics may underlie the request for penile augmentation.	Strong
Consider the use of penile traction therapy as a conservative treatment to increase penile length.	Weak
Do not use vacuum erection devices to increase penile length.	Weak
Use endocrinological therapies to restore penile size in boys with micropenis or disorders of sex development.	Strong
Do not use testosterone therapy or other hormonal therapies to increase penile size in men after puberty.	Strong

9.3.2 ***Surgical Treatments***

9.3.2.1 *Surgical treatment of adult acquired buried penis*

9.3.2.1.1 Adult acquired buried penis surgical procedures classification

According to the classification proposed by Pariser *et al.* different procedures may range from low complexity (including un-burying of penile shaft, reconstruction of penile shaft with the use of skin flaps or grafts, plastic surgical techniques to reconstruct the scrotum) to high complexity [including surgical removal of the suprapubic fat pad (escutcheonectomy) and operations to skin and subcutaneous fat layers of the abdominal wall (apronectomy] [1191].

The purpose of any surgical approach is to unbury the penile shaft, reconstruct genital teguments and eventually remove peri-genital or excess abdominal tissue in order to reduce the risk of recurrence. The goal is to balance an effective surgical procedure aiming to improve patient QoL, while minimising the incidence of postoperative complications. Lifestyle changes and risk factors modification, particularly weight loss, are widely considered as a proactive approach to minimise AABP surgical complications and should be encouraged before surgical intervention is undertaken. The broad spectrum of surgical interventions described to manage AABP is summarised in Table 25.

Table 25: Surgical interventions to manage adult acquired buried penis [1174]

Study	Year	n	Type of intervention (%)	Classification of intervention* (%)
Ngaage *et al.* [1180]	2021	15	3 (20%) abdominoplasty, 5 (33%) panniculectomy, 11 (73%) monsplasty, 3 (20) shaft reconstruction with scrotal flap, 7 (47%) STSG.	7 category II, 5 category IV, 3 category V
Kara *et al.* [1181]	2021	13	13 (100%) circumcision, penile liberation and STSG.	13 category II
Zhang *et al.* [1182]	2020	26	26 (100%) suprapubic liposuction and a modified Devine's technique.	26 category IV
Monn *et al.* [1183]	2020	67	53 (79.1%) split-thickness skin graft (STSG), 19 (28.4%) ligament fixation, 38 (56.7%) pubic lipectomy, 10 (14.9%) pubic liposuction, 17 (25.4%) abdominal panniculectomy, 16 (23.9%) urethroplasty.	-
Gao *et al.* [1184]	2020	32	32 (100%) suprapubic liposuction, suspensory ligament release and preputioplasty.	32 category IV
Aube *et al.* [1189]	2019	24	17 (70.8%) STSG, 17 (70.8%) penopubic ligament fixation, 17 (70.8%) pubic lipectomy, 9 (37.5%) abdominal panniculectomy, 3 (12.5%) pubic liposuction.	-
Cocci *et al.* [1190]	2019	47	(27.66%) circumcision, (19.14%) scrotoplasty, (4.25%) V-Y plasty of the pre-pubic region, (12.76%) thin STSG, (36.17%) thick STSG, (57.44%) suprapubic fat pad excision, (25.53%) abdominoplasty, (36.17%) division of the suspensory ligament.	-
Erpelding *et al.* [1185]	2019	16	2 (12.5%) penile liberation and STSG, 1 (6.2%) penile liberation, STSG, eschutcheonectomy and urethroplasty, 1 (6.2%) penile liberation, STSG and urethroplasty, 4 (25%) penile liberation, STSG, eschutcheonectomy and urethroplasty, 4 (25%) penile liberation, STSG, eschutcheonectomy and scrotoplasty, 4 (25%) penile liberation, STSG, eschutcheonectomy.	4 category II, 12 category IV

Hesse *et al.* [1186]	2019	27	27 (100%) Penile liberation, STSG, panniculectomy, abdominoplasty and monsplasty.	-
Zhang *et al.* [1187]	2019	15	15 (100%) suprapubic liposuction, penile suspensory ligament release and insertion of folded acellular dermal matrix between corpora cavernosa and pubis symphysis.	15 category IV
Monn *et al.* [1188]	2019	13	6 (46.2%) penile liberation, full thickness graft to the penis using the escutcheon tissue as a graft source, 7 (53.8%) penile liberation, panniculectomy, full thickness graft to the penis using the escutcheon tissue as a graft source.	6 category IV, 7 category V
Pariser *et al.* [1191]	2018	64	3 (5%) penile unburying with local skin flap, 17 (27%) skin graft to the shaft, 7 (11%) scrotal surgery (scrotectomy or scrotoplasty), 33 (52%) escutcheonectomy, 4 (6%) abdominal panniculectomy.	3 category I, 17 category II, 7 category III, 33 category IV, 4 category V
Theisen *et al.* [1192]	2018	16	16 (100%) escutcheonectomy, scrotectomy, and penile STSG.	16 category IV
Fuller *et al.* [1193]	2017	12	12 (100%) escutcheonectomy, scrotoplasty and penile STSG.	12 category IV
Voznesensky *et al.* [1194]	2017	12	11 (92%) debridement of penile skin and STSG to the penis, 12 (100%) escutcheonectomy, 10 (83%) abdominoplasty, 7 (59%) scrotoplasty, 12 (100%) securing the supra-penile dermis to the pubic dermal or periosteal tissue.	12 category IV/V
Hampson *et al.* [1177]	2017	42	42 (100%) limited suprapubic panniculectomy, radical excision of penile shaft skin and reconstruction with STSG and scrotoplasty if needed.	42 category IV
Ghanem *et al.* [1195]	2017	10	10 suprapubic liposuction.	10 category IV
Tausch *et al.* [1172]	2016	56	25 (45%) phalloplasty with or without a scrotal flap (if significant abdominal component panniculectomy to remove the excess suprapubic fat), 12 (21%) penile shaft reconstruction with STSG, 19 (34%) penile shaft reconstruction with STSG following excision of the involved tissues with any necessary adjunctive procedures.	-
Westerman *et al.* [1196]	2015	15	15 (100%) phalloplasty with ventral slit scrotal flap.	15 category II
Rybak *et al.* [1197]	2014	11	11 (100%) penile release, 10 (90.9%) STSG.	1 category I, 10 category II
Shaeer *et al.* [1198]	2009	64	64 (100%) adhesiolysis, suprapubic and lateral lipectomy, anchoring the penoscrotal and penopubic junctions, and skin coverage by a local flap.	64 category IV

The current evidence highlights the efficacy of AABP surgical treatment which has a low incidence of recurrence and satisfactory functional outcomes, as shown in Table 26, yet there is a significant incidence of post-operative complications (up to 3.5% of grade V according to Clavien-Dindo Classification) [1277].

Table 26: Surgical and functional outcomes of adult acquired buried penis repair [1174]

Study	Year	Overall post-operative complications	Recurrence of burying	Sexual outcomes	Urinary outcomes	Cosmetic outcomes
Ngaage *et al.* [1180]	2021	6 (44%)	2 (13%)	Spontaneous erections in 5 (83%)	7 (78%) voiding in standing position	-
Kara *et al.* [1181]	2021	4 (30%)	-	Increase in IIEF & SSS	-	All patients were pleased with the cosmetic outcome

Zhang *et al.* [1182]	2020	21 (80.8%)	-	-	-	Most patients had positive feedback toward their result of the operation, with a mean grade of 4.5+0.7.17 patients (65%) who were very satisfied with the outcome. Six patients (23%) were satisfied with the outcome. Three patients (12%) were neither satisfied nor dissatisfied with the outcome. None of the patients were dissatisfied nor very dissatisfied with the outcome
Monn *et al.* [1183]	2020	24 (57.1%)	-	33 (49.3%) patients with erection post-operatively	-	Satisfied 25 (37.3%); unsatisfied 9 (13.4%); neutral 33 (49.3%)
Gao *et al.* [1184]	2020	-	-	Increase in IIEF	-	-
Aube *et al.* [1189]	2019	15 (62.5%)	-	Good postoperative erection	-	Patient satisfaction in the case of a successful procedure was: 16 patients (76.2%) satisfied with the procedure, 5 patients (23.8%) neutral/not responding and no patients (0%) dissatisfied
Erpelding *et al.* [1185]	2019	3 (18.7%)	-	-	-	-
Hesse *et al.* [1186]	2019	15 (55.5%)	-	-	-	Nearly all patients (96%) reported early satisfaction with the procedure
Zhang *et al.* [1187]	2019	11 (73.3%)	-	No difficulty in sexual intercourse	None of the patients reported difficulty in urination	10 patients (66.7%) were very satisfied with the outcome, 4 patients (26.6%) were satisfied with the outcome, 1 patient (6.7%) was neither satisfied nor dissatisfied with the outcome, and no patient was dissatisfied with the appearance and function
Cocci *et al.* [1190]	2019	7 (14.9%)	-	Increase in IIEF of 3 points, vaginal penetration became possible in 97.87% of patients, erectile function improved in 42.55%, 48.93% needed to take PDE5i to enhance their nocturnal erections, improvement in penile erogenous sensation was recorded in 6.38%	-	-
Monn *et al.* [1188]	2019	5 (38.4%)	-	-	-	All patients reported subjective satisfaction with the cosmesis of their surgical outcome

Pariser *et al.* [1191]	2018	42 (65%)	-	-	-	-
Theisen *et al.* [1192]	2018	2 (10.5%)	1 (5.2%)	Significant improvement in 10 of 13 questions (77%)	Significant improvement in 10 of 12 questions (83%)	
Fuller *et al.* [1193]	2017	0 (0%)	-	-	-	-
Voznesensky *et al.* [1194]	2017	9 (75%)	9 (75%)	Improvement or the same degree of sexual activity (75%).	Improvement in urination (92%)	-
Ghanem *et al.* [1195]	2017	-	-	-	-	3 (30%) of the patients were very satisfied with the result, 5 (50%) patients were satisfied, 1 patient (10%) was neither satisfied nor dissatisfied, and 1 (10%) patient was dissatisfied. No patients were very dissatisfied.
Tausch *et al.* [1172]	2016	-	-	-	-	-

Summary of evidence	**LE**
Various surgical procedures may be considered to restore genital anatomy in adult acquired buried penis (AABP) patients.	3
Adult acquired buried surgery is burdened by a significant incidence of postoperative complications.	3
Lifestyle changes and risk factors modification, particularly weight loss, are widely considered as a proactive approach to minimise AABP surgical complications.	4
Adult acquired buried surgery may provide satisfactory functional outcomes with a low incidence of recurrence.	3

Recommendations	**Strength rating**
Extensively counsel patients on the benefits and complications of adult acquired buried penis (AABP) surgery.	Strong
Initiate lifestyle changes and modification of risk factors, particularly weight loss, to minimise AABP surgical complications and to optimise surgical outcomes.	Strong
Consider surgical treatment to address AABP.	Weak

9.3.2.2 Surgical treatment of congenital intrinsic penile shortness

Current literature reports a wide spectrum of possible surgical interventions aimed to address penile shortness. Nonetheless, the proposed spectrum of surgical interventions starts from less invasive procedures - such as suspensory ligament release (SLR) - to more complex genital reconstruction - such as total phallic reconstruction (TPR) [1278, 1279].

9.3.2.2.1 Suspensory ligament release (SLR)

This technique involves a surgical incision and SLR of the penis which attaches the penis to the pubic bone. The surgical access is via an infrapubic incision and may be combined with an elongating V-Y skin plasty [1279]. Several authors reported outcomes of SLR in the context of a congenital intrinsic penile shortness (Table 27).

Table 27: Suspensory ligament release [1278]

Author (year)	Year	n	Study design	Age, years	Follow-up, months	Stretched penile length gain, cm
Littara *et al.* [1280]	2019	21	Retrospective	38.08 ±1.1	12	1.1
Zhang *et al.* [1187]	2019	15	Retrospective	33.2 ± 4.6	3	4.3 ±1.6
Li *et al.* [1279]	2006	27	Retrospective	NR	16	1.1 ±1.1
Spyropoulos *et al.* [1250]	2005	11	Retrospective	25-25	Not reported	1.6 (1–2.3)

Measurements are expressed as median/mean, (IQR)/±SD.

9.3.2.2.2 Ventral phalloplasty/scrotoplasty

This intervention is based on a ventral shaft skin plasty to move the peno-scrotal angle proximally and increase the exposure of the penile shaft. A longitudinal incision or Z-plasty at the penoscrotal junction, securing the tunica albuginea to the proximal tunica dartos was performed by Xu *et al.* in 41 patients [1281]. The correction was successful in all patients with an improved median length of +2.1 cm in the flaccid state.

9.3.2.2.3 Suprapubic lipoplasty/liposuction/lipectomy

This intervention aims to reduce the thickness of the suprapubic fat pad either with a minimally invasive approach (liposuction) or surgically (lipectomy). The flattening of the suprapubic fat pad aims to increase penile shaft exposure.

Ghanem *et al.*, performed liposuction in ten patients using a 50-cc syringe with a 3- and 6-mm liposuction needle [1195]. The amount of fat removed ranged from 325 to 850 mL with a mean of 495.50 ± 155.39 mL. Three (30%) of the patients were very satisfied with the post-operative result, five (50%) patients were satisfied, one patient (10%) was neither satisfied nor dissatisfied, and one (10%) patient was dissatisfied. No patients were very dissatisfied. Shaeer's monsplasty technique was investigated in 20 patients [1282]. At three months post-operatively, the flaccid visible length was 7.1 ± 2.1cm, with a 57.9% improvement in length, and the erect visible length was 11.8 ± 2.1cm, with a 32% improvement in length. At final follow-up (eighteen months) a 73.1% improvement in satisfaction rate was detected.

9.3.2.2.4 Total phallic reconstruction (TPR)

This represents the most complex genital reconstruction possible, aiming to create a new phallus with a neo-urethra. The operation is reserved for severe penile insufficiency cases (e.g., congenital micropenis, exstrophy-epispadias complex) as the benefit should be balanced over possible complications [1278].

Lumen *et al.*, treated seven male patients (aged 15 to 42 years) with phalloplasty (6 with radial forearm free flap and 1 with anterolateral thigh flap) and implant surgery was offered approximately 1 year after the phallic reconstruction [1283]. There were no complications after surgical formation of the neophallus. Two complications were reported in the early post-operative period. Two patients developed urinary complications (stricture and/or fistula). Patient satisfaction after surgery was high in six cases and moderate in one case. Four patients underwent penile implant surgery and 50% were subsequently removed.

Perovic *et al.*, conducted TPR using musculocutaneous latissimus dorsi (MLD) in twelve patients [1284]. The mean (range) follow-up was 31 (6–74) months, and the penile size was 16 (14–18) cm long and 13 (11–15) cm in circumference. There was no flap loss or partial skin necrosis.

Garaffa *et al.*, reported a series of TPR using the radial artery forearm free flap in 16 patients with bladder/cloacal exstrophy and micropenis-epispadias complex [1285]. In one patient the distal third of the phallus was lost due to acute thrombosis of the arterial anastomosis immediately post-operatively. Almost all (93%) were fully satisfied in terms of cosmesis and size. Urethral stricture and fistula were the most common complications, which developed only at the native neourethral anastomosis. They were successfully managed by revision surgery. Sexual intercourse was achieved in 11 of the 12 patients who underwent PPI.

9.3.2.2.5 Summary of evidence and recommendations for surgical treatment of congenital intrinsic penile shortness

Summary of evidence	LE
Considering the wide spectrum and the complexity of surgical interventions aimed at addressing penile shortness, this surgery should be reserved to high volume centres.	4
Suspensory ligament release, ventral phalloplasty and suprapubic lipoplasty/liposuction/lipectomy provide an objective increase in penile length.	3
Suspensory ligament release, ventral phalloplasty and suprapubic lipoplasty/liposuction/lipectomy are associated with a significant incidence of complications.	3
Total phallic reconstruction provides satisfactory surgical and functional outcomes in men with micropenis.	3

Recommendations	Strength rating
Perform penile augmentation surgery in high-volume centres.	Strong
Use suspensory ligament release (SLR), ventral phalloplasty and suprapubic lipoplasty/ liposuction/lipectomy to address penile lengthening.	Weak
Extensively discuss possible complications related to suspensory ligament release, ventral phalloplasty and suprapubic lipoplasty/liposuction/lipectomy.	Strong
Use total phallic reconstruction to restore genital anatomy in patients affected by congenital micropenis.	Weak

9.3.2.3 Surgical treatment of acquired penile shortness

9.3.2.3.1 Penile prosthesis implantation (PPI)

The literature fails to show a direct relationship between PPI and penile length in men with ED and no concomitant PD. In a study by Deveci *et al.*, SPL was evaluated in men undergoing primary implant surgery due to diabetes or RP [1286]. Either three-piece (Alpha-1, Mentor, USA) and two-piece implants (Ambicor, AMS, Boston Scientific, USA) were used and most patients (72%) reported a subjective decrease in penile length, although no statistically significant difference was demonstrated in measured SPL [1286]. In another study, 45 patients with PD with no deformity or penile curvature < 30° or severe penile fibrosis/scarring were implanted with an AMS 700 LGX [1287]. The mean stretched penile length improved from 13.1 ± 1.2 cm to 13.7 ± 1.1 cm and 14.2 ± 1.2 cm at six and twelve months, respectively. A significant difference was also observed in the length of the stretched flaccid penis between six and twelve months [1287].

Some authors have evaluated the erect penile length following PPI. In a prospective study where patients with PD were excluded, erect penile length was compared from baseline achieved by intracavernosal injection and after PPI inflation. The authors demonstrated that there were 0.83 ± 0.25, 0.75 ± 0.20 and 0.74 ± 0.15 cm decreases in erect penile length six weeks, six months, and one year post-operatively, respectively [1288]. A study where patients with PD were excluded confirmed these results as the median pre-operative pharmacologically induced length (14.25 ± 2 cm) was decreased to median post-prosthesis penile length (13.5 ± 2.13 cm) [1289].

9.3.2.3.2 Penile disassembly

Penile disassembly has been described as a technique for penile lengthening [1290]. It consists of the separation of the penis into its anatomical components and the insertion of autologous cartilage in the space created between the glans cap and the tip of corpora cavernosa. Perovic *et al.*, in a study with 19 patients submitted to penile disassembly and implantation of autologous rib cartilage followed by VED therapy, reported an increase of 3 cm and 3.1 cm in SPL and erect length, respectively [1290]. The results of this surgery are poorly documented and significant complications such as glans necrosis can ensue.

9.3.2.3.3 Lengthening corporal manoeuvres

Penile length restoration with the use of the sliding technique (ST) and concomitant PPI was first described in a small series of three patients in 2012, and further supported by a larger series of 28-patient in a multi-centre study in 2015 [1110, 1114]. Although this technique is only used in cases of end-stage PD with severe shortening of the shaft, 95% of men were satisfied with their increase in length with an average penile lengthening of 3.2 cm (range, 2.5-4 cm). The modified sliding technique (MoST) and multiple slit technique (MuST) are further modifications of the original ST [1111, 1112]. In a series by Egydio *et al.*, 143 patients with

penile shortening and narrowing due to PD amongst other aetiologies underwent MoST or MuST procedures. The mean (range) penile length gain was 3.1 (2-7) cm at a median (range) follow-up of 9.7 (6-18) months [1111].

9.3.2.3.4 Total phallic reconstruction (TPR)

Radial forearm free flap is the most used reconstructive approach for TPR. In a single-centre study, Falcone *et al.*, reported their experience of ten patients who underwent TPR using RAFFF after traumatic penile loss [1291]. In six individuals, the urethral stump was sufficient for primary anastomosis and neourethra formation. The remaining patients had total penile avulsion and were voiding via a perineal urethrostomy. Consequently, a two-stage urethroplasty was necessary. Two patients developed an acute arterial thrombosis of the microsurgical anastomosis, which was successfully treated with emergency exploration. One patient had a neourethral stricture and fistula that required revision. All patients who underwent complete urethral repair were able to void and ejaculate through the phallus. After a median follow-up of 51 months, all patients were satisfied with the acquired size, cosmesis, and sensation. Six patients received a PPI and were able to also engage in penetrative intercourses. However, three patients had revision surgery (two due to infection and one due to mechanical failure) [1291].

9.3.2.3.5 Summary of evidence and recommendations for surgical treatment of acquired penile shortness

Summary of evidence	**LE**
Penile prosthesis implantation is not effective in increasing penile length.	3
The evidence for the use of penile disassembly manoeuvres and the lengthening corporal manoeuvres are limited.	3
Total phallic reconstruction yields to satisfactory outcomes despite the high incidence of post-operative complications.	3

Recommendations	**Strength rating**
Do not recommend penile prosthesis implantation, penile disassembly or lengthening corporal manoeuvres to patients seeking penile lengthening options.	Strong
Use total phallic reconstruction to restore genital anatomy in genetic males with penile inadequacy due to traumatic loss.	Weak

9.3.2.4 Penile girth enhancement

9.3.2.4.1 Penile Girth enhancement history

Nomograms were created for penile girth measurements, including flaccid penis circumference (n = 9407, 9.31 ± 0.90 cm) and erect circumference (n = 381, 11.66 ± 1.10 cm) [1136]. Unlike penile lengthening, there are no precise definitions or indications for penile girth enlargement in the literature or existing international guidelines [1292]. In recent years, men have increasingly approached urologists for penile girth enhancement to increase their self-confidence, to be cosmetically satisfied or to satisfy their partners [1293]. Current reports on penile girth enhancement techniques are from recent years [1293, 1294]. Although these surgical techniques are more and more frequently requested, the level of evidence for their use in clinical practice is low, notwithstanding the ethical considerations of surgery in this vulnerable group of patients.

9.3.2.4.2 Injection therapy

Injectable filling materials can be classified according to their different properties. They can be autologous, biological or synthetic. The fat injection material is obtained from the patient's own tissue (autologous), usually by liposuction (see the following surgical therapy section). Biological fillers can be of human and animal (collagen) or bacterial (Hyaluronic acid) origin. Poly-l-lactic acid (PLA), hydroxyethyl methacrylate, polyalkylimide hydrogel (PAAG), polymethylmethacrylate (PMMA), calcium hydroxyapatite (CHA), silicon and paraffin constitute filler materials of synthetic origin (Table 28) [1295].

Table 28: Origin of injectable filling materials

Autologous	Autologous fat tissue
Biological	Hyaluronic acid
Synthetic	Poly-l-lactic acid, hydroxyethyl methacrylate, polyacrylamide hydrogel, polymethylmethacrylate, calcium hydroxyapatite, silicon, paraffin

9.3.2.4.2.1 Soft tissue fillers (Hyaluronic acid and PMMA)

Hyaluronic acid

Injection of hyaluronic acid (HA) gel is one of the most commonly used injectable fillers in the field of plastic surgery [1237, 1296]. The application of HA for penile girth enhancement has recently gained increasing popularity due to its biocompatibility and infrequent mild temporary side effects. The newly invented cross-linked HA has a more lasting effect over time [1297]. Hyaluronic acid has been used for patients for penile girth enhancement. Studies have reported that an increase of 1.4 to 3.78 cm in penile girth is achieved with HA injection (Table 29). Patient satisfaction is high (78-100%) and no severe side effects have been reported [704, 1298-1301].

Table 29: Published data on evaluation of Hyaluronic acid injection therapy on penile girth enhancement

Author	Year	n	Study design	Age, years	Follow-up, months	Girth gain, cm	Complications, n (%)
Zhang *et al.* [1302]	2022	38	Retrospective	31.2 ± 6.7	12	2.44 ± 1.14	3 (7.9)
Ahn *et al.* [704]	2021	32	Multi-centre RCT	20-65	5-6	2.27± 1.26	2 (6.3)

Summary		N/A	N/A	19-66	5-18	1.40 – 3.78	0-9.1

Measurements are expressed as median/mean, (IQR)/±SD.

Polymethylmethacrylate (PMMA)

Polymethylmethacrylate (PMMA) microspheres have been injected as a wrinkle filler. An average increase in penile circumference of 3.5 cm was reported in two studies using PMMA for penile girth enhancement [1304, 1305]. The authors reported that post-operative swelling and inflammatory reaction resolved within a few days and no pattern of PMMA microspheres migration to neighbouring regions was seen.

Poly-l-lactic acid

Poly-l-lactic acid (PLA) is another widely used soft tissue filler. Poly-l-lactic acid has enhanced effects by stimulating fibroblast proliferation and increasing collagen deposition in tissue. An average increase of 1.2 to 2.4 cm has been reported in the penile girth with PLA injection. No complications other than temporary local pain and swelling were reported in the treated patients [1298, 1306].

9.3.2.4.2.2 Other Fillers (silicone, paraffin)

Foreign body injections are still frequently practised in many countries (especially in East Asia and East Europe), either by the patient himself or by healthcare workers, using various substances such as paraffin, silicone or petroleum jelly (Vaseline), to increase the circumference of the penis [1307]. This results in a chronic granulomatous inflammatory foreign body reaction [1307, 1308]. The result of this practice is a pathological condition called sclerosing lipogranuloma of the penis also referred as paraffinoma or siliconoma according to the substance used [1307]. The resultant inflammatory process ranges from oedema and infection to Fournier's gangrene. Penile reconstructive surgeries may be required when siliconoma and paraffinoma require excision [1307-1313].

9.3.2.4.3 Surgical therapy

9.3.2.4.3.1 Autologous fat injection

This is a surgical technique based on thinning the lower abdomen with liposuction and injecting the harvested fat tissue into the penile shaft [1314-1317]. In retrospective studies, an average increase of 2 to 3.5 cm in penile circumference was reported in patients who underwent autologous fat injection. No statistically significant

decrease was observed in IIEF scores and no serious adverse events, such as penile abscess or deformity requiring reoperation occurred. Post-operative satisfaction survey showed that more than 75% of patients were satisfied (Table 30) [1280, 1314, 1315, 1318].

Table 30: Published data on the evaluation of autologous fat injection on penile girth enhancement

Author (year)	Year	n	Study design	Age (years)	Follow-up (months)	Girth gain (cm)	Complications, n (%)
Littara *et al.* [1280]	2019	334	Retrospective	36	12	2.76	49 (14.67)
Salem *et al.* [1318]	2019	15	Prospective	33 (23-45)	6	2-3.5	N/A

Measurements are expressed as median/mean, (IQR)/±SD.

9.3.2.4.3.2 Grafting procedures (albugineal and peri-cavernosal)
Until more rigorous multi-institutional studies reporting on complications and validated outcomes are known, penile girth enhancement procedures using grafts should be considered experimental (Table 31).

In a study of 69 patients using the porcine dermal acellular matrix graft (InteXen; American Medical Systems, Minnetonka, MN, USA) a 3.2 cm increase in flaccid state and 2.4 cm in erect state was reported at one year following surgery. The procedure was performed with an infrapubic incision, and 68 of 69 patients reported significant satisfaction using the Augmentation Phalloplasty Patient Selection and Satisfaction Inventory. Graft fibrosis has been observed in up to 13% of patients, and a mean reduction in penile length of 0.5 cm has been reported in patients with fibrosis [1319].

Techniques using venous grafts for penile girth enhancement have also been described [1320]. Initial results are encouraging, but better designed RCTs are needed.

Dermal fat grafts are free only grafts composed of deepithelialized dermis and subcutaneous fat. An area of approximately 10 x 5 cm is required for graft harvesting. An increase in penile girth of 1.67 to 2.3 cm has been reported in studies with the dermal fat graft technique. Penile oedema up to 27%, painful erection up to 27%, and curvature due to graft fibrosis up to 9% have been reported. Side effects such as penile hypoesthesia, skin necrosis, and infection were not reported [1250, 1321, 1322].

Table 31: Published data on evaluation of grafting techniques on penile girth enhancement

Author (year)	Year	n	Study design	Technique	Age, years	Follow up (months)	Girth gain (cm)	Complications, n (%)

Summary	N/A	N/A	N/A	N/A	18-68	6-48	0-4.9	0-44.44%

9.3.2.4.3.3 Biodegradable scaffolds

This is a technique based on using fibroblasts (harvested from patients' own scrotum skin and dartos tissue) in tissue cultures and seeding them in microporous biodegradable poly-lacti-co-glycolic acid (PLGA) scaffolds and implanting these scaffolds between Dartos and Buck's fascia. A limited number of studies have reported girth gain of up to 4.02 cm with implantation of biodegradable scaffolds [1326-1328] (Table 32).

Table 32: Published data on the evaluation of implantation of biodegradable scaffolds

Author	Year	n	Study design	Age (years)	Follow up (months)	Girth gain (cm)	Complications, n (%)
Djordjevic *et al.* [1326]	2018	21	Retrospective	28 (22-37)	38 (13-66)	Flaccid: 1.1 ± 0.4; Erect: 1±0.3	2 (9.52)
Jin *et al.* [1327]	2011	69	Multi-centre non-controlled	33±9.14	6	Flaccid: 4.01; Erect: 4.02	6 (8.69)
Perovic *et al.* [1328]	2006	84	Multi-centre prospective non-controlled	28.77±6.61	24.67	Flaccid: 3.35; Erect: 2.47	8 (9.52)
Summary	N/A	N/A	N/A	18-60	6-60	1-4.02	8.69-9.52%

9.3.2.4.3.4 Subcutaneous penile implant (Penuma®)

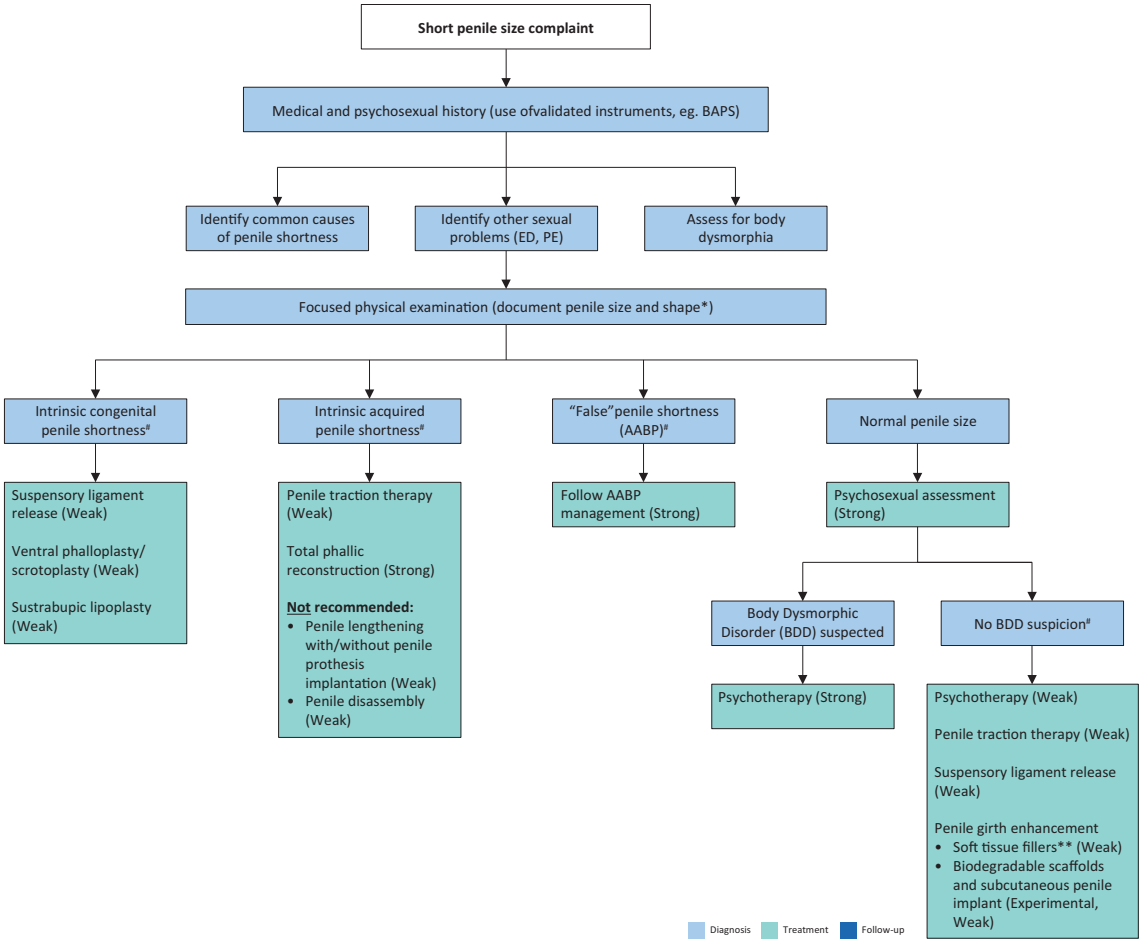
Recently, a silicone penile implant called "Penuma®" (International Medical Devices [Beverly Hills, CA, USA]) has been approved and has shown promising results for penile girth enhancement. Penuma® is a soft silicone subcutaneous implant placed on 3/4 of the penile shaft and fixed to the glans with a polyester mesh [1323]. Studies have reported an average increase in penile circumference of 2 to 5 cm with Penuma® insertion. According to published data complication rates (usually mild and transient, occur in <5%) and the removal rate (1%) of the implant has been reported to be relatively low [1323, 1329].

9.3.2.4.4 Summary of evidence and recommendations for penile girth enhancement

Summary of evidence	LE
Various surgical approaches with specific outcomes and complications have been considered to address penile girth enhancement, with limited benefit.	3
Hyaluronic acid (HA), Poly-l-lactic acid (PLA), hydroxyethyl methacrylate, polyacrylamide hydrogel (PAAG), polymethylmethacrylate (PMMA), calcium hydroxyapatite are used as injectable materials for penile girth enhancement.	3
Patient satisfaction with soft tissue fillers (especially HA, PMMA and PLA) is high (> 78%).	3
No complications other than temporary local pain and swelling were reported in patients treated with soft tissue fillers.	3
Using silicone, paraffin and petroleum jelly (Vaseline) in penile girth enhancement causes a range of complications ranging from oedema up to infection to Fournier's gangrene.	3
Not enough long term data are available on autologous fat injection for penile girth enhancement.	4
Not enough long term data are available on grafting procedures (dermal acellular matrix graft, venous grafts or dermal fat grafts).	4
Grafting procedures are associated with high complication rate and low rate of patient's satisfaction.	3
Not enough long term data are available on biodegradable scaffolds and subcutaneous penile implant (Penuma®) .	4

Recommendations	Strength rating
Counsel patients extensively regarding the risks and benefits of penile girth enhancement techniques.	Strong
Do not use silicone, paraffin and petroleum jelly (Vaseline) to address penile girth enhancement.	Strong
Use hyaluronic acid, soft tissue fillers and autologous fat injection to address penile girth enhancement.	Weak
Do not use hyaluronic acid, soft tissue fillers and autologous fat injection to address penile girth enhancement in men with penile dysmorphic disorder.	Weak
Do not use grafts in penile girth enhancement as they are considered experimental.	Strong
Do not use biodegradable scaffolds and subcutaneous penile implant (Penuma®) to address penile girth enhancement as experimental.	Strong

Figure 11: Management of short penile size



** Penile length should be measured stretched both from the penopubic skin junction-to-glans tip (STT) and from the pubic bone-to-glans tip (BTT).*

 # There is a lack of evidence to recommend one treatment over another.

***Hyaluronic acid (HA), poly-l-lactic acid (PLA), hydroxyethyl methacrylate, polymethylmethacrylate (PMMA), polyacrylamide hydrogel (PAAG) and calcium hydroxyapatite are considered as injectable materials for penile girth enhancement. Although the level of evidence is low, there is more evidence for HA, PLA and PMMA. Do not use silicone, paraffin or Vaseline (Strong evidence against).*

The strength of recommendations is depicted between brackets where appropriate.

9.3.2.5 Functional outcomes: sexual function, sensitivity, impact on quality of life and emotional adjustment

Cosmetic treatments, including surgery, help to restore self-esteem, reduce anxiety, social phobia, and depressive mood states regarding body concerns, and increase individuals' well-being and QoL [1123, 1124]. Therefore, we can expect men with genuine short penis to use available resources to adjust the length or girth of their penis as a mean to improve their sense of identity and fit cultural standards regarding penile size and function. Currently, the results of penile augmentation techniques seem mixed. The utilization of fillers led to enhanced genital self-image and self-esteem, as well as reduced symptoms of PDD. However, no effects were observed in terms of self-confidence or satisfaction with sexual relationship [1257]. Likewise, penile lengthening or girth enhancement surgery seem to result in poor satisfaction, poor erectile function and sensitivity in men with normal penis size [1134]. Despite those negative outcomes, cases of increased satisfaction have been registered [1330]. Male genital self-image has been related to IIEF domains: sexual desire, orgasmic and erectile function, intercourse and overall satisfaction [1247]. Similarly, perceived penis size seems to predict erectile function more than objective size [1130]. In addition, reduced penetrative and receptive oral sex is associated with men's dissatisfaction regarding their penis [1331]. For these reasons, more efforts should be made in order to clarify the impact of penile augmentation treatments on men's and partners' well-being and QoL. As for men with BDD, they have shown reduced erectile and orgasmic function, as well as less intercourse satisfaction as compared with controls, while men with SPA revealed reduced satisfaction. Sexual desire seemed untouched in BDD and SPA cases [1257, 1332].

9.3.2.6 Final remarks

The complaint of "short penis" is variable in presentation and aetiology. Some patients demonstrate anatomical and pathological conditions while others do not. A vast array of treatments for different aetiologies of "short penis," both surgical and non-surgical, have been reviewed. If psychopathological symptoms are detected, the patient must be referred for further medical diagnosis. Treatment for short-penis syndrome requires a multi-disciplinary approach, including medical and ethical considerations, and the majority of reported outcomes are based on a paucity of evidence.

10. PRIAPISM

Priapism is a persistent or prolonged erection in the absence of sexual stimulation that fails to subside. It can be divided into ischaemic, non-ischaemic and stuttering priapism. The guidelines are based on three systematic reviews addressing the medical and surgical management of ischaemic and non-ischaemic priapism and the overall management of priapism related to sickle cell disease [1333-1335].

10.1 Ischaemic (Low-Flow or Veno-Occlusive) Priapism

10.1.1 Epidemiology, aetiology, pathophysiology and Diagnosis

Ischaemic priapism is a persistent erection marked by rigidity of the corpora cavernosa and by little or no cavernous arterial inflow [1336]. Ischaemic priapism is the most common subtype of priapism, accounting for > 95% of all episodes [1336, 1337]. In ischaemic priapism, there are time-dependent metabolic alterations within the corpus cavernosum progressively leading to hypoxia, hypercapnia, glucopenia and acidosis [1338, 1339].

Ischaemic priapism that lasts beyond 4 hours is similar to a compartment syndrome and characterised by the development of ischaemia within the closed space of the corpora cavernosa, which severely compromises the cavernosal circulation. Emergency medical intervention is required to minimise irreversible consequences, such as smooth muscle necrosis, corporal fibrosis and the development of permanent erectile dysfunction (ED) [1340, 1341]. The duration of ischaemic priapism represents the most significant predictor for irreversible consequences, thus including ED. In this context, interventions beyond 48-72 hours of onset may help to relieve the erection and pain, but have little clinical benefit in preventing long-term ED [1342].

No specific pathophysiological causes of ischaemic priapism can be identified in most cases [1336, 1343], although the common aetiological factors include sickle cell disease (SCD), haematological dyscrasias, neoplastic syndromes, and several pharmacological agents (e.g., intracavernosal PGE1 therapy) (Table 33). Ischaemic priapism may occur (0.4-35%) after intracavernosal injection of erectogenic agents [1336, 1340, 1344-1346]. The risk is higher with papaverine-based combinations [1347], while the risk of priapism is < 1% following prostaglandin E1 injection [1348].

Second-generation antipsychotics (33.8%), other medications (11.3%), and alpha-adrenergic antagonists (8.8%) accounted for the greatest percentage of published drug-induced priapism cases [1349]. Isolated cases of priapism have been described in men who have taken PDE5Is [1336]. Data from the FDA Adverse Reporting System Public Dashboard showed that PDE5Is-induced priapism accounted for only 2.9% of drug-induced priapism. However, most of these men also had other risk factors for priapism, and it is unclear whether PDE5Is *per se* can cause ischaemic priapism [1336, 1350]. Since most men who experience priapism following PDE5I treatment have additional risk factors for ischaemic priapism, PDE5Is use is usually not regarded as a risk factor in itself. In terms of haemoglobinopathies, SCD is the most common cause of priapism in childhood, accounting for 63% of cases. It is the primary aetiology in 23% of adult cases [1348].

Mechanisms of SCD-associated priapism may involve derangements of several signalling pathways in the penis [1351]. Contrary to traditional belief, maintenance of physiological testosterone levels does not cause priapism, but rather preserves penile homeostasis and promotes normal erectile function [1352, 1353]. Testosterone deficiency is considered a controversial risk factor: it is prevalent in patients with SCD, but recent evidence indicates that it may not be a risk factor for priapism [1354].

Priapism resulting from metastatic or regional infiltration by tumour is rare and usually reflects an infiltrative process, more often involving the bladder and prostate as the primary cancer sites [1355]. In a large retrospective study including 412 men with ischaemic priapism, eleven (3.5%) had malignant priapism, of which seven cases were a consequence of local invasion while the others were secondary to haematological malignancy [1356]. The conventional therapeutic recommendations for pharmacological treatment are unlikely to be effective and all of these men should have MRI of the penis and be offered supportive care and medical intervention for their primary cancer. In selected cases where palliative treatment options fail to control penile pain, a palliative penectomy can be considered.

Partial priapism, or idiopathic partial segmental thrombosis of the corpus cavemosum, is a rare condition. It is often classified as a subtype of priapism limited to a single crura without ischaemia, but rather a thrombus is present within the corpus cavernosum. Its aetiology is unknown, but bicycle riding, trauma, drug use, sexual intercourse, haematological diseases and α-blocker intake have all been associated with partial segmental thrombosis [1357]. The presence of a congenital web within the corpora is also a risk factor [1358].

Table 33: Aetiological factors for the development of priapism

Idiopathic
-
Haematological dyscrasias, vascular and other disorders
• SCD • thalassemia • leukaemia • multiple myeloma • haemoglobin Olmsted variant • fat emboli during hyperalimentation • haemodialysis • glucose-6-phosphate dehydrogenase deficiency • factor V Leiden mutation • vessel vasculitis • (e.g., Henoch-Schönlein purpura; Behçet's disease; anti-phospholipid antibodies syndrome)
Infections (toxin-mediated)
• scorpion sting • spider bite • rabies
Metabolic disorders
• amyloidosis • Fabry's disease • gout

Neurogenic disorders
• syphilis • spinal cord injury • cauda equina • syndrome • autonomic neuropathy • lumbar disc herniation • spinal stenosis • cerebrovascular accident • brain tumour • spinal anaesthesia
Neoplasms (metastatic or regional infiltration)
• prostate • urethra • testis • bladder • rectal • lung, kidney
Medications
• Vasoactive erectile agents (i.e., papaverine, phentolamine, prostaglandin E1/alprostadil, combination of intracavernous therapies) • α-adrenergic receptor antagonists (i.e., prazosin, terazosin, doxazosin and tamsulosin) • Anti-anxiety agents (hydroxyzine) • Anticoagulants (heparin and warfarin) • Antidepressants and antipsychotics (i.e., trazodone, bupropion, fluoxetine, sertraline, lithium, clozapine, risperidone, olanzapine, chlorpromazine, thioridazine, phenothiazines and methylphenidate) • Antihypertensives (i.e., hydralazine, guanethidine and propranolol) • Hormones (i.e., gonadotropin-releasing hormone and testosterone) • Recreational drugs (i.e., alcohol, marijuana, cocaine [intranasal and topical], and crack, cocaine)

10.1.1.1 Summary of evidence on the epidemiology, aetiology and pathophysiology of ischaemic priapism

Summary of evidence	LE
Ischaemic priapism is the most common type, accounting for more than 95% of all cases.	1b
Ischaemic priapism is identified as idiopathic in most patients, while sickle cell disease is the most common cause in childhood.	1b
Ischaemic priapism occurs relatively often (about 5%) after intracavernous injections of papaverine-based combinations, while it is rare (< 1%) after prostaglandin E1 monotherapy.	2a
Priapism is rare in men who have taken Phosphodiesterase Type 5 Inhibitors, with only sporadic cases reported.	4

10.1.2 ***Diagnostic evaluation***

10.1.2.1 History

Taking a comprehensive history is critical in priapism diagnosis and treatment [1336, 1359]. The medical history must specifically enquire about SCD or any other haematological abnormality [1360, 1361] and a history of pelvic, genital or perineal trauma. The sexual history must include the duration of the erection; the presence and degree of pain; prior drug treatment and recreational drug use; history of priapism and methods of treatment; and erectile function prior to the last priapism episode [1336]. The history can help to determine the underlying priapism subtype (Table 34). Ischaemic priapism is classically associated with progressive penile pain and the erection is rigid. Conversely, non-ischaemic priapism is often painless and the erections often fluctuate in rigidity.

Table 34: Key findings in priapism (adapted from Broderick *et al.* [1336])

	Ischaemic priapism	Non-ischaemic priapism
Corpora cavernosa fully rigid	Typically	Seldom
Penile pain	Typically	Seldom
Abnormal penile blood gas	Typically	Seldom
Haematological abnormalities	Sometimes	Seldom
Recent intracavernosal injection	Sometimes	Sometimes
Perineal trauma	Seldom	Typically

10.1.2.2 Physical examination

In ischaemic priapism, the corpora are fully rigid and tender, but the glans penis is soft. The patient usually complains of severe pain. Pelvic examination may reveal an underlying pelvic or genitourinary malignancy [1356].

10.1.2.3 Laboratory testing

Laboratory testing should include a complete blood count, white blood cell count with blood cell differential, platelet count and coagulation profile to assess anaemia and detect haematological abnormalities [1336, 1359].

Aspiration of blood from the corpora cavernosa is compulsory as an entry level investigation. It usually reveals dark ischaemic blood. Blood gas analysis is essential to differentiate between ischaemic and non-ischaemic priapism (Table 34). Further laboratory testing should be directed by the history, clinical examination and laboratory findings. These may include specific tests (e.g., haemoglobin electrophoresis) for diagnosis of SCD or other haemoglobinopathies.

10.1.2.4 Penile imaging

Colour Doppler US of the penis and perineum is recommended after clinical diagnosis and can differentiate ischaemic from non-ischaemic priapism as an alternative or adjunct to blood gas analysis (Figure 12) [1362-1365]. Colour Doppler US can identify the presence of the fistula as a blush with 100% sensitivity and 73% specificity [1364].

Ultrasound of the penis should be performed before corporal blood aspiration in ischaemic priapism to prevent aberrant blood flow which can mimic a non-ischaemic or reperfusion picture after intervention for low-flow priapism [1366].

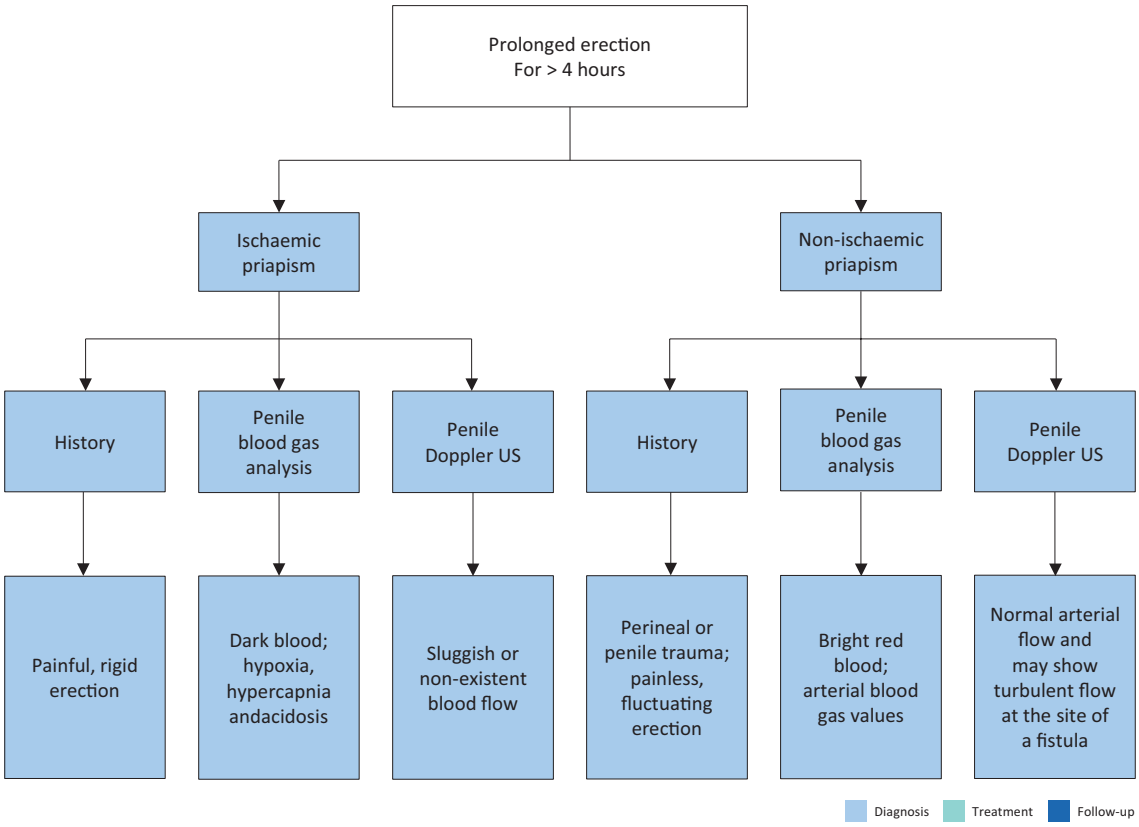
Penile MRI can be used in the diagnostic evaluation of priapism and may be helpful in selected cases of ischaemic priapism to assess the viability of the corpora cavernosa and the presence of penile fibrosis. In cases of refractory priapism or delayed presentation (> 48 hours), smooth muscle viability can be indirectly assessed. In a prospective study of 38 patients with ischaemic priapism, the sensitivity of MRI in predicting non-viable smooth muscle was 100%, when correlated with corpus cavernosum biopsies [1366]. All patients with viable smooth muscle on MRI maintained erectile function on clinical follow-up with the non-viable group being offered early prosthesis.

Table 34: Typical blood gas values (adapted from Broderick *et al.* [1336])

Source	pO_2 (mmHg)	pCO_2 (mmHg)	pH
Normal arterial blood (room air) (similar values are found in arterial priapism)	> 90	< 40	7.40
Normal mixed venous blood (room air)	40	50	7.35
Ischaemic priapism (first corporal aspirate)	< 30	> 60	< 7.25

pCO_2 partial pressure of carbon dioxide; pO_2 partial pressure of oxygen

Figure 12: Differential diagnosis of priapism



10.1.2.5 Summary of evidence and recommendations for the diagnosis of ischaemic priapism

Summary of evidence	LE
Medical history including the assessment of known haematological abnormalities (e.g., SCD), history of pelvic/perineal/genital trauma, prior drug treatment or recreational drug use is essential to identify the possible a etiology and the type of priapism	3
Blood gas analysis performed before blood aspiration from the corpora can differentiate between ischaemic and non-ischaemic priapism. A full blood count and haemoglobinopathy screen could reveal haematological alterations.	3
Penile Colour Doppler US can differentiate from ischaemic and non-ischaemic priapism when performed before corporal blood aspiration.	3
Penile MRI can predict non-viable smooth muscle in patients with ischaemic priapism.	3

Recommendations	Strength rating
Take a comprehensive history to establish the diagnosis which can help to determine the priapism subtype.	Strong
Include a physical examination of the genitalia, perineum and abdomen in the diagnostic evaluation.	Strong
Include a full blood count, white blood cell count with blood cell differential, platelet count and coagulation profile. Directed further laboratory testing should be performed depending upon the history and clinical and laboratory findings. In children with priapism, perform a complete evaluation of all possible causes.	Strong
Perform a haemoglobinopathy screen in patients with low flow priapism who are at high risk of sickle cell disease or thalassemia.	Strong
Analyse the blood gas parameters from blood aspirated from the penis to differentiate between ischaemic and non-ischaemic priapism.	Strong

Perform colour duplex ultrasound of the penis and perineum before aspiration to differentiate between ischaemic and non-ischaemic priapism.	Strong
Use magnetic resonance imaging of the penis in cases of prolonged ischaemic priapism or refractory priapism, as an adjunct to predict smooth muscle viability.	Weak

10.1.3 ***Disease management***

Acute ischaemic priapism is a medical emergency. Urgent intervention is mandatory and should follow a stepwise approach. The aim of any treatment is to restore penile detumescence, without pain, in order to prevent corporal smooth muscle fibrosis and subsequent ED.

10.1.3.1 Medical Management – first-line treatment

First-line medical treatments for ischaemic priapism of more than 4 hours duration are strongly recommended before any surgical treatment. Conversely, first-line treatments initiated beyond 48 hours, while relieving priapism, have little documented benefit in terms of long-term erectile function preservation. This is likely to be the consequence of irreversible smooth muscle hypoxia and damage that begins to be established by approximately 48 hours of the onset of ischaemia [1340-1342]. It has been shown in a series of 50 patients with low-flow priapism who were successfully treated and followed-up for a mean of 66 months, that those with priapism lasting for more than 48 hours had a significant risk of ED [1340].

Historically, several first-line treatments have been described including exercise, ejaculation, ice packs, cold baths, and cold water enemas [1336]. However, there is limited evidence for the benefit of these measures and they may even exacerbate the condition in SCD patients. Success rates for these conservative measures alone have rarely been reported. In a small series, cold water enemas have been reported to induce detumescence in six out of ten cases [1367]. In another study 24.5% of 122 patients achieved detumescence following priapic episodes lasting for more than 6 hours by cooling of the penis and perineum, and walking upstairs [1368].

10.1.3.1.1 Penile anaesthesia/analgesia

Blood aspiration and intracavernous injection of a sympathomimetic agent can be performed without any anaesthesia; however, anaesthesia may be necessary when there is severe penile pain. Whilst anaesthesia may not alleviate the ischaemic pain, cutaneous anaesthesia facilitates subsequent therapies. The treatment options for penile anaesthesia/systemic analgesia include:

- dorsal nerve block;
- circumferential penile block;
- subcutaneous local penile shaft block;
- oral conscious sedation (for paediatric patients).

10.1.3.1.2 Aspiration ± irrigation with 0.9% w/v saline solution

The first intervention for an episode of priapism lasting more than 4 hours consists of corporal blood aspiration to drain the stagnant blood from the corporal bodies, making it possible to relieve the compartment-syndrome-like condition within the corpus cavernosum. Blood aspiration may be performed with intracorporeal access either through the glans or via percutaneous needle access to the lateral aspect of the proximal penile shaft, using a 16 or 18 G angio-catheter or butterfly needle. The needle must penetrate the skin, the subcutaneous tissue and the tunica albuginea to drain blood from the corpus cavernosum .

Some clinicians advocate using two angiocatheters or butterfly needles at the same time to accelerate drainage, as well as aspirating and irrigating simultaneously with a saline solution [1368]. Aspiration should be continued until bright red, oxygenated blood is aspirated.

Several case series have reported outcomes for first-line treatments; however, in most cases, aspiration and irrigation were combined with intracavernosal injection of sympathomimetic agents [1334], thus making it difficult to draw conclude the success rate of aspiration + irrigation
alone [1334]. Overall, case series and retrospective studies reported a success rate ranging from 0 to 100% of cases [1334]. In an RCT, 70 patients with ischaemic priapism lasting more than 6 hours secondary to intracavernosal injection were treated with aspiration plus saline irrigation at different temperatures [1368]. The study reported an 85% success rate with the optimum results achieved using a 10°C saline infusion after blood aspiration.

There is insufficient data to determine whether aspiration followed by saline intracorporeal irrigation is more effective than aspiration alone.

10.1.3.1.3 Aspiration ± irrigation with 0.9% w/v saline solution in combination with intracavernous injection of pharmacological agents.

This combination is currently considered the standard of care for the treatment of ischaemic priapism [1336, 1369, 1370]. Pharmacological agents include sympathomimetic drugs or α-adrenergic agonists. Intracavernous sympathomimetic agents include phenylephrine, etilephrine, ephedrine, epinephrine, norepinephrine and metaraminol with a resolution rate of up to 80% [1336, 1369, 1371-1378]. The use of intracavernous adrenaline injection alone has also been sporadically reported [1379]. It has been reported that the use of a sympathomimetic agent combined with prior intracavernosal aspiration or irrigation had a resolution ranging from 80 to 100% of cases as compared with 58% in those who had a sympathomimetic injection alone [1334, 1370].

The potential treatment-related adverse effects of intracavernous phenylephrine (and other sympathomimetic agents) include headache, dizziness, hypertension, reflex bradycardia, tachycardia and palpitations and sporadic subarachnoid haemorrhage [347]. Monitoring of blood pressure and pulse should be performed during intracavernous administration of sympathomimetic agents. As intracavernous sympathomimetic agents can cause hypertension, the Guidelines Panel is of the opinion that these agents are contraindicated in patients with malignant or poorly controlled hypertension, as there are case reports of significant cardiovascular and neurological complications following the use of these pharmacological agents for priapism [1372, 1380, 1381]. Similarly, data suggest that sympathomimetic agents cause a hypertensive crisis when given with monoamine oxidase inhibitors, hence these medications should not be used together [1382].

10.1.3.1.4 Intracavernosal and oral pharmacological agents

Pharmacological agents for the treatment of priapism are discussed in more detail in the following section. Table 35 summarises dosing and administration of these agents.

- *Phenylephrine*

Phenylephrine is a selective α-1-adrenergic receptor agonist that has been observed in small case series to be effective at producing detumescence in priapism, when given as an intracavernosal injection, with few adverse effects [1377, 1383]. Phenylephrine is the recommended adrenergic agonist drug of choice due to its high selectivity for the α-1-adrenergic receptor, without concomitant β-mediated inotropic and chronotropic cardiac effects [1371, 1375, 1376].

Phenylephrine has potential cardiovascular adverse effects [1336, 1369, 1371, 1372, 1375, 1376] and it is recommended that blood pressure and pulse are monitored every fifteen minutes for one hour after injection. This is particularly important in older men with pre-existing cardiovascular diseases. After injection, the puncture site should be compressed and the corpus cavernosum massaged to facilitate drug distribution.

- *Etilephrine*

Etilephrine is also an adrenergic agonist that directly stimulates both α and β adrenergic receptors [1370]. Most of the literature describing the use of etilephrine for treatment of priapism is related to men with SCD but there are small retrospective case series that have reported its benefits for priapism secondary to iatrogenic causes [1384, 1385]. Etilephrine is the second most widely used sympathomimetic agent [1372].

- *Methylene blue*

Methylene blue is a guanylate cyclase inhibitor, that may be a potential inhibitor of endothelial-mediated cavernous smooth muscle relaxation. Small retrospective case series have reported its successful use for treating short-term pharmacologically-induced priapism [1386, 1387]. Treatment-related adverse effects include a transient burning sensation and blue discolouration of the penis.

- *Adrenaline*

Adrenaline produces both α-adrenergic receptor agonist and β-adrenergic receptor activity. Intracavernosal adrenaline has been used in patients with ischaemic priapism due to an intracavernous injection of vasoactive agents. The limited literature [1379, 1388] suggests that adrenaline can achieve detumescence in short-term priapism, with one small case series reporting a success rate of over 50% after a single injection, with an overall success rate of 95% with repeated injections [1379, 1388].

- *β-2-agonists*

Oral terbutaline is a β-2-agonist with minor β-1 effects and some α-agonist activity; although its mechanism of action is not yet fully understood [1389-1391]. The main use of terbutaline is for prevention of recurrent episodes of prolonged erection. Oral treatment with terbutaline was tested in three placebo-controlled RCTs

[1390-1392] showing a success rate of 30 to 60% in patients with ischemic priapism associated with intracavernous injection of erectogenic agents. Terbutaline should be given cautiously in patients with coronary artery disease, increased intravascular fluid volume, oedema or hypokalaemia [1391]. In a single multi-centre prospective study, another β-2-agonist, salbutamol, has been reported to induce detumescence in 34% of cases of prolonged erection (more than three hours) after intracavernous injection of erectogenic agents [1393]. However, more robust data are needed to recommend oral salbutamol for the treatment of ischaemic priapism.

Table 35: Medical treatment of ischaemic priapism

Drug	Dose/Instructions for use
Phenylephrine	• Intracavernous injection of 200 µg every 3-5 minutes. • Maximum dosage is 1 mg within 1 hour. • Lower doses are recommended in children and patients with severe cardiovascular diseases.
Etilephrine	• Intracavernosal injection at a concentration of 2.5 mg in 1-2 mL normal saline.
Methylene blue	• Intracavernous injection of 50-100 mg, left for 5 minutes. It is then aspirated and the penis is compressed for an additional 5 minutes.
Adrenaline	• Intracavernous injection of 2 mL of 1/100,000 adrenaline solution up to five times over 20 minutes.
Terbutaline	• Oral administration of 5 mg for priapism lasting more than 2.5 hours, after intracavernous injection of vasoactive agents.

10.1.3.1.5 Management of priapism related to sickle cell disease

The results of a systematic review on the overall management of priapism related to SCD found that few studies were conducted exclusively on patients with SCD and studies on mixed populations usually did not report separate data on SCD patients [1335]. Clear and systematic reporting of patient characteristics, interventions and outcomes was lacking, and the length of follow-up, if reported, varied significantly among the studies. Overall, the quality of studies was deemed poor to allow high-quality, evidence-based recommendations to be made.

Urgent intervention is essential and the general approach is similar to that described for other cases of ischaemic priapism and should be co-ordinated with a haematologist [1394-1396].

However, as with other haematological disorders, other therapeutic interventions may also need to be implemented [1394, 1396, 1397]. Specific measures for SCD-related priapism include intravenous hydration and narcotic analgesia while preparing the patient for aspiration and irrigation. Additionally, supplemental oxygen administration and alkalinisation with bicarbonate can be helpful [1395].

Haemoglobin S (HbS) percentage should be measured in all SCD patients with acute priapism. Exchange blood transfusion has also been proposed, with the aim of increasing tissue delivery of oxygen [1398]. The transfused blood should be sickle cell haemoglobin negative and Rh and Kell antigen matched [1399]; however, the evidence is inconclusive as to whether exchange transfusion itself helps to resolve priapism. A systematic review reported that the mean time to detumescence was eleven days with exchange transfusions compared to eight days with conventional treatment. Moreover, there were nine cases of ASPEN syndrome (association of SCD, priapism, exchange transfusion and neurological events) as a consequence of blood transfusion [1400].

A series of ten patients with SCD-related priapism showed that it was safe to perform exchange transfusion [1398]; however, several reports suggest that exchange transfusion may result in serious neurological sequelae [1400]. Therefore, routine use of exchange transfusion is not recommended as a primary treatment intervention in this group unless there is a risk of SCD-related symptoms. However, in patients who failed medical management, transfusion may be required to enable general anaesthesia to be safely administered prior to definitive surgery [1401].

10.1.3.2 Surgical management- second-line treatments

Second-line intervention typically refers to surgical intervention in the form of penile shunt surgery and penile implant insertion for refractory or delayed ischaemic priapism, and should only be considered when other medical management options have failed. There is no evidence detailing the time frames before moving

on to surgery after first-line treatment, although a period of at least 1 hour of first-line treatment without detumescence can be considered prior to moving to surgical intervention.

A number of clinical indicators suggest failure of first-line treatment including continuing corporal rigidity, cavernosal acidosis, anoxia, severe glucopenia, absence of cavernosal artery inflow by penile colour duplex US, and elevated intracorporal pressure [1402].

10.1.3.2.1 Penile shunt surgery

Penile shunt surgery aims to produce an outflow for ischaemic blood from the corpus cavernosum into the corpus spongiosal tissues, thereby allowing restoration of normal circulation within these structures. Accordingly, a shunt creates an opening in the tunica albuginea, with either the glans, corpus spongiosum, or a vein for blood drainage (Table 50) [1336, 1369, 1403].

The type of shunt procedure is chosen according to the surgeon's preference and familiarity with the procedure. It is conventional practice for distal shunt procedures to be tried before considering proximal shunting.

It is important to assess the success of surgery by direct observation of penile rigidity or by repeated testing (e.g., cavernous blood gas testing) [1336, 1369, 1404, 1405]. The use of penile colour US may not give appropriate information because of the hyperaemic (reperfusion) period that follows decompression after the ischaemic state [1406].

The recovery rates of erectile function in men undergoing shunt surgery following prolonged episodes of priapism are low and are directly related to the duration of priapism, pre-operative erectile status and age [1404, 1405, 1407]. If ischaemic priapism resolves within 24 hours of onset, it has been reported that 78-100% of patients regain spontaneous functional erections (with or without PDE5Is use). In contrast, other studies have shown that priapism for more than 36-48 hours appears to result in both structural and functional effects on corporal smooth muscle, with poorer outcomes (ED > 90%) [1404]. In general, shunt procedures undertaken after this period (36-48 hours) may only serve to limit pain without any beneficial effects on erectile function and early penile prosthesis insertion can be considered [1342, 1409].

Procedures for shunting require incision through the tunica albuginea and expose collagen to coagulation factors in the penile blood and thus activate the blood-clotting cascade. Peri-operative anti-coagulation is advocated to facilitate resolution of the priapism. There was an 84% decrease in priapism recurrence in the shunt group that received peri-procedural anti-thrombotic treatment (325 mg acetylsalicylic acid pre-operatively, and 5000 IU intraoperative heparin, 81 mg acetylsalicylic acid and 75 mg clopidogrel post-operatively for 5 days) compared with the group that did not receive peri-procedural anti-thrombotic treatment after failed aspiration [1410].

Four categories of shunt procedures have been reported [1336, 1370, 1403, 1409]. The limited data available does not allow one procedure to be recommended over another. However, distal shunts are less invasive and associated with lower rates of post-operative ED and therefore are recommended as the first surgical intervention of choice (Appendix 6 Table 10.1).

- *Percutaneous distal (corpora-glanular) shunts*

Winter's procedure uses a Trucut biopsy needle to create a fistula between the glans penis and each corpus cavernosum [1336, 1348, 1370, 1406, 1411]. Post-operative sequelae are uncommon [1412]. Winter's shunt is easy to perform, but has been reported as the least successful operation to create a distal shunt [1405]. This is because the diameter of the Trucut needle is only 1.6 mm (14-18 g) and therefore cannot accommodate the increased blood flow from post-ischaemic hyperaemia, resulting in poor drainage, increased intracavernous pressure and consequent premature closure of the shunt [1406].

Ebbehoj's technique involves making multiple tunical incision windows between the glans and each tip of the corpus cavernosum by means of a size 11 blade scalpel passed several times percutaneously [1336, 1370, 1406, 1413, 1414].

T-Shunt involves performing a bilateral procedure using a scalpel with a size 10 blade inserted through the glans just lateral to the urethral meatus until it enters the tip of the corpus cavernosum. The blade is then rotated 90° away (to the lateral side) from the urethral meatus and withdrawn [1336, 1370, 1406, 1415] (LE: 3). If unsuccessful, the procedure is repeated on the opposite side. The T-shunt can be followed by a tunnelling procedure using a size 8/10 Hegar dilator inserted through the glans and into the corpus cavernosum, which

can also be performed using US guidance, mainly to avoid urethral injury [1415]. The entry sites in the glans are sutured following detumescence. Tunnelling with a 7 mm metal sound or 7/8 Hegar dilator is necessary in patients with priapism duration > 48 hours. Tunnelling is a potentially attractive procedure as it combines the features of distal and proximal shunts with proximal drainage of the corpus cavernosum and may ameliorate the profibrotic effect of sludged blood retained in the corpus cavernosum [1407, 1409, 1415].

- *Open distal (corpora-glanular) shunts*

Al-Ghorab's procedure consists of an open bilateral excision of circular cone segments of the distal tunica albuginea via the glans penis, along with subsequent glans closure by running suture with absorbable material. A transverse incision on the glans may compromise arterial blood flow because distal deep dorsal arteries run longitudinally in the glans [1336, 1370, 1406, 1416-1418].

Burnett's technique (Snake manoeuvre) is a modification of the Al-Ghorab corpora-glanular shunt. It involves retrograde insertion of a 7/8 Hegar dilator into the distal end of each corpus cavernosum through the original Al-Ghorab glandular excision. After removal of the dilator from the corpus cavernosum, blood evacuation is facilitated by manual compression of the penis sequentially from a proximal to distal direction. After detumescence, the glans penis is closed as in the Al-Ghorab procedure [1336, 1370, 1406, 1419, 1420]. Reported complications include wound infection, penile skin necrosis and urethrocutaneous fistulae [1420].

- *Open proximal (corpora-spongiosal) shunts*

Quackles's technique uses a trans-scrotal or perineal approach; a proximal open shunt technique creates a communication between the corpus cavernosum and the corpus spongiosum. The most frequent complications include an unwanted urethro-cavernous fistula and urethral stricture or cavernositis [1336, 1370, 1403, 1421]. The risk of urethral injury is less with a perineal approach to the bulb of the corpus spongiosum. Proximal shunts are more invasive and ED rates are documented to be higher [1402].

- *Peno-scrotal decompression*

More recently a proximal decompression technique with the aim to spare the glans with high success rates has been described. The technique is based upon opening of the proximal corpus cavernosum combined with proximal and distal tunnelling using a suction tip [1422]. In a cohort of 25 patients, 12 had undergone previous corpora-glanular shunt surgery. Recurrence was observed in two of 25 patients with unilateral peno-scrotal decompression. In the 15 patients who had follow-up data, 40% had ED. Whilst, representing a promising technique, PSD in cases of refractory priapism may further delay penile prosthesis insertion with detrimental effects on surgical outcomes including penile shortening and prosthetic infection.

- *Vein anastomoses/shunts*

Grayhack's procedure mobilises the saphenous vein below the junction of the femoral vein and anastomoses the vein end-to-side onto the corpus cavernosum. Venous shunts may be complicated by saphenofemoral thrombus formation and by pulmonary embolism [1336, 1370, 1423-1425].

10.1.3.2.2 Immediate penile prosthesis implantation

The studies pertaining to penile implantation surgery are principally retrospective non-randomised case series (Appendix 9 online supplementary evidence). All of the studies described priapism resolution rate, sexual function and surgical adverse events although the follow-up period was variable [1333].

Refractory, therapy-resistant, acute ischaemic priapism or episodes lasting more than 48 hours usually result in complete ED, and possibly significant penile deformity in the long-term. In these cases, immediate penile prosthesis implantation surgery is advocated [1426, 1427, 1429].

Gadolinium-enhanced penile MRI [1366] and cavernosal smooth muscle biopsy have been used to diagnose smooth muscle necrosis (which, if present, would suggest that shunting is likely to fail) and may help in decision-making and patient counselling in cases of refractory or delayed presentation (> 48 hours) that may be considered for immediate penile prosthesis insertion.

Early implantation of a penile prosthesis is associated with lower infection rates (6-7% vs. 19-30%), penile shortening (3% vs. 40%) and revision rates (9% vs. 27%) compared to late insertion. General satisfaction rate for early implantation is higher (96%) than for late implantation (60%) [1342] (Appendix 10 online supplementary evidence). Potential complications that could compromise immediate penile prosthesis implantation include distal erosion and infection [1426, 1428], along with a small rate of revision surgery [1426]. Early surgery also offers the opportunity to maintain penile length and girth and prevent penile curvature due to cavernosal

fibrosis. The prosthesis can be exchanged for an inflatable prosthesis at a later date, which may allow upsizing of the implant cylinders [1430].

The decision on which type of implant to insert is dependent on patient suitability, surgeons' experience, and availability and cost of the equipment. The immediate insertion of a malleable penile prosthesis is recommended to avoid the difficulty and complications of delayed prosthetic surgery in the presence of corporal fibrosis.

There are no randomised trials comparing the efficacy and complication rates of malleable and inflatable penile prostheses. Despite the higher infection rate in priapism patients compared to those with virgin prosthesis, in patients who are well-motivated and counselled prior to the procedure, immediate inflatable penile prosthesis implantation may be undertaken, although in most cases a semi-rigid implant is more suitable as it is easier to implant and reduces operative time and hence the risk of prosthetic infection. A further issue with immediate insertion of an inflatable penile prosthesis is that the patient must begin cycling the device immediately to avoid a fibrous capsule forming and contracting. Early cycling of an inflatable penile prosthesis prevents penile curvature and shortening [1342].

Currently, there are no clear indications for immediately implanting a penile prosthesis in men with acute ischaemic priapism, although this can be considered in men with delayed or refractory priapism [1369].

Relative indications include [1336]:

- Ischaemia that has been present for more than 48 hours.
- Failure of aspiration and sympathomimetic intracavernous injections in delayed priapism (> 48 hours).
- Magnetic resonance imaging or corporal biopsy evidence of corporal smooth muscle necrosis [1336, 1426].
- Failure of a shunting procedure; although, in delayed cases (> 48 hours), implantation might be considered ahead of shunt surgery.
- Refractory priapism in patients who have undergone shunting procedures.

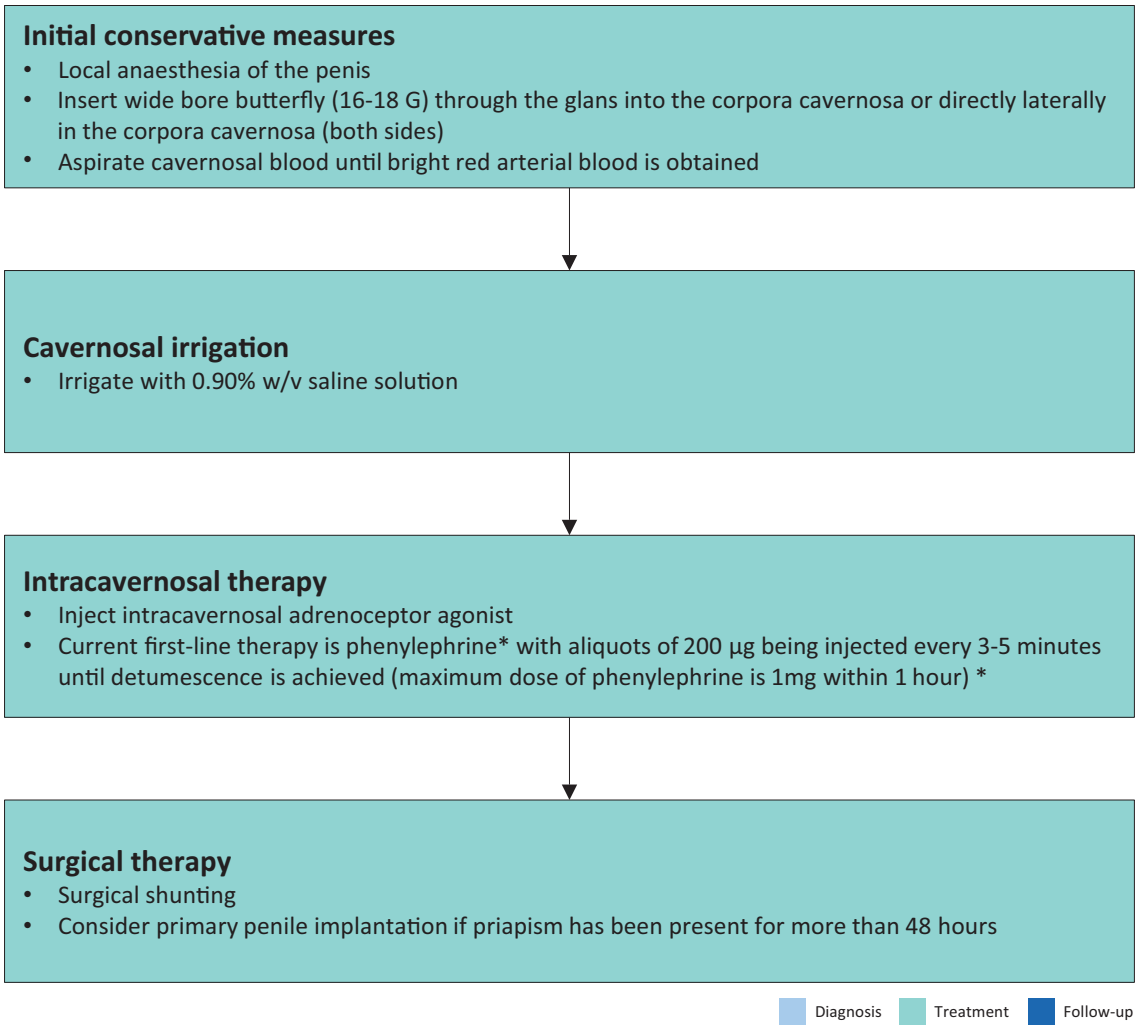
The optimal time for implantation is within the first three weeks from the priapism episode [1342, 1402, 1431]. If shunt surgery has been performed, penile prosthesis implantation can be further delayed in order to allow reduction of oedema, wound healing and risk of prosthetic infection. A vacuum device to avoid fibrosis and penile shortening may be used during this waiting period [1432].

10.1.3.2.3 Surgery for non-acute sequelae after ischaemic priapism

Structural changes may occur after ischaemic priapism including cavernosal tissue necrosis and fibrosis with consequent penile scarring, megalophallic deformities, penile shortening, and occasional penile loss [1403, 1426, 1433, 1434]. Erectile dysfunction is also often observed [1336, 1435]. Unfortunately, these outcomes can still occur despite apparently successful first or second-line treatment in detumescence of the penis.

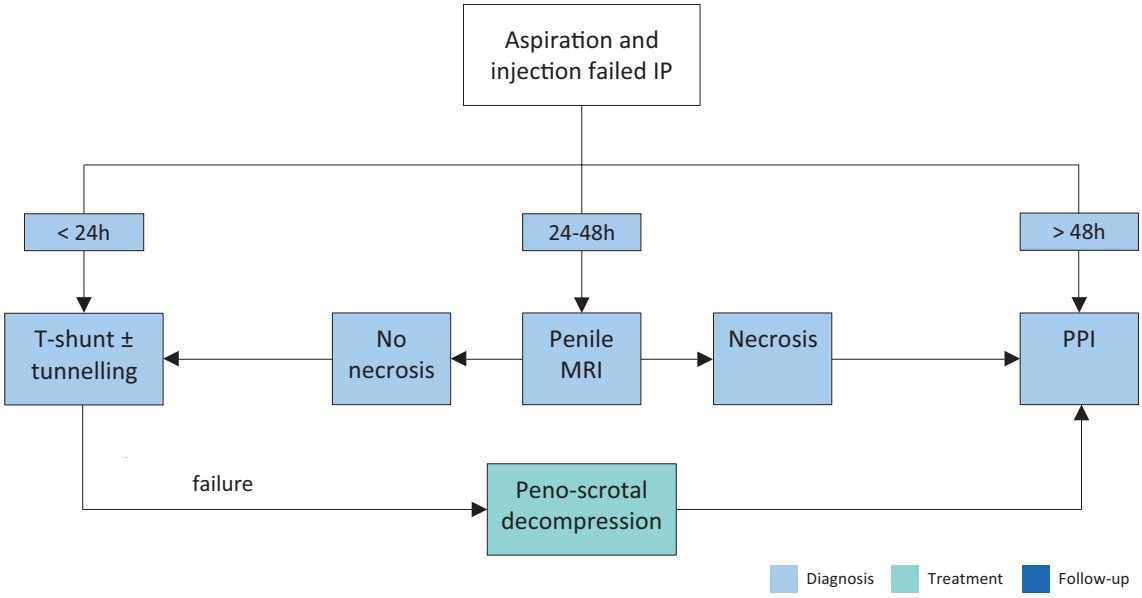
Penile prosthesis implantation is occasionally indicated in SCD patients with severe ED because other therapeutic options, such as PDE5Is and intracavernous injections are avoided as they may provoke a further priapism event [1336, 1369]. In severe corporal fibrosis, narrow-based prosthetic devices are preferable because they are easier to insert and need less dilatation [1426]. After severe priapism that has resulted in penile destruction with complicated deformities or even loss of penile tissue, it may be necessary to make changes to the surgical technique. Multiple corporotomies, corporal excavation, optical corporotomy-Shaeer technique, dilatation with Carrion-Rosello cavernotome, Uramix or Mooreville cavernotome, excision of scar tissue, and use of small-diameter prosthesis, or penile reconstruction using grafts can be utilised, if concomitant prosthesis implantation is considered [1408, 1436].

Figure 13: Management work-up of ischaemic priapism



(*) Dose of phenylephrine should be reduced in children. It can result in significant hypertension and should be used with caution in men with cardiovascular disease. Monitoring of pulse and blood pressure is advisable in all patients during administration and for one hour afterwards. Its use is contraindicated in men with a history of cerebro-vascular disease and significant hypertension.

Figure 14: Surgical management of priapism



MRI = Magnetic resonance imaging; PPI = penile prosthesis implantation; IP = ischaemic priapism.

10.1.4 Summary of evidence and recommendations for treatment of ischaemic priapism

Summary of evidence	LE
Ischaemic priapism is a medical emergency and immediate intervention is mandatory.	2b
Erectile function preservation is directly related to the duration of ischaemic priapism, age and pre-operative erectile status.	2b
Medical treatment is variably effective in case of priapism lasting less than 48 hours.	2b
Aspiration ± irrigation with 0.9% results in over 80% success rate when combined with intracavernous injection of sympathomimetic drugs.	2b
Phenylephrine is the recommended drug due to its favourable safety profile in the cardiovascular system compared to other drugs. Phenylephrine is usually diluted in normal saline with a concentration of 100-500 µg/mL and given in 200 µg doses every three to five minutes directly into the corpus cavernosum. Maximum dosage is 1 mg within one hour. Patient monitoring is highly recommended.	2b
Oral terbutaline has a success rate in up to 60% of cases when priapism is associated with intracavernous injection of erectogenic agents.	1b
Exchange transfusion in patients with priapism associated with SCD may result in serious neurological sequelae.	2b
Shunt procedures are effective to resolve priapism and provide pain relief. No clear recommendation of the superiority of one type of shunt over another can be given. Distal shunts are less invasive and associated with lower rate of erectile dysfunction.	2b
Peri- and post-operative anticoagulant prophylaxis (325 mg acetylsalicylic acid pre-operatively, 5,000 IU heparin intra-operatively and 81 mg acetylsalicylic acid and 75 mg clopidogrel five days post-operatively) may prevent priapism recurrence.	3
Erectile dysfunction is almost inevitable in prolonged cases or ischaemic priapism. Early implantation of penile prosthesis is associated with lower infection rates and complications compared to late implantation.	2b

Recommendations	Strength rating
Start management of ischaemic priapism as early as possible (within four to six hours) and follow a stepwise approach.	Strong
Decompress the corpus cavernosum by penile aspiration and washout until fresh red blood is obtained as first treatment step.	Strong

Replace blood aspiration with intracavernous injection of a sympathomimetic drug as the first step in priapism secondary to intracavernous injections of vasoactive agents.	Strong
Perform intracavernous injection of a sympathomimetic drug in priapism that persists despite aspiration.	Strong
Repeat aspiration and intracavernous injection of a sympathomimetic drug in cases that persist despite prior aspiration and intracavernous injection of a sympathomimetic drug, before considering surgical intervention.	Strong
Treat ischaemic priapism associated with sickle cell disease in the same fashion as idiopathic ischaemic priapism. Do not use exchange transfusion as a primary treatment. Provide other supportive measures (intravenous hydration, oxygen administration with alkalisation with bicarbonate, blood exchange transfusions), but do not delay initial treatment to the penis.	Strong
Proceed to surgical treatment only when blood aspiration and intracavernous injection of sympathomimetic drugs have failed.	Strong
Perform distal shunt surgical procedures first and combine them with tunnelling if necessary.	Weak
Use proximal procedures in cases of distal shunt failure (< 48 hours) or in patients who do not wish to proceed with immediate penile implant insertion.	Weak
Discuss implantation of a penile prosthesis in cases of delayed presentation (> 48 hours) and in cases refractory to injection therapy and distal shunting.	Weak
Delay implantation of a penile prosthesis if a shunt has been performed, to minimise the risk of infection and erosion of the implant.	Strong
Decide on which type of implant to insert based on: • patient suitability; • surgeons' experience; and • availability and cost of equipment. If a malleable penile prosthesis is implanted it can be exchanged later for an inflatable penile implant.	Strong

10.2 Priapism in Special Situations

*10.2.1 **Stuttering (recurrent or intermittent) priapism***

Stuttering priapism, also termed intermittent or recurrent priapism, is a distinct condition that is characterised by repetitive and painful episodes of prolonged erections. Erections are self-limiting with intervening periods of detumescence [1395, 1437]. These are analogous to repeated episodes of ischaemic priapism. In stuttering priapism the duration of the erections is generally shorter than in ischaemic priapism [1370]. The frequency and/or duration of these episodes are variable and a single episode can sometimes progress into prolonged ischaemic priapism.

Robust epidemiological studies of stuttering priapism are lacking [1438, 1439]. However, recurrent priapism episodes are common in men with SCD (42-64%) [1440, 1441] while in adolescents and young men the incidence of priapism is 35%, of whom 72% have a history of stuttering priapism [1438].

The aetiology of stuttering priapism is similar to that of ischaemic priapism. Whilst SCD is the most common cause, idiopathic cases and cases due to a neurological disorder have been reported. Men who have acute ischaemic priapism, especially which has been prolonged (for more than four hours) are at risk of developing stuttering priapism [1435].

Several studies have proposed alternative mechanisms for stuttering priapism including inflammation, cellular adhesion, NO metabolism, vascular reactivity and coagulation [1336, 1352, 1395, 1437, 1442-1445]. Although debated, androgens have also been observed to have an association with priapism [1446]. Therefore, one of the options for the treatment of stuttering priapism is to reduce serum testosterone levels to hypogonadal levels, which then suppresses androgen-associated mechanisms believed to be involved in triggering recurrent priapism.

10.2.1.1 Diagnostic evaluation

History, physical examination, laboratory testing and penile imaging follow the same principals as ischaemic priapism. In stuttering priapism there is a history of recurrent episodes of prolonged erections. These episodes can occur from several daily to isolated incidents every few months, continuously or followed by incident-free periods, of unknown duration, even months and years [1447]. The onset of the priapic episodes usually occurs

during sleep and detumescence does not occur upon waking. These episodes can be painful and may be the reason that the patient first seeks medical attention. Erections are painful and the penis is rigid as in ischaemic priapism, but the duration of events is usually shorter. Between erections the penis is usually normal, but in some cases signs of fibrosis can be found. Rarely, the penis may become enlarged, a condition known as megalo-phallus.

Recommendations for the diagnosis of stuttering priapism are the same as those described in section 10.1.2.5

10.2.1.2 Disease management

The primary goal in the management of patients with stuttering priapism is the prevention of further episodes and limiting the chances of developing a prolonged ischaemic priapism that is refractory to conventional treatment options. In most cases, stuttering priapism can be managed by pharmacological treatment. The management of each acute episode is similar to that for ischaemic priapism; aspiration/irrigation in combination with intracavernous injections of α-adrenergic agonists.

10.2.1.2.1 α-Adrenergic agonists

Studies of oral α-adrenergic agonists have suggested some prophylactic benefit for daily treatment with these agents [1448]. Adverse effects include tachycardia and palpitations. Pseudoephedrine is widely used as an oral decongestant and can be a first-line treatment option for stuttering priapism [1390]. However, its effect on corporal smooth muscle is not fully understood. Etilephrine has been used successfully to prevent stuttering priapism caused by SCD. It is usually taken orally at doses of 5-10 mg daily, with response rates of up to 72% [1449-1451]. In a placebo-controlled RCT comparing medical prophylaxis with etilephrine and ephedrine, there was no difference in efficacy between the two drugs [1451].

10.2.1.2.2 Hormonal manipulations of circulating testosterone

The aim of hormonal manipulation is to down-regulate circulating testosterone levels to suppress the action of androgens on penile erection [1351, 1395, 1452]. This can be achieved by GnRH agonists or antagonists, antiandrogens or oestrogens [1453, 1454]. Potential adverse effects may include hot flushes, gynaecomastia, ED, loss of libido, and asthenia. All approaches have a similar efficacy profile while the potential cardiovascular toxicity of oestrogens limits their clinical use. Alternative endocrine approaches that have been used with some success include 5-α-reductase inhibitors [1455, 1456] and ketoconazole; an anti-fungal agent that reduces adrenal and testicular androgen production [1452, 1457].

The duration of hormonal treatment for effective suppression of recurrent priapism is problematic. It is not possible to draw any conclusions on the dose, duration of treatment and the efficacy. Caution is strongly advised when prescribing hormonal treatments to pre-pubertal boys and adolescents, and specialist advice from paediatric endocrinologists should be sought. Likewise, hormonal agents have a contraceptive effect and interfere with normal sexual maturation and spermatogenesis and affect fertility. Therefore, men who are trying with their partner to conceive should be comprehensively counselled before using hormonal treatment. Moreover, sperm cryopreservation may be considered to mitigate any potential effects of anti-androgen therapy on fertility.

10.2.1.2.3 Digoxin

Digoxin is a cardiac glycoside and positive inotrope that is used to treat congestive heart failure. Digoxin regulates smooth muscle tone through several different pathways leading to penile detumescence [1351, 1395, 1458]. The use of maintenance digoxin doses (0.25-0.5 mg/daily) in idiopathic stuttering priapism reduces the number of hospital visits and improves QoL [1395]. In a small, clinical, double-blind, placebo-controlled study, digoxin decreased sexual desire and excitement with a concomitant reduction in penile rigidity, regardless of any significant change in plasma levels of testosterone, oestrogens and LH [1458]. Adverse effects include decreased libido, anorexia, nausea, vomiting, confusion, blurred vision, headache, gynaecomastia, rash and arrhythmia.

10.2.1.2.4 Terbutaline

Terbutaline has been used to prevent stuttering priapism with detumescence rates of 36% in patients with alprostadil-induced priapism [1390]. The only RCT (n = 68) in patients with pharmacologically-induced priapism, demonstrated detumescence in 42% of the terbutaline-treated group compared to only 15% in the placebo-treated group [1391]. Adverse effects include nervousness, shakiness, drowsiness, palpitations, headache, dizziness, hot flushes, nausea and weakness.

10.2.1.2.5 Gabapentin

Gabapentin has anticonvulsant, antinociceptive and anxiolytic properties and is widely used as an analgesic and anti-epileptic agent. Its proposed mechanism of action is to inhibit voltage-gated calcium channels, which attenuates synaptic transmission [1452], and reduces testosterone and FSH levels [1459]. It is given at a dose of 400 mg, four times daily, up to 2,400 mg daily, until complete penile detumescence occurs, with subsequent maintenance administration of 300 mg/daily [1460]. Adverse effects include anorgasmia and impaired erectile function.

10.2.1.2.6 Baclofen

Baclofen is a gamma-aminobutyric acid (GABA) derivative that acts as a muscle relaxant and anti-muscle spasm agent. It can inhibit penile erection and ejaculation through GABA activity and prevents recurrent reflexogenic erections or prolonged erections from neurological diseases [1351]. Oral baclofen has little efficacy and it is not usually used in stuttering priapism but intrathecal administration is more effective [1395, 1461-1463]. Adverse effects include drowsiness, confusion, dizziness, weakness, fatigue, headache, hypotension and nausea.

10.2.1.2.7 Hydroxyurea

Hydroxyurea blocks the synthesis of deoxyribonucleic acid (DNA) by inhibiting ribonucleotide reductase, which has the effect of arresting cells in the S-phase [1452, 1464]. Hydroxyurea is an established treatment for ameliorating SCD and improving life expectancy [1394, 1465]. For patients with recurrent priapism, there is limited evidence to suggest a prophylactic role of hydroxyurea [1452, 1464, 1466]. Adverse effects include oligo-zoospermia and leg ulcers.

10.2.1.2.8 Phosphodiesterase type 5 inhibitors

Low doses of PDE5Is have a paradoxical effect in alleviating and preventing stuttering priapism; mainly in patients with idiopathic and SCD-associated priapism [1351, 1395, 1443, 1467-1471]. It is important to remember that therapy should be started when the penis is in its flaccid state and not during an acute episode. There is a delay of one week before treatment is effective. There are no reported impairments in male sexual function.

10.2.1.2.9 Intracavernosal injections

Some patients with stuttering priapism, who have started on systemic treatment to prevent recurrence of unwanted erections, may not see therapeutic benefits immediately and temporarily require intracavernous self-injections at home with sympathomimetic agents [1351, 1395]. The most commonly used drugs are phenylephrine and etilephrine [1336, 1370, 1439, 1450].

Tissue plasminogen activator (TPA) is a secreted serine protease that converts the pro-enzyme plasminogen to plasmin, which acts as a fibrinolytic enzyme. Limited clinical data have suggested that a single intracavernous injection of TPA can successfully treat patients with recalcitrant priapism [1452, 1472]. Mild bleeding is the most commonly observed adverse effect.

10.2.1.2.10 Penile prosthesis

Patients with medically refractory stuttering priapism require frequent visits to the emergency department and are always at risk of a major ischaemic episode, which can be mitigated with insertion of a penile prosthesis [1408, 1429, 1473]. Nevertheless, penile prosthesis for preventing stuttering priapism should not be offered before medical treatment and a penile prosthesis should be performed only in carefully selected patients as a last resort [1408]. In patients with permanent ED due to stuttering priapism, medical treatments for ED should be used cautiously because of the risk of inducing an ischaemic episode and a penile prosthesis can be considered [1408, 1474].

10.2.1.3 Summary of evidence and recommendations for treatment of stuttering priapism

Summary of evidence	LE
The primary goal in the management of patients with stuttering priapism is prevention of future episodes, which can generally be achieved pharmacologically.	2b
Hormonal therapy with GnRH agonists or antagonists or antiandrogens is able to reduce the risk of recurrent priapism episodes although it is associated with adverse events (hot flushes, gynaecomastia, ED, loss of libido, asthenia and infertility)	3
Phosphodiesterase type 5 inhibitors have a paradoxical effect in alleviating and preventing stuttering priapism, mainly in patients with idiopathic and sickle cell disease-associated priapism.	3
The evidence with other systemic drugs (digoxin, α-adrenergic agonists, baclofen, gabapentin and terbutaline, hydroxyurea) is limited.	3

Recommendations	Strength rating
Manage each acute episode according to the treatment recommendations for ischaemic priapism (section 10.1.4).	Strong
Use hormonal therapies (mainly gonadotropin-receptor hormone agonists or antagonists) and/or anti-androgens for the prevention of future episodes in patients with frequent relapses. Do not use them before sexual maturation is reached.	Weak
Initiate treatment with phosphodiesterase type 5 inhibitors only when the penis is in its flaccid state.	Weak
Use digoxin, α-adrenergic agonists, baclofen, gabapentin or terbutaline only in patients with frequent and uncontrolled relapses.	Weak
Use intracavernous self-injections of sympathomimetic drugs at home for treatment of acute episodes on an interim basis until ischaemic priapism has been alleviated.	Weak

10.2.1.4 Follow-up

Follow-up for stuttering priapism includes history and clinical examination to assess the efficacy of treatment in preventing or alleviating erectile events as well as assessing erectile function and penile fibrosis.

*10.2.2 **Priapism in children***

The classification of priapism in children is similar to that in adults. In addition to ischaemic, stuttering and non-ischaemic priapism, a fourth type, neonatal priapism is also described [1336]. Priapism in children is considered rare as no data on its prevalence exist. Sickle cell disease is the major cause of priapism in children, followed by leukaemia (10%), trauma (10%), idiopathic causes (19%) and drugs (5%) [1475]. One study showed that 25% of children experienced SCD-related priapism in a pre-pubertal period [1476]. Another study revealed that 90% of men with SCD had their first priapism episode before age 20 years [1441]. Priapism in children should be evaluated and treated in a timely manner, as untreated ischaemic priapism may lead to ED and psychosexual disorders in adulthood [1477]. A multi-disciplinary team approach should be utilised with specialist input from haematologists and paediatric endocrinologists.

10.3 Non-ischaemic (high-flow or arterial) priapism

Non-ischaemic priapism is a persistent erection caused by unregulated cavernous arterial inflow [1336]. According to aetiology, non-ischaemic priapism can be categorised into four types: traumatic, neurogenic, iatrogenic and idiopathic in origin.

*10.3.1 **Epidemiology/aetiology/pathophysiology***

Epidemiological data on non-ischaemic priapism are almost exclusively derived from small case series [1336, 1364, 1478-1480]. Non-ischaemic priapism is significantly less common than the ischaemic type, comprising only 5% of all priapism cases [1336]. The most frequent cause of non-ischaemic priapism is blunt perineal or penile trauma [1481]. The injury results in a laceration in the cavernosal artery or branches, leading to a fistula between the artery and the lacunar spaces of the sinusoidal space [1480]. The resultant increased blood flow results in a persistent and prolonged erection [1482].

There is often a delay between the trauma and the development of the priapism that may be up to two to three weeks [1483]. This is suggested to reflect either spasm or ischaemic necrosis of the injured artery, with the fistula only developing as the spasm resolves or when the ischaemic segment "blows up". The priapism typically occurs after a nocturnal erection or an erection related to sexual activity, resulting in the sudden increase of blood flow and pressure in the cavernous arteries [1484]. The patient typically reports an erection that is not fully rigid and is not associated with pain because the venous drainage is not compromised and the penile tissue does not become ischaemic [1485].

Non-ischaemic priapism can occur after acute spinal cord injury, presumably due to loss of sympathetic input, leading to predominant parasympathetic input and increased arterial flow [1486]. It has also been reported to occur following internal urethrotomy [1487], Nesbit procedure [1488], circumcision [1489], transrectal prostate biopsy [1490], and brachytherapy for prostate cancer [1491]. Some cases have also been described following shunting procedures performed for ischaemic priapism due to a lacerated cavernosal artery (conversion of low-flow to high-flow priapism) [1492-1494]. Although SCD is usually associated with ischaemic priapism, occasional cases of high-flow priapism have been reported; however, the pathophysiological mechanism remains unclear [1495]. Finally, metastatic malignancy to the penis can also rarely cause non-ischaemic priapism [1496, 1497].

*10.3.2 **Diagnostic evaluation***

10.3.2.1 History

A comprehensive history is mandatory in non-ischaemic priapism diagnosis and follows the same principles as described in section 10.1.2.1. Arterial priapism should be suspected when the patient reports a history of pelvic, perineal, or genital trauma; no penile pain (discomfort is possible); and a persistent, not fully rigid erection. The corpus cavernosum can become fully rigid with sexual stimulation, so sexual intercourse is usually not compromised. The onset of post-traumatic non-ischaemic priapism can be delayed by several hours to weeks following the initial injury [1336].

10.3.2.2 Physical examination

In non-ischaemic priapism, the corpora are tumescent but not fully rigid. Abdominal, penile and perineal examination may reveal evidence of trauma [1336]. Neurological examination is indicated if a neurogenic aetiology is suspected.

10.3.2.3 Laboratory testing

Laboratory testing should include a blood count with white blood cell differential and a coagulation profile to assess for anaemia and other haematological abnormalities. Blood aspiration from the corpus cavernosum shows bright red arterial blood in arterial priapism, while blood is dark in ischaemic priapism. Blood gas analysis is essential to differentiate between non-ischaemic and ischaemic priapism. Blood gas values in high-flow priapism show normal arterial blood [1336] (Table 34).

10.3.2.4 Penile imaging

Colour duplex US of the penis and perineum is recommended and can differentiate non-ischaemic from ischaemic priapism [1362-1364]. Ultrasound must be performed without intracavernosal vasoactive drug injection [1498]. In non-ischaemic priapism, US helps to localise the fistula site and appears as a characteristic colour blush and turbulent high-velocity flow on Doppler analysis [1499]. Patients with non-ischaemic priapism have normal to high blood velocities in the cavernous arteries [1365, 1500].

Selective pudendal arteriography can reveal a characteristic blush at the site of injury in arterial priapism [1501, 1502]. However, due to its invasiveness, it should be reserved for the management of non-ischaemic priapism when embolisation is being considered [1336, 1359].

The role of MRI in the diagnostic evaluation of priapism is controversial. Its role in non-ischaemic priapism is limited because the small penile vessels and fistulae cannot be easily demonstrated [1503].

10.3.2.5 Summary of evidence and recommendations for the diagnosis of non-ischaemic priapism

Summary of evidence	LE
Non-ischemic priapism is less common than ischemic and is usually associated with blunt perineal or penile trauma leading to the development of intracavernosal fistula	2b
Medical history and blood gas analysis are able to differentiate between ischemic and non-ischemic priapism	2b
Blood aspiration from the corpora in case of non-ischemic priapism reveal bright red arterial blood with normal arterial gas values	2b
Penile duplex US is able to identify intracavernosal fistula responsible for non-ischemic priapism	2b

Recommendations	Strength rating
Take a comprehensive history to establish the diagnosis, which can help to determine the priapism subtype.	Strong
Include a physical examination of the genitalia, perineum and abdomen in the diagnostic evaluation.	Strong
Include a neurological examination if neurogenic non-ischaemic priapism is suspected.	Strong
Include complete blood count, white blood cell differential, and coagulation profile for laboratory testing.	Strong
Analyse the blood gas parameters from blood aspirated from the penis to differentiate between ischaemic and non-ischaemic priapism.	Strong
Perform colour duplex ultrasound of the penis and perineum to differentiate between ischaemic and non-ischaemic priapism.	Strong
Perform selected pudendal arteriography when embolisation is planned for non-ischaemic priapism.	Strong

10.3.3 ***Disease management***

Although the conventional belief is that the management of non-ischaemic priapism is not an emergency because the corpus cavernosum does not contain ischaemic blood; however, recent data indicate that the duration of non-ischaemic priapism can also impact EF. In a case series consisting of six patients with high-flow priapism after median follow-up of 4.5 (2-12) weeks, all patients reported development of ED or distal penile flaccidity [1430]. The goal of treatment is closure of the fistula. Non-ischaemic priapism can be managed conservatively or by direct perineal compression. Failure of conservative treatment requires selective arterial embolisation [1504]. The optimal time interval between conservative treatment and arterial embolisation is under debate. Definitive management can be performed at the discretion of the treating physician and should be discussed with the patient so that they can understand the risks of treatment [1336, 1359].

10.3.3.1 Conservative management

Conservative management may include applying ice to the perineum or perineal compression, which is typically US-guided. The fistula occasionally closes spontaneously. Even in cases where the fistula remains patent, intercourse is still possible [1364, 1479, 1505, 1506]. Androgen deprivation therapy (e.g., leuprolide injections, bicalutamide and ketoconazole) has been reported in case series to enable closure of the fistula reducing spontaneous and sleep-related erections [1507]. However, sexual dysfunction due to these treatments must be considered. Patients may develop ED or distal penile flaccidity while undergoing conservative treatment [1430].

Blood aspiration is not helpful for the treatment of arterial priapism and the use of α-adrenergic antagonists is not recommended because of potential severe adverse effects (e.g., transfer of the drug into the systemic circulation).

10.3.3.2 Selective arterial embolisation

Selective arterial embolisation can be performed using temporary substances, such as autologous blood clot [1508-1510] and gel foam [1509, 1511], or permanent substances such as microcoils [1509, 1511-1513], ethylene-vinyl alcohol copolymer (PVA), and N-butyl-cyanoacrylate (NBCA) [1514]. It is assumed that temporary embolisation provides a decreased risk of ED, with the disadvantage of higher failure/recurrence rates, as a consequence of artery embolisation using temporary materials. However, there is insufficient evidence to

support this hypothesis. Success rates ranging between 61.7 and 83.3%, and ED rates from 0-33.3% after the first arterial embolization have been reported, suggesting that failure/recurrence may not be significantly higher with temporary embolisation materials, and preservation of erectile function may not be that different between the two modalities either [1484]. Other potential complications of arterial embolisation include penile gangrene, gluteal ischaemia, cavernositis, and perineal abscess [1336, 1515]. Repeated embolisation is a reasonable option for treating non-ischaemic priapism, both in terms of efficacy and safety [1484].

10.3.3.3 Surgical management

Surgical ligation of the fistula is possible through a transcorporeal or inguinoscrotal approach, using intra-operative Doppler US. Surgery is technically challenging and associated with significant risks, particularly of ED [1516]. Surgery is rarely performed and should only be considered when there are contraindications for selective embolisation, if embolisation is unavailable, or repeated embolisations have failed. If the patient desires more definitive treatment and is not sexually active or has pre-existing ED, surgical intervention can be an appropriate option [1484]. Erectile dysfunction rates ranging from 0-50% have been reported following treatment for non-ischaemic priapism, with surgical ligation having the highest reported rates [1484]. Patients can require penile prosthesis implantation for ED in the long-term [1408].

10.3.3.4 Summary of evidence and recommendations for the treatment of non-ischaemic priapism

Summary of evidence	**LE**
Non-ischaemic priapism can cause erectile dysfunction over time and early definitive management should be undertaken.	3
Conservative management applying ice to the perineum or site-specific perineal compression is an option in all cases. The use of androgen deprivation therapy may enable closure of the fistula reducing spontaneous and sleep-related erections.	3
Selective artery embolisation, using temporary or permanent substances, has high success rates. No definitive statement can be made on the best substance for embolisation in terms of sexual function preservation and success rate.	3
Repeated embolisation is a reasonable option for the treatment of non-ischaemic priapism.	2b
Selective surgical ligation of the fistula is associated with high risk of erectile dysfunction.	3

Recommendations	**Strength rating**
Perform definitive management for non-ischaemic priapism at the discretion of the treating physician as it is not a medical emergency.	Weak
Manage non-ischaemic priapism conservatively with the use of site-specific perineal compression as the first step. Consider androgen deprivation therapy only in adults.	Weak
Perform selective arterial embolisation when conservative management has failed.	Strong
Perform the first selective arterial embolisation using temporary material.	Weak
Repeat selective arterial embolisation with temporary or permanent material for recurrent non-ischaemic priapism following selective arterial embolisation.	Weak
Reserve selective surgical ligation of a fistula as a final treatment option when repeated arterial embolisations have failed.	Weak

10.3.3.5 High-flow priapism in children

Non-ischaemic priapism is a rare condition, especially in children. The embarrassment that children may have in speaking about it to their parents can lead to misdiagnosis and underestimating the prevalence of this condition [1517]. The aetiology, clinical presentation, diagnostic and therapeutic principles are comparable with those of arterial priapism in adults. However, some differentiating features should be noted.

Idiopathic non-ischaemic priapism can be found in a significant percentage of children [1518]. Perineal compression with the thumb may be a useful manoeuvre to distinguish ischaemic and non-ischaemic priapism, particularly in children, where it may result in immediate detumescence, followed by the return of the erection with the removal of compression [1484]. Conservative management using ice applied to the perineum or site-specific perineal compression may be successful, particularly in children [1519, 1520]. Although reportedly successful, embolisation in children is technically challenging and requires treatment within a specialist paediatric vascular radiology department [1374, 1521].

10.3.3.6 Follow-up

During conservative management of non-ischaemic priapism, physical examination and colour duplex US can be useful tools to assess treatment efficacy. Close follow-up using colour duplex US and MRI can help detect distal penile fibrosis and be beneficial in clinical decision-making to intervene with embolisation earlier [1430]. Follow-up after selective arterial embolisation should include clinical examination, colour duplex US, and erectile function assessment. If in doubt, repeat arteriography is required. The goals are to determine if the treatment was successful, identify signs of recurrence, and verify any anatomical and functional sequelae [1498].

11. MALE INFERTILITY

11.1 Definition and classification

Infertility is defined by the inability of a sexually active, non-contraceptive couple to achieve spontaneous pregnancy within twelve months [1522]. Primary infertility refers to couples that have never had a child and cannot achieve pregnancy after at least 12 consecutive months having sex without using birth control methods. Secondary infertility refers to infertile couples who have been able to achieve pregnancy at least once before (with the same or different sexual partner).

In 30-40% of cases, no male-associated factor is found to explain the underlying impairment of sperm parameters and historically was referred to as idiopathic male infertility. These men present with no previous history of diseases affecting fertility and have normal findings on physical examination and endocrine, genetic and biochemical laboratory testing, although semen analysis may reveal pathological findings (see Section 11.3.2). It is now believed that idiopathic male infertility may be associated with several previously unidentified pathological factors, which include but are not limited to endocrine disruption as a result of environmental pollution, generation of reactive oxygen species (ROS)/sperm DNA damage, or genetic and epigenetic abnormalities [1523]. Unexplained male infertility is defined as infertility of unknown origin with normal sperm parameters and partner evaluation. Between 20 and 30% of couples will have unexplained infertility.

11.2 Epidemiology/aetiology/pathophysiology/risk factors

*11.2.1 **Introduction***

About 15% of couples do not achieve pregnancy within one year and seek medical treatment for infertility [1524]. One in eight couples encounter problems when attempting to conceive a first child and one in six when attempting to conceive a subsequent child [1525]. In 50% of involuntarily childless couples, a male-infertility-associated factor is found, usually together with abnormal semen parameters [1522]. For this reason, in all infertile couples the male should undergo medical evaluation by a urologist trained in male reproduction.

Male fertility can be impaired as a result of many different conditions (Table 36), thus including [1522]:

- congenital or acquired urogenital abnormalities;
- genetic abnormalities;
- varicocele;
- urogenital tract infections;
- increased scrotal temperature (e.g., as a consequence of varicocele);
- endocrine disturbances;
- immunological factors;
- iatrogenic factors (e.g., previous scrotal surgery);
- malignancy;
- gonadotoxic exposure (e.g., radiotherapy or chemotherapy);

Advanced paternal age has emerged as one of the main risk factors associated with the progressive increase in the prevalence of male factor infertility [1526-1533].

Advanced maternal age must be considered in the management of every infertile couple, and in the subsequent decisions throughout the diagnostic and therapeutic strategy of the male partner [1534, 1535]. This should include the age and ovarian reserve of the female partner, since these parameters might determine decision-making in terms of timing and therapeutic strategies (e.g., assisted reproductive technology [ART] vs. surgical intervention) [1526-1529]. Earlier evaluation is still a matter of debate in couples in with female partners older than 35 years who have not conceived for 6 months as ovarian reserve may fall [1536-1538].

Table 36 summarises the main male-infertility-associated factors.

Table 36: Male infertility causes and associated factors and percentage of distribution in 10,469 patients [1539]

Diagnosis	Unselected patients (n = 12,945)	Azoospermic patients (n = 1,446)
All	100%	11.2%
Infertility of known (possible) cause	42.6%	42.6%
Maldescended testes	8.4	17.2
Varicocele	14.8	10.9
Sperm auto-antibodies	3.9	-
Testicular tumour	1.2	2.8
Others	5.0	1.2
Idiopathic infertility	30.0	13.3
Hypogonadism	10.1	16.4
Klinefelter syndrome (47, XXY)	2.6	13.7
XX male	0.1	0.6
Primary hypogonadism of unknown cause	2.3	0.8
Secondary (hypogonadotropic) hypogonadism	1.6	1.9
Kallmann syndrome	0.3	0.5
Idiopathic hypogonadotropic hypogonadism	0.4	0.4
Residual after pituitary surgery	< 0.1	0.3
Late-onset hypogonadism	2.2	-
Constitutional delay of puberty	1.4	-

11.2.2 Summary of evidence and recommendations on epidemiology and aetiology of male infertility

Summary of evidence	LE
Infertility affects 15% of couples of reproductive age.	3
A male factor infertility can be identified in about 50% of infertile couples.	2a
A pure male factor infertility can be identified in about 20% of infertile couples.	2a
Several risk factors such as genetic factors, urogenital abnormalities, endocrine disorders, malignant diseases and gonadotoxic treatments can cause male infertility.	2a

Recommendations	Strength rating
Perform infertility evaluation in couples who have not conceived after twelve months of regular, unprotected intercourse.	Strong
Investigate both partners simultaneously to categorise the cause of infertility.	Strong
Investigate all men belonging to couples seeking medical help for fertility problems.	Strong

11.3 Diagnostic work-up

Important treatment decisions are based on the results of semen analysis and most studies indicate semen parameters are a surrogate outcome for male fertility. However, a semen analysis *per se* cannot distinguish fertile from infertile men [1540].

The Guidelines panel concludes that a comprehensive andrological examination is always indicated in infertile couples, both if semen analysis shows abnormalities and in men with normal sperm parameters as compared with reference values [1541-1543].

Focused evaluation of male patients should include: a medical and reproductive history; physical examination; semen analysis – with strict adherence to World Health Organization (WHO) reference values for human semen characteristics [1544, 1545], and hormonal evaluation [1546]. Other investigations (e.g., genetic analysis and imaging) may be required depending on the clinical features and semen parameters.

*11.3.1 **Medical/reproductive history and physical examination***

11.3.1.1 Medical and reproductive history

Medical history should evaluate any risk factors and behavioural patterns that could affect male partner's fertility, such as lifestyle, family history (including, testicular cancer), comorbidities (including systemic diseases; e.g., hypertension, diabetes mellitus, obesity, MetS, testicular cancer, etc.), genito-urinary infections (including sexually transmitted infections), history of testicular surgery and exclude any potential known gonadotoxic medication or recreational drugs [1547].

Typical findings from the history of a patient with infertility include:

- cryptorchidism (uni- or bilateral);
- testicular torsion and trauma;
- genitourinary infections;
- exposure to environmental toxins;
- gonadotoxic medications (e.g., anabolic drugs, chemotherapeutic agents, etc.);
- exposure to radiation or cytotoxic agents.

11.3.1.2 Physical examination

A focused physical examination is compulsory in the evaluation of every infertile male, including presence of secondary sexual characteristics. The size, texture and consistency of the testes must be evaluated. In clinical practice, testicular volume is assessed by Prader's orchidometer [1548]; orchidometry may over-estimate testicular volume compared to US assessment [1549]. There are no uniform reference values in terms of Prader's orchidometer-derived testicular volume, due to differences in the populations studied (e.g., geographic area, nourishment, ethnicity and environmental factors) [1548-1550]. The mean Prader's orchidometer-derived testis volume reported in the European general population is 20.0 ± 5.0 mL [1548], whereas in infertile patients it is 18.0 ± 5.0 mL [1548, 1551-1553]. The presence of the vas deferens, fullness of epididymis and presence of a varicocele should be always determined. Likewise, palpable abnormalities of the testis, epididymis, and vas deferens should be evaluated. Other physical alterations, such as abnormalities of the penis (e.g., phimosis, short frenulum, fibrotic nodules, epispadias, hypospadias, etc.), abnormal body hair distribution and gynecomastia, should also be evaluated.

Typical findings from the physical examination of a patient with characteristics suggestive for testicular deficiency include:

- abnormal secondary sexual characteristics;
- abnormal testicular volume and/or consistency;
- testicular masses (potentially suggestive of cancer);
- absence of testes (uni-bilaterally);
- gynaecomastia;
- varicocele.

*11.3.2 **Semen analysis***

The 6th edition the WHO Manual for the Examination and Processing of Human Semen [1545] has been published on July 2021 and comprises of three sections: i) semen examination; ii) sperm preparation and cryopreservation; and, iii) quality assessment and quality control.

Procedures for semen examination are divided:

- Basic examinations, that should be performed by every laboratory, based on standardised procedures and evidence-based techniques.
- Extended analyses, which are performed by choice of the laboratory or by special request from the clinicians.
- Advanced examinations.

Basic examination summary [1544]:

- Assessment of sperm numbers: the laboratory should not stop assessing the number of sperm at low concentrations (2 million/mL), as suggested in the 5th edition, but report lower concentrations, noting that the errors associated with counting a small number of spermatozoa may be high. It is recognised that the total sperm numbers per ejaculate (sperm output) have more diagnostic value than sperm concentration; therefore, semen volume must be measured accurately.
- Assessment of sperm motility: the categorisation of sperm motility has reverted back to fast progressively motile, slow progressively motile, non-progressively motile and immotile (grade a, b, c or d) because presence (or absence) of rapid progressive spermatozoa is recognised to be clinically important.
- Assessment of sperm morphology: the 6th edition has recommended the Tygerberg strict criteria by sperm adapted Papanicolaou staining.
- Assessment of vitality should not be performed in all samples, only if more than 60% of spermatozoa are immotile.

Extended examinations

This chapter contains procedures to detect leukocytes and markers of genital tract inflammation, sperm antibodies, indices of multiple sperm defects, sequence of ejaculation, methods to detect sperm aneuploidy, semen biochemistry and sperm DNA fragmentation.

Reference ranges and reference limits

The lower fifth percentile of the distribution of semen analysis values from approximately 3500 men in 12 countries who have contributed to a natural conception within 12 months of trying does not represent a limit between fertile and infertile men. For a general prediction of live birth *in vivo* as well as *in vitro*, a multiparametric interpretation of the entire men's and partner's reproductive potential are needed. Reference values for semen parameters are represented in Table 37 [1541].

Moreover, more complex testing (e.g., sperm DNA fragmentation) than classic semen analysis may be required in everyday clinical practice, particularly in men belonging to couples with recurrent pregnancy loss from natural conception or ART and in men with unexplained male infertility. Although definitive conclusions cannot be drawn, given the heterogeneity of the studies, increased sperm DNA damage is associated with pregnancy failure [1523, 1554, 1555].

Table 37: Lower reference limits (5th centiles and their 95% CIs) for semen characteristics

Parameter	**2021 Lower reference limit (95% CI)**
Semen volume (mL)	1.4 (1.3-1.5)
Total sperm number (106/ejaculate)	39 (35-40)
Sperm concentration (106/mL)	16 (15-18)
Total motility (PR + NP, %)	42 (40-43)
Progressive motility (PR, %)	30 (29-31)
Vitality (live spermatozoa, %)	54 (50-56)
Sperm morphology (normal forms, %)	4 (3.9-4.0)

Other consensus threshold values	
pH	> 7.2
Peroxidase-positive leukocytes (10^6/mL)	< 1.0
Tests for antibodies on spermatozoa	
MAR test (motile spermatozoa with bound particles, %)	No evidence-based reference values. Each laboratory should define its normal reference ranges by testing a sufficiently large number of fertile men.
Immunobead test (motile spermatozoa with bound beads, %)	No evidence-based reference limits.
Accessory gland function	
Seminal zinc (µmol/ejaculate)	≥ 2.4
Seminal fructose (µmol/ejaculate)	≥ 13
Seminal neutral α-glucosidase (mU/ejaculate)	≥ 20

CIs = confidence intervals; MAR = mixed antiglobulin reaction; NP = non-progressive; PR = progressive (a+b motility).

** Distribution of data from the population is presented with one-sided intervals (extremes of the reference population data). The lower 5th percentile represents the level under which only results from 5% of the men in the reference population were found.*

If semen analysis is normal according to WHO criteria, a single test is sufficient. If the results are abnormal on at least two tests, further andrological investigation is indicated.

None of the individual sperm parameters (e.g., concentration, morphology and motility), are diagnostic *per se* of infertility. According to WHO reference criteria 5th edn., it is important to differentiate between the following [1556]:

- oligozoospermia: < 16 million sperm/mL;
- asthenozoospermia: < 32% progressive motile sperm;
- teratozoospermia: < 4% normal forms.

According to the WHO reference criteria 6th edn., this subdivision is not reported, although the EAU Guidelines panel considers this further segregation still clinically relevant in the everyday clinical practice.
